Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editor assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Foreword

The profession of dentistry, and in particular the field of implant dentistry, has been significantly changed and improved by Dr. Carl E. Misch. More important, however, is the dental patient who has been the major recipient of the innovations and clinical advancement of this field. From single-tooth implant placement to complex bone augmentation with multiple implant positioning, this textbook provides the science and peer-reviewed research enhancing implant success and improving clinical outcomes.

This textbook leads the clinician through a logical sequence of "growth and maturation" as an implant dentist. Basic chapters on medical history, bone, and pharmacology lead into increasingly complex surgical approaches that include virtually every clinical venue faced by the implant dentist. These well-illustrated chapters with outstanding clinical teaching cases will serve as a basic guide for the dental clinician and as a valuable resource in one's reference library.

A quarter of a century of experience at the Misch International Implant Institute is evident in this textbook. Clinical and teaching approaches that have been proved over time are directly applied in each chapter. The thousands of general dentists and specialists who have successfully completed the comprehensive series of Misch Institute three-day–weekend courses (which includes several years of Temple University and University of Pittsburgh periodontology residents) have provided significant feedback, resulting in continuous outcomes assessments of clinical procedures and research methods highlighted in this text. The reader will not only improve their clinical skills, but also their confidence with Dr. Misch. I speak from personal experience as a board-certified periodontist who completed his first surgical placement of a dental implant under the tutelage of Dr. Misch (while on a giant video monitor viewed by more than 60 dentists during one of the Misch Institute courses) over a decade ago. I continue to be mentored by Dr. Misch and feel fortunate to call him a professional colleague, research collaborator, and true friend.

About the Author

Carl E. Misch, DDS, MDS, PhD(hc)

Carl E. Misch is a Clinical Professor and Director of Implant Dentistry in the Department of Periodontology and Implant Dentistry at Temple University Kornberg School of Dentistry. He is also a Clinical Professor in the Department of Periodontics/Geriatrics at the University of Michigan School of Dentistry. Dr. Misch is currently a Clinical Professor in the Department of Restorative Dentistry at the University of Detroit Mercy School of Dentistry. He is also a Board of Trustee member-at-large for the University of Detroit Mercy School. In addition, he is an Adjunct Professor at the University of Alabama at Birmingham, School of Engineering, Department of Biomechanics. He was Co-Director or Director of the Oral Implantology Residency Program at the University of Pittsburgh School of Dental Medicine from 1986 to 1996.

Dr. Misch graduated *magna cum laude* in 1973 from the University of Detroit Dental School and received his Prosthodontic Certificate, Implantology Certificate, and Master's Degree in Dental Science from the University of Pittsburgh. He has been awarded two honoris causa PhD degrees, from the University of Yeditepe in Istanbul, Turkey, and the Carol Davila University of Medicine and Pharmacy in Bucharest, Romania. Other graduate honors include 13 fellowships in dentistry, including Fellow of the American College of Dentistry, Fellow of the International College of Dentists, Fellow of the Royal Society of Medicine, Fellow of the American Association of Hospital Dentistry, Fellow of the Academy of Dentistry International, and Fellow of the Pierre Fauchard Academy. Dr. Misch has more than 10 patents related to implant dentistry and is co-inventor of the BioHorizons Dental Implant System.

Dr. Misch is a diplomate and past president of the American Board of Oral Implantology/Implant Dentistry and served as member of the diplomate examining committee for 7 years. He is a past president of the International Congress of Oral Implantologists, the American Academy of Implant Dentistry, the Academy of Implants and Transplants, and the American College of Oral Implantologists. He is currently the Co-Chairman of the Board of Directors of the International Congress of Oral Implantologists, which represents more than 85 countries and is the world's largest implant organization.

In 1984, Dr. Misch founded the Misch International Implant Institute, which is co-sponsored with Temple University School of Dentistry. Currently, training centers for the institute are located in Michigan, Pennsylvania, Nevada, and Toronto, Canada. Over the years, the Misch International Implant Institute has had training centers in Korea, Italy, Brazil, Japan, the United Kingdom, Monaco, and Spain. In the United States and Canada, past training centers have been located in Florida, Texas, Nevada, New York, Vancouver, and Montreal. As director, Dr. Misch has trained more than 3500 doctors in a hands-on, yearly forum of education in implant dentistry. Programs are offered in both the surgical and prosthetics aspects of patient care.

Dr. Misch has now edited three editions of *Contemporary Implant Dentistry* as well as the first edition of *Dental Implant Prosthodontics*. These textbooks have been translated into Japanese, Spanish, Portuguese, Italian, and Korean, and they are used in dental schools around the world for graduate programs and postgraduate programs. Dr. Misch has published more than 250 articles related to implant dentistry. During the past 30 years, Dr. Misch has lectured more than 1000 times in all 50 states of the United States and in 47 countries throughout the world.

Dr. Misch is married to Francine Misch-Dietsh, a prosthodontist and past editor of *Contemporary Implant Dentistry*. They have six children: Paula, Carl, Lara, David, Jonathan, and Angela. Dr. Misch has maintained a private practice restricted to implant surgery (bone grafting and implant placement) and related prosthetics for more than 30 years.

Preface

In the 1990s fixed partial dentures to replace missing teeth in a partially edentulous patient were vehemently opposed, and removable partial dentures were strongly encouraged. In 1911, Hunter blamed the "mausoleum of gold over a mass of sepsis" for complicating systemic conditions of anemia, gastritis, kidney disease, and lesions of the spinal cord.[1] Despite this popular belief, fixed partial dentures became the standard of care to replace missing teeth and are still taught in every dental school in North America. In fact, if a dental student does not perform a traditional fixed partial denture, they do not graduate and join the dental community.

In the 1970s the mere mention of dental implants was controversial. Organized dentistry feared that these devices would always fail and could lead to a brain abscess or heart failure, because there was often no barrier between the oral bacteria and the systemic pathways. A few hundred dentists around the world observed that patients readily accepted dental implants to support a mandibular complete denture or believed that a fixed implant prosthesis was more desirable than using removable restorations or preparing and joining adjacent teeth for fixed prostheses.

Today we are in the midst of a dental implant revolution. There are more scientific and clinical articles written on dental implants than any other topic in dentistry. From 1950 to 1985 there were approximately 500 refereed articles published on dental implants. Between the years 1985 and 1995 there were more than 1500 articles published on dental implants. More recently, from 1995 to 2005, there have been over 5000 articles published in refereed journals on topics related to dental implants. The dental implant is now accepted as a promising method to replace a single tooth or multiple adjacent missing teeth, or to support a removable prosthesis for a completely edentulous patient.

In the United States, the total sales of implant products to the dental profession from 1950 to 1985 was less than $1 million each year, and from 1985 to 1995 the sales increased to $100 million per year. The sale of implant-related products from 1995 to 2005 has skyrocketed to $1 billion per year. However, this dramatic increase in sales has a downside. The rapid growth of dental implants as man-made abutments to replace missing teeth has caused technology to develop quickly and often without guidelines for evaluation. The driving force behind implant treatment should not be directed by dental advertising from manufacturers. Procedures should be based on what is predictable.

An underlying theme of *Contemporary Implant Dentistry* is to base the treatment of missing teeth on the sciences related to implant dentistry. This book does not attempt to be an encyclopedia of all that is possible in implant dentistry. Instead, it is a text that relates one chapter to every other chapter and presents a common thread of science and past experience to the art of replacing teeth. Every chapter is carefully blended to be consistent in purpose: to provide a predictable outcome.

The third edition of *Contemporary Implant Dentistry* addresses the science and discipline of implant dentistry. This book has nearly doubled in size and has added new chapters in treatment planning, bone grafting, and implant surgery. In addition, more than 2000 illustrations have been used to detail related concepts.

The first part of *Contemporary Implant Dentistry* presents the rationale for the use of dental implants as man-made abutments and why biomechanics should be used as a basis of implant treatment planning as a way to reduce complications. It also presents a generic seven-step process for treatment planning. More than 50 dental criteria may influence treatment planning and prognosis. Implant dentistry does not guarantee a result, nor is it without complications. However, there is a consistent theme to reduce and eliminate many complications, and this theme starts with a biomechanically based treatment plan.

The second part of this book concentrates on specific diagnoses and treatment plans for both the partial and complete edentulous jaw. These chapters organize and present clinical considerations in a logical sequence. The chapters relate the previous general concepts to the clinical conditions most often observed in practice: the posterior missing single tooth is addressed separately from the anterior missing tooth, and the completely edentulous mandible is different from the maxilla.

The third part of *Contemporary Implant Dentistry* provides information from the related basic sciences of medical evaluation, applied anatomy, bone physiology, pharmacology, biomechanics, and biomaterials.

The fourth part organizes and presents implant surgery with generic concepts and expands the surgery by implant location and anatomic variables. These procedures blend the science of implant surgery with three decades of experience to improve clinical outcomes. This part also addresses immediate loading for a single tooth, overdentures, multiple adjacent missing teeth, and full arch fixed restorations.

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

The fifth part of the book presents soft and hard tissue rehabilitation. It begins with the keys necessary for predictable results, proceeds with the traumatic extraction of a hopeless tooth, and lastly discusses barrier membrane bone grafts. This section also includes sinus grafts (complete with specific evaluation, pathology, and complications related to the maxillary sinus). Autograft block bone grafts from intraoral donor sites are also covered in detail, followed by extraoral block and particulate grafts from the ilium and tibia.

The final part of *Contemporary Implant Dentistry* presents the long-term evaluation and maintenance of dental implants. A clinical evaluation and treatment is emphasized.

Contemporary Implant Dentistry has been used over the years as a textbook for dental students, interrelated dental residents, postgraduate programs, implant residents, specialists, and generalists. Its translation into many languages and its widespread acceptance have provided a thinking process for oral implantology. This most recent edition attempts to help further elevate the science and discipline of implant dentistry and allow predictable treatment to replace missing teeth for the patients we treat and the doctors we train.

Acknowledgments

In this fourth book, I attempt to share my experience, training, and knowledge in a discipline to which I have dedicated my life. As in all of the other books, I must again acknowledge the undying efforts of my wife, Dr. Francine Misch-Dietsh. She is responsible for most of the literature review in every chapter of which I am the primary author. She directed and worked with the illustrator to ensure each drawing was accurate and clear. She read every line of every chapter repeatedly, ensuring the message was consistent and referenced. She co-coordinated my staff and the publisher in the final preparations of the book. I publicly thank her for the constant dedication to me, our family, and the profession.

There are many additional people to acknowledge and thank in the preparation and publication of *Contemporary Implant Dentistry,* third edition. Allow me to begin with all participating authors: Martha Warren Bidez, Diana Bronstein, Marco Degidi, Giovanna Iezzi, Louis T. Kircos, Jack E. Lemons, Matthew Lyman, Francine Misch-Dietsh, Adriano Piatelli, Ana Emília Farias Pontes, Girish Ramaswamy, Randolph R. Resnik, W. Eugene Roberts, David P. Sarment, Antonio Scarano, Gerard M. Scortecci, Mohammed Sharawy, Miles L. Singer, J. Todd Strong, Jon B. Suzuki, and Lynn D. Terracciano-Mortilla. Their dedication to implant dentistry, and especially their friendship and personal support to me, is greatly appreciated.

My original three mentors—Ken Judy, Hilt Tatum, and Leonard Linkow—must always be acknowledged. Implant dentistry needed early pioneers to blaze the trails for the profession. Their concepts for bone grafting, implant surgery, prosthetics, implant education, and leadership created a foundation 40 years ago that allowed the profession to build the current structure we have in implant dentistry. I especially thank each of them for providing their personal continued guidance and support to me over the last 35 years.

I would also like to acknowledge James Cole, the dental illustrator who worked overtime to meet the demands of this project and never became frustrated at the many redos to satisfy our desire for an acceptable outcome. Thank you to Jill Bertelson, Heidi Cartagena, Debi Leblanc, and Lara Vandekerckhove, our personal assistants and secretaries, for typing and coordinating each chapter (especially since each chapter was rewritten 10 to 15 times).

Each book takes a personal toll on my immediate family. During this project, not only my wife Francine, but my youngest daughter Angela bore the brunt of the time and pressures to write this book. Thank you for understanding and giving up our personal time.

I would also like to acknowledge the acquisitions editor, John Dolan of Elsevier. Thank you for your experience and guidance during this process. Without your help, this project would have not come to fruition.

The third edition of *Contemporary Implant Dentistry* is also a reflection of the thousands of doctors I have trained at the Misch International Implant Institute over the last 25 years. Those doctors have contributed by the questions asked and their desire for an organized approach to help their patients. I wish to thank each of them for their professional support.

Chapter 1

Rationale for Dental Implants

Carl E. Misch

The goal of modern dentistry is to restore the patient to normal contour, function, comfort, esthetics, speech, and health, whether by removing caries from a tooth or replacing several teeth. What makes implant dentistry unique is the ability to achieve this goal, regardless of the atrophy, disease, or injury of the stomatognathic system.[1] However, the more teeth a patient is missing, the more challenging this task becomes. As a result of continued research, diagnostic tools, treatment planning, implant designs, materials, and techniques, predictable success is now a reality for the rehabilitation of many challenging clinical situations.

The number of dental implants used in the United States increased more than tenfold from 1983 to 2002, and another fivefold from 2000 to 2005. More than 1 million dental implants are inserted each year. This number continues to increase steadily, with almost $550 million of implant products sold to North American dentists in 2005, compared with $10 million in 1983, with an expected yearly growth sustained at 12% to 15% for the next several years.[2,3] When bone grafting materials are included in implant products, it is estimated the field of implant dentistry will sell $10 billion in services to patients by 2010.[4] More than 90% of interfacing surgical specialty dentists currently provide dental implant treatment on a routine basis in their practices, 90% of prosthodontists restore implants routinely, and more than 80% of general dentists have used implants to support fixed and removable prostheses, compared with 65% 15 years ago.[5-9]

The increased need and use of implant-related treatments result from the combined effect of several factors, including (1) aging population living longer, (2) tooth loss related to age, (3) consequences of fixed prosthesis failure, (4) anatomical consequences of edentulism, (5) poor performance of removable prostheses, (6) consequences of removable partial dentures, (7) psychological aspects of tooth loss and needs and desires of aging baby boomers, (8) predictable long-term results of implant-supported prostheses, (9) advantages of implant-supported restorations, and (10) increased public awareness.

EFFECTS OF AN AGING POPULATION

According to the literature, age is directly related to every indicator of tooth loss.[10,11] Therefore the aging population is an important factor to consider in implant dentistry. When Alexander the Great conquered the ancient world, he was only 17 years old. However, life expectancy at that time was only 22 years of age. From 1000 BC to AD 1800, life span remained less than 30 years (Figure 1-1). Since 1960, the increase in life expectancy has been more rapid than at any other time in history. In 1980, 30% of the U.S. population was older than age 45, 21% was older than 50, and 11% was older than 65. In 1995, 15 years later, all these individuals were older than age 60. The group older than age 65 is projected to increase from 12%

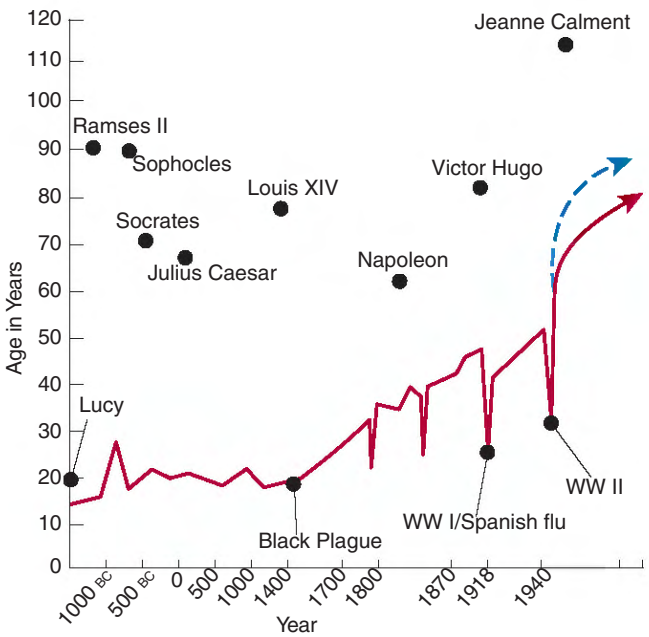

Figure 1-1 Average life expectancy remained approximately 20 to 30 years for several hundred years of human civilization. Since the late eighteenth century, there has been a gradual increase in life span. *(Redrawn from* Le Figaro Magazine, *Paris, 2004.)*

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

in 2000 to more than 20% of the population within the next 25 years[12] (Figure 1-2).

In addition, not only is the percentage of the population over 65 years increasing, but the overall population is also increasing. The population in 2000 was 282 million and is projected to increase 49% to 420 million by 2050. Considering the effect of both a population increase and a greater percentage of that population being older than age 65, a dramatic overall increase in patient numbers can be expected. In 2003, 35 million people were older than age 65. This number is expected to increase 87% by 2025, resulting in almost 70 million people being older than age 65[13] (Figure 1-3). Because older people are more likely to be missing teeth, the need for implant dentistry will dramatically increase over the next several decades.

Life expectancy has increased significantly past the age of retirement. In 1965 the average life span was 65 years; in 1990 it was 78 years. Life expectancy in 2001 was 85 years for a nonsmoking individual of normal weight.[14] A 65-year-old person can now expect to live more than 20 additional years, and an 80 year old can expect to live 9.5 more years[15-17] (Figure 1-4). Women represent two thirds of the population older than age 65.[18] It is not unusual for a 70-year-old patient to ask, "Is it worth it for me to spend $30,000 to repair my mouth at my age?" The response should be very positive, as the patient's life expectancy will extend for two more decades, and their current oral situation will normally become worse if not corrected.

Social pleasures, including dining and dating, continue throughout advanced life. In the past, geriatric dentistry meant inexpensive treatment emphasizing nonsurgical approaches. The poverty rate for the elderly, however, is less than 10%, and retiree median income has grown 8% in recent years. According to the last census, the median net worth of retirees is 15 times the net worth of those younger than age 35 and three times as high as "working families" ages 35 to 44 years.[18,19] Close to 20% of today's retirees have a net worth of more than a quarter of a million dollars. Today, the full scope of dental services for elderly patients is increasing in importance to both the public and the profession because of the increasing age of our society. Treatment alternatives that consider fixed prostheses with implant support should be presented to almost any patient. Only when all treatment options are discussed can a person's desires related to the benefit of implant dentistry be truly appreciated.

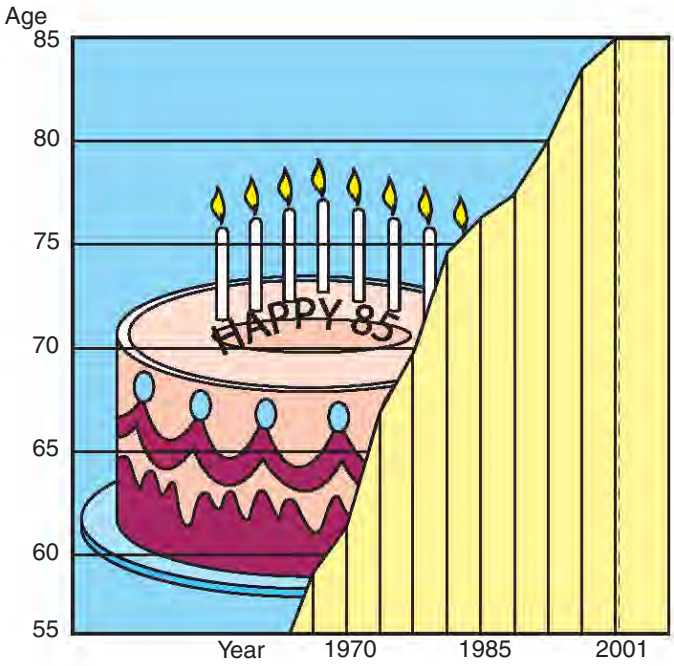

Figure 1-2 Life expectancy has increased more rapidly since 1960 than at any other time in history. Because tooth loss is directly related to age, a growing number of adults are missing teeth.

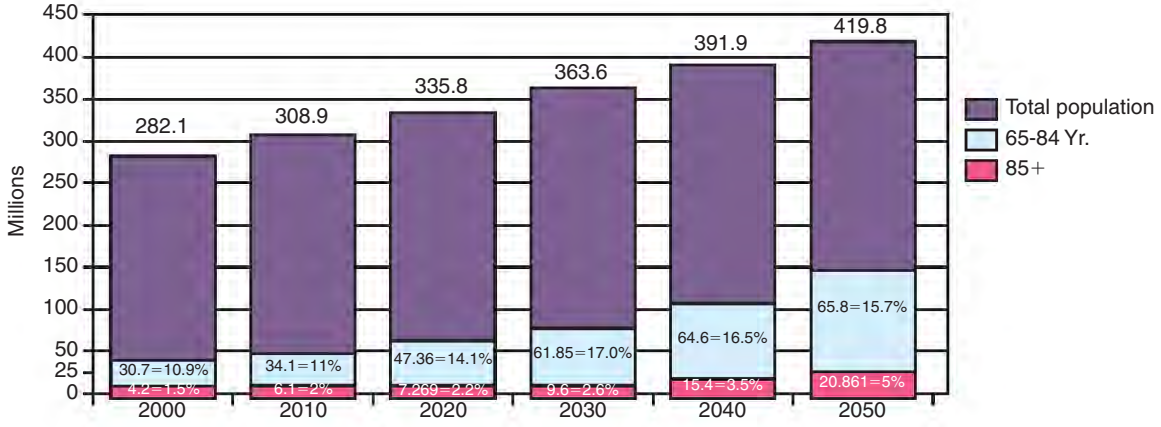

Figure 1-3 By 2050, 20.7% of the population will be older than age 65. In addition to the increasing percentage of 65 year olds, the population is also increasing. As a result, 34.9 million people were older than 65 in 2000, and 86.6 million people will reach this milestone by 2050.

This ebook is uploaded by dentalebooks.com
t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

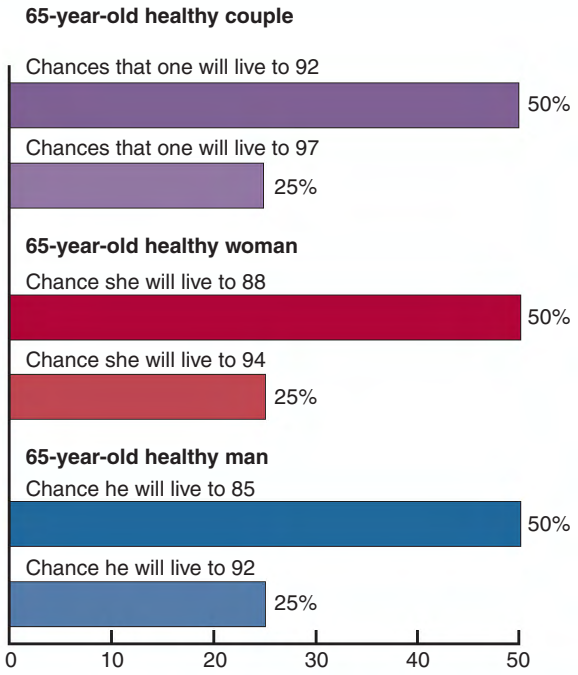

Figure 1-4 When a person reaches age 65, he or she often feels an investment in health is less appropriate. A 65-year-old healthy woman will live 23 more years 50% of the time, and 29 more years 25% of the time. Her present oral condition will become worse during this extended time frame if treatment is not rendered.

Figure 1-5 A posterior missing tooth is a frequent occurrence in a general practice. Almost 80% of the time the adjacent teeth are unrestored or have minimum restoration.

Dental services for elderly patients clearly represent a growing demand for the dental profession. In 2000, 28.8% of all income from a dentist came from patients age 60 and older—a group that represented only 12% of income in 1988. When the dentist is older than age 40, income from those older patients represents 64.3% of the dentist's income, whereas in 1988 it was 30.3%.[20] Clearly, the demographics of our population have dramatically changed the economics of dental practice.

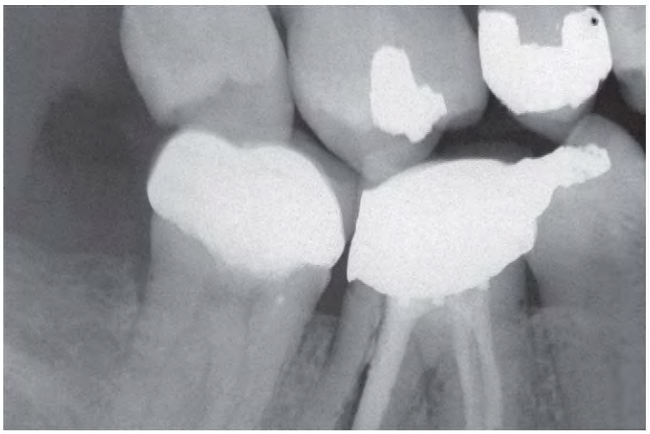

Figure 1-6 A posterior endodontically treated tooth has an increased risk of fracture or failure of the endodontic therapy.

AGE-RELATED TOOTH LOSS

Single-Tooth Edentulism

The posterior regions of the mouth often require the replacement of a single tooth[21-23] (Figure 1-5). The first molars are the first permanent tooth to erupt in the mouth and, unfortunately, are often the first teeth lost as a result of decay, failed endodontic therapy or fracture (usually after endodontics). They are important teeth for maintenance of the arch form and proper occlusal schemes. In addition, the adult patient often has one or more crowns, as a consequence of previous larger restorations required to repair the integrity of the tooth. Longevity reports of crowns have yielded very disparate results. The mean life span at failure has been reported as 10.3 years. Other reports range from a 3% failure rate at 23 years to a 20% failure rate at 3 years. The primary cause of failure of the crown is caries followed by endodontic therapy.[24-33] The tooth is at risk for extraction as a result of these complications, which are the leading causes of single posterior tooth loss in the adult (Figure 1-6). It has been estimated that a $425 crown for a 22-year-old patient will cost $12,000 during the patient's lifetime to replace and/or repair.[26]

Fixed Partial Dentures

The most common choice to replace a posterior single tooth is a three-unit fixed partial denture (FPD). This type of restoration can be fabricated within 1 to 2 weeks and satisfies the criteria of normal contour, comfort, function, esthetics, speech, and health. Because of these benefits, FPD has been the treatment of choice for the last 6 decades. Bone and soft tissue considerations in the missing tooth site are few. Every dentist is familiar with the procedure, and it is widely accepted by the profession, patients, and dental insurance companies.

In the United States, 70% of the population is missing at least one tooth. Almost 30% of the 50 to 59 year olds examined in a U.S. National Survey exhibited

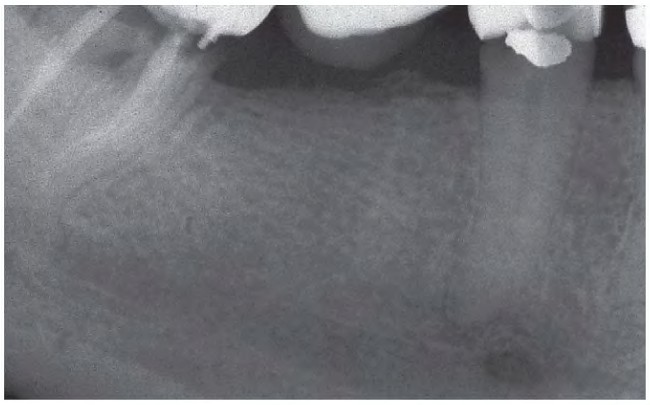

Figure 1-7 A three-unit fixed partial denture most often fails because of caries on a crown margin, next to the pontic.

either single or multiple edentulous spaces bordered by natural teeth. In 1990, more than 4 million FPDs were placed in the United States.[23-25] Treatments to replace single teeth with a fixed prosthesis represent 7% of the annual dental reimbursement from insurance companies and more than $3 billion each year. Only one third of our population in the United States has dental insurance and of those who do, only 50% of treatment costs are reimbursed. Hence, the entire three- to four-unit FPD costs in the United States may approach more than $10 billion each year.

A three-unit FPD also presents survival limitations to the restoration and, more importantly, to the abutment teeth.[30,32] In an evaluation of 42 reports since 1970, Creugers et al. calculated a 74% survival rate for FPDs for 15 years.[29] Mean life spans of 9.6 to 10.3 years have been reported by Walton et al.[31] and Schwartz et al.,[24] respectively. However, reports are very inconsistent, with as little as 3% loss over 23 years to 20% loss over 3 years.[23-32] Caries and endodontic failure of the abutment teeth are the most common causes of prostheses failure.[31,32] Up to 15% of abutment teeth for an FPD require endodontic therapy, compared with 3% of nonabutment teeth that have crown preparations. The long-term periodontal health of the abutment teeth, including bone loss, may also be at greater risk.[29]

Unfavorable outcomes of FPD failure include both the need to replace the failed prosthesis and the loss of an abutment and the need for additional pontics and abutment teeth in the replacement bridge. The abutment teeth of an FPD may be lost at rates as high as 30% within 14 years.[30] Approximately 8% to 12% of the abutment teeth holding an FPD are lost within 10 years. The most common reason for single tooth loss is endodontic failure or fracture of a tooth (usually after endodontic therapy). Because 15% of abutment teeth require endodontics, and root canal therapy may be 90% successful at the 8-year mark, abutment teeth are at increased risk of loss. In addition, abutment teeth are more prone to caries when splinted together with

Box 1-1 Single-Tooth Replacement—Fixed Partial Denture

- Estimated mean life span of FPD (50% survival) reported at 10 years
- Caries most common cause of FPD failure
- 15% of FPD abutments require endodontics
- Failure of abutment teeth of FPD 8% to 12% at 10 years and 30% at 15 years
- 80% of teeth adjacent to missing teeth have no or minimal restoration

FPD, Fixed partial denture.

Figure 1-8 A single-tooth implant in the posterior region of the mouth is most often the treatment of choice.

an intermediary pontic. Individual crowns have decay rates below 2%; however, the risk of caries in abutment teeth is approximately 20%, mainly because the pontic region acts as a plaque reservoir. The carious lesion at the crown margin may cause structural failure, even if endodontic treatment is possible (Figure 1-7).

Almost 80% of abutments prepared for a three-unit FPD have no existing or only minimal restorations.[34] Rather than removing sound tooth structure and crowning two or more teeth—thus increasing the risk of decay and endodontic therapy (and splinting teeth together with pontics, which have the potential to cause additional tooth loss)—a dental implant may replace the single tooth (Box 1-1).

Single-Tooth Implants

A treatment option to replace a posterior single missing tooth is a single-tooth implant (Figure 1-8). For years, patients were advised to put their desires aside and accept the limitations of an FPD. However, many feel the most natural method to replace a tooth is to use an implant, rather than preparing adjacent teeth and joining them together with a prosthesis. The primary reasons for suggesting the FPD were its clinical ease and reduced treatment time. However, if this concept were expanded, extractions would replace endodontics and dentures could even replace orthodontics. The primary

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

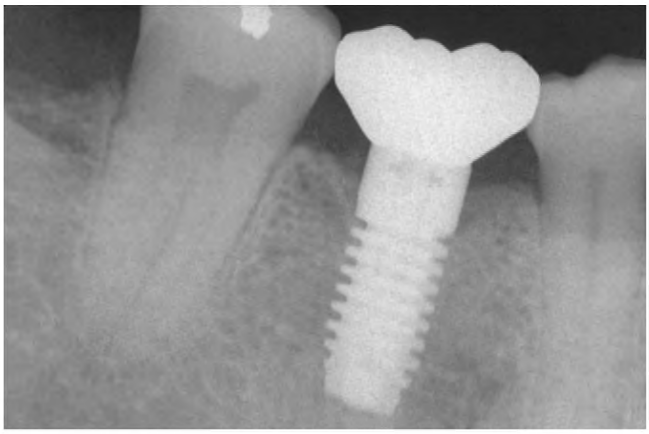

Figure 1-9 A single-tooth implant to replace a missing tooth has the highest success rate, and the adjacent teeth are less likely to decay, require endodontics, or result in additional tooth loss.

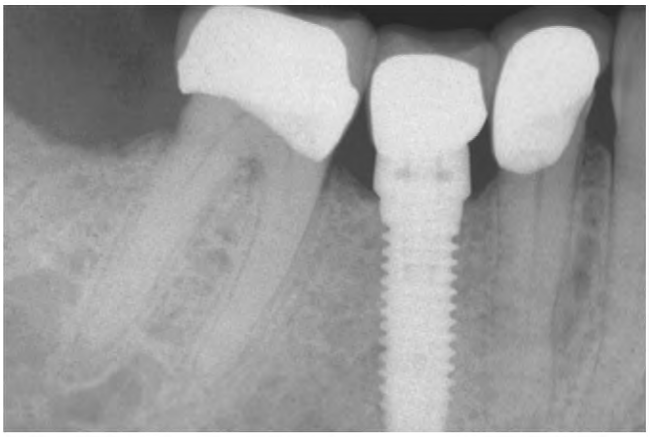

Figure 1-10 Even when teeth adjacent to the missing tooth require crowns, an implant is the treatment of choice because single crowns on teeth adjacent to implants have fewer complications and increased longevity compared with abutments for a three-unit fixed partial denture.

Box 1-2 Single-Tooth Implants—Advantages

- High success rates (above 97% for 10 years)
- Decreased risk of caries of adjacent teeth
- Decreased risk of endodontic problems on adjacent teeth
- Improved ability to clean the proximal surfaces of the adjacent teeth
- Improved esthetics of adjacent teeth
- Improved maintenance of bone in the edentulous site
- Decreased cold or contact sensitivity of adjacent teeth
- Psychological advantage
- Decreased abutment tooth loss

reason to suggest or perform a treatment should not be related to treatment time or difficulty of the procedure, but instead should consider the best possible long-term solution for each individual.

From 1993 to the present, single-tooth implant survival reports have validated this procedure as the most predictable method of tooth replacement. There are more refereed reports in the literature for single-tooth implant replacement than for any other method of tooth replacement,[35-47] and all reports demonstrate a higher survival rate for single-tooth implants. Goodacre et al. performed a Medline literature review from 1980 to 2001 and found the single-tooth implant success rate to be in the range of 97%—higher than any other implant restoration.[35] In 1995, Haas et al. reported on 76 single-tooth implants over a 6-year period and found a 97% survival rate and a 2.6% implant loss.[38] Fugazzotto evaluated 1472 implants over a 13-year period and found a 97% survival rate during that period.[39]

Although posterior single-tooth replacement is a relatively new treatment alternative, many studies have been published since 1990, and survival rates reported range from a low of 94.6% to a high of 100% for 1 to 15 years.[35-45] The median of these reports is a 2.8% implant loss with a mode of 5 years. In comparison, FPD failure rates may be as high as 20% within 3 years, and 50% rates at 10 years are expected. As a result, the single-tooth implant exhibits the highest survival rates presented for single-tooth replacement. As important, no reports indicate a loss of an adjacent tooth, which is a considerable advantage. On the other hand, the longevity of the implant crown has not been adequately determined, as these reports do not extend as long as those of other treatment options.

Despite some limitations and obvious clinical challenges, the single-tooth implant represents the treatment of choice from both a health and value standpoint. When adjacent teeth are healthy, or when the patient refuses their preparation for the fabrication of a traditional three-unit fixed partial restoration, a posterior single-tooth implant is an excellent solution (Figure 1-9). Health-related advantages of this modality over a fixed partial restoration are listed in Box 1-2 and include a decreased risk of decay and periodontal disease, decreased risk of abutment tooth loss from endodontic failure or caries, and improved esthetics (Figure 1-10). Psychological advantages, especially with congenitally missing teeth or the loss of a tooth after a crown restoration, are significant as well. These advantages are so significant to the health and periodontal condition of the adjacent teeth and maintenance of the arch form that the single-tooth implant has become the treatment of choice in most situations. Economical considerations may play in disfavor of the implant restoration only during the first 7 years. The single-tooth implant becomes more advantageous economically, not only for health considerations, after the break-even point of 7 years, at which time the patient will not need a replacement prosthesis. The savings will offset the initial higher cost.[47]

Partial Edentulism

The prevalence of partial edentulism is also of interest because a growing number of implants are used in these patients. A 1988 to 1991 survey in the United States found that only 30% of these patients had all 28 teeth. Partially dentate patients had an average of 23.5 teeth.[10,23,48] In the 1999 to 2002 follow-up survey, the average number of missing teeth was fewer than two of 28 teeth for the 20- to 39-year-old group. However, this number rapidly increased to an average of nine teeth missing in adults older than age 60. Partially edentulous seniors older than age 60 age have lost an average of 10 teeth, with older seniors having lost three more teeth than the younger seniors. Statistics for partial edentulism are similar for both men and women. The greatest transition from an intact dental arch to a partially edentulous condition in the 1987 study occurred in the 35- to 54-year-old group.[20,23] The growth rate of this baby boomer portion of the population was approximately 30% in 1982 and is continuing to increase, more than any other age group. For example, in 1982 the baby boomer age group (born from 1946 to 1964) increased from 39 million Americans to 79 million in 2005. Although the number of teeth missing per patient may seem to decrease, the overall number of missing teeth will continue to increase. Therefore the need for implant services in partially edentulous patients will dramatically increase during the next several decades.[15]

The most common missing teeth are molars.[22] Partial free-end edentulism is of particular concern because in these patients, teeth are often replaced with removable partial prostheses. This condition is rarely found in persons younger than age 25. Mandibular free-end edentulism is greater than its maxillary counterpart in all age groups. Unilateral free-end edentulism is more common than bilateral edentulism in both maxillary and mandibular arches in the younger age groups (ages 25 to 44). About 13.5 million persons in these younger age groups have free-end edentulism in either arch.

In 45- to 54-year-old patients, 31.3% have mandibular free-end edentulism and 13.6% have free-end edentulism in the maxillary arch. Approximately 9.9 million persons in the 45- to 54-year-old group have at least one free-end edentulous quadrant, and almost half of these have bilateral partial edentulism.[11] The pattern of posterior edentulism evolves in the 55- to 64-year-old group, in which 35% of mandibular arches show free-end edentulism, compared with 18% of maxillary arches. As a result, approximately 11 million individuals in this age group are potential candidates for implants. An additional 10 million show partial free-end edentulism at age 65 or older. Additional studies have documented that in the population of noninstitutionalized U.S. civilians, 1 of 5 had a removable prosthesis of some type.[49-51] The total number of potential patients in the U.S. survey with at least one quadrant of posterior missing teeth is more than 44 million people.[11] If each of these arches requires three implants to support a fixed prosthesis, 132 million implants added to the 192 million for edentulous patients would be required.

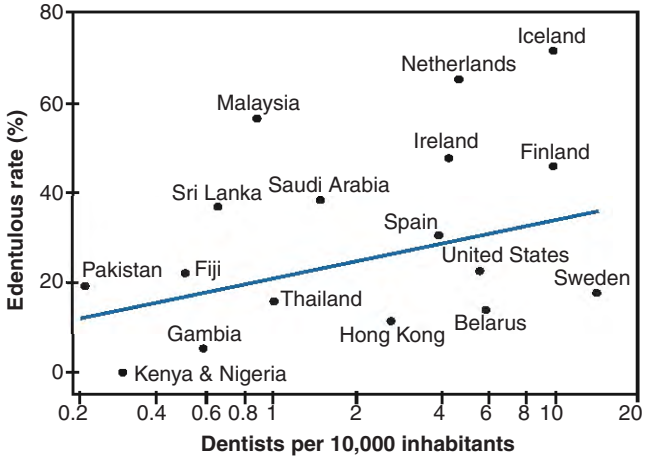

Figure 1-11 The incidence of complete edentulism averages 20% of the adult population around the world. It is interesting to note that often the greater the number of dentists per population, the greater the rate of edentulism. *(Adapted from Mojon P: The world without teeth: demographic trends. In Feine JS, Carlsson GE, editors:* Implant overdentures: the standard of care for edentulous patients, *Carol Stream, Ill, 2003, Quintessence.)*

Total Edentulism

Edentulism is not an eventual, healthy occurrence in an adult population. Rather it is most often the result of repeated tooth extractions from the combined pathologic processes of dental caries, periodontal disease, or a method to reduce the costs associated with dental treatment.[52-54] Similar to other pathologic outcomes of disease, the occurrence of total loss of teeth is directly related to the age of the patient. The rate of edentulism increases at 4% per 10 years in early adult years and increases to more than 10% per decade after age 70.[54]

The average total edentulous rate around the world is 20% at age 60, although there is wide disparity from the countries with the highest and lowest rates[54] (Figure 1-11). For example, from the 65- to 74-year age group, the total edentulous rate in Kenya and Nigeria was 0%, whereas the Netherlands and Iceland have a 65.4% and 71.5% rate, respectively. The edentulous Canadian rate was 47% at 65 to age 69 and 58% from ages 70 to 98 (with Quebec at 67% for those older than age 65, compared with Ontario with a 41% rate). One of the main factors influencing total edentulism was the level of education. In data from the Canadian Health Promotion Survey from 1990, the least educated had an edentulous rate of 50%, whereas those with a college education had a low 4% rate.[55] The United States showed a similar pattern in the period 1988 to 1994, with an edentulous rate of 22% for those with less than 8 years of education, 12% for those with 9 to

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

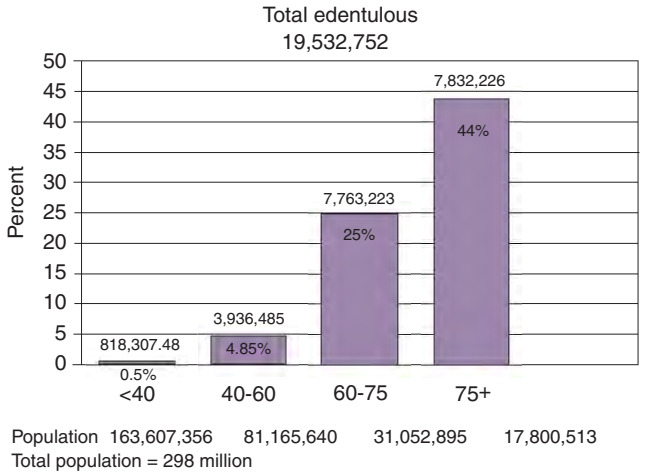

Figure 1-12 The U.S. population completely edentulous rate ranges from 5% for 40 year olds to 44% for those older than age 75. As a result, 20 million people (10.5% of the population) in the United States have no teeth. An additional 12 million people (7% of the adult population) have no maxillary teeth opposing at least some mandibular teeth.

11 years of school, 8% for those with 12 years of school, and 5% for individuals with more than 12 years of education.[48] Income is often related to education and may also play a role in the rate of edentulism.

In the National Institute of Dental Research national surveys, the occurrence of total edentulism (absence of teeth) of a single arch (35 times more frequent in the maxilla) was slight in the 30- to 34-year-old age group, but it increased at around age 45 to 11% and then remained constant after 55 years at approximately 15% of the adult population. A total of approximately 12 million individuals in the United States have edentulism in one arch, representing 7% of the adult population overall.

The 1999 to 2002 survey found that total edentulism of both arches occurred in 7.7% of the adult population in the United States, or almost 20 million people.[48] The present younger population is benefiting from today's advanced knowledge and restorative techniques. Edentulism has been noted in 5% of employed adults ages 40 to 44, gradually increasing to 26% at age 65, and almost 44% in seniors older than age 75[10] (Figure 1-12). As expected, older persons are more likely to be missing all their teeth. Gender was not found to be associated with tooth retention or tooth loss once adjustments were made for age.

The percentages of one- or two-arch edentulism translate into more than 30 million people or about 17% of the entire U.S. adult population.[17] To put these numbers in perspective, 30 million people represent approximately the entire U.S. African American population, or the whole population of Canada. Although the edentulism rate is decreasing every decade, the elderly population is rising so rapidly that the adult population in need of one or two complete dentures will actually *increase* from 33.6 million adults in 1991 to 37.9 million adults in 2020. The total number of edentulous arches is estimated at 56.5 million in 2000, 59.3 million in 2010, and 61 million in 2020.[56] Complete edentulism, therefore, remains a significant concern, and affected patients often require implant dentistry to solve several related problems. If four implants were used to help support each complete edentulous arch in 2000, a total of 226 million implants would be required. Yet only 1 million implants were inserted for all patient treatment (partially or completely edentulous) each year. Almost 70% of dentists spend less than 1% to 5% of their treatment time on edentulous patients, leaving a great unfulfilled need for implant dentistry.

When the partially edentulous figures are added to the complete edentulous percentages, almost 30% of the adult U.S. population are candidates for a complete or partial removable prosthesis. The need for additional retention, support, and stability and the desire to eliminate a removable prosthesis are common indications for dental implants. As a result, 74 million adults (90 million arches) are potential candidates for dental implants. Because a minimum of five appointments is required to implant and restore a patient, every U.S. dentist would need approximately 20 appointments every month for 20 years to treat the present posterior partial and complete edentulous population with implant-supported prostheses. The population's evolution to an increased average age, combined with the existing population of partially and completely edentulous patients, guarantee implant dentistry's future for several generations of dentists.

ANATOMICAL CONSEQUENCES OF EDENTULISM

Consequences on the Bony Structures

Basal bone forms the dental skeletal structure, contains most of the muscle attachments, and begins to form in the fetus before teeth develop. Alveolar bone first appears when Hertwig's root sheath of the tooth bud evolves[57] (Figure 1-13). The alveolar bone does not form in the absence of primary or secondary tooth development. The close relationship between the tooth and the alveolar process continues throughout life. Wolff's law (1892) states that bone remodels in relationship to the forces applied.[58] Every time the function of bone is modified, a definite change occurs in the internal architecture and external configuration.[59] In dentistry, the consequences of complete edentulous and remaining bone volume was noted by Misch in 1922, where he described the skeletal structure of a 90-year-old woman without teeth for several decades.[60]

Bone needs stimulation to maintain its form and density. Roberts et al.[61] report that a 4% strain to the skeletal system maintains bone and helps balance the resorption and formation phenomena. Teeth transmit

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

Figure 1-13 The alveolar bone forms as a result of the tooth root formation. When no tooth root is present, the alveolar process does not form (i.e., ectodermal dysplasia when partial or complete anodontia of both primary and secondary teeth occurs).

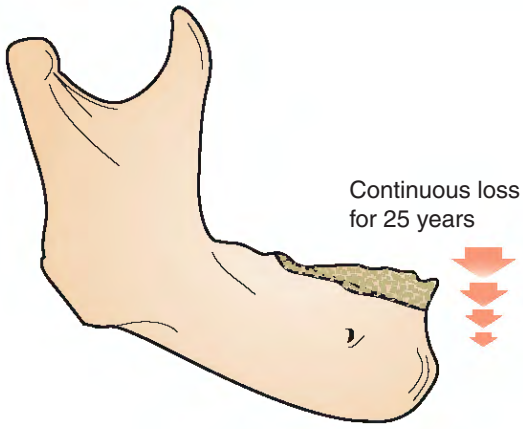

Figure 1-14 After the initial extraction of teeth, the average first-year bone loss is more than 4 mm in height and 30% in crestal bone width. Although the rate of bone loss is slower after the first year, the bone loss is continuous throughout life.

compressive and tensile forces to the surrounding bone. These forces have been measured as a piezoelectric effect in the imperfect crystals of durapatite that compose the inorganic portion of bone.[62] When a tooth is lost, the lack of stimulation to the residual bone causes a decrease in trabeculae and bone density in the area, with loss in external width, then height, of the bone volume.[63] There is a 25% decrease in width of bone during the first year after tooth loss and an overall 4-mm decrease in height during the first year after extractions for an immediate denture.[64] In a longitudinal 25-year study of edentulous patients, lateral cephalograms demonstrated continued bone loss during this time span; a fourfold greater loss was observed in the mandible[65] (Figure 1-14). However, because initially the mandible height is twice that of the maxilla, maxillary bone loss is also significant in the long-term edentulous patient.

A tooth is necessary to the development of alveolar bone, and stimulation of this bone is required to maintain its density and volume. A removable denture (complete or partial) does not stimulate and maintain bone; rather, it accelerates bone loss. The load from mastication is transferred to the bone surface only, not the whole bone. As a result, blood supply is reduced and total bone volume loss occurs.[66] This issue, which is of utmost importance, has been observed but not addressed in the past by traditional dentistry. Doctors most often overlook the insidious bone loss that will occur after tooth extraction. The patient is often not educated about the anatomical changes and the potential consequences of continued bone loss. The bone loss accelerates when the patient wears a poorly fitting soft tissue–borne prosthesis. Patients do not understand that bone is being lost over time and at a greater rate beneath poorly fitting dentures (Figure 1-15). Patients do not return for regular visits for evaluation of their condition; instead, they return after several years when denture teeth are worn down or can no longer be tolerated. Hence the traditional method of tooth replacement often affects

Figure 1-15 Atwood described six different stages of resorption in the anterior mandible. Stage 1 represents the tooth and surrounding alveolar process and basal bone. Stages II and III illustrate the initial residual ridge after tooth loss. Stages IV to VI primarily describe a continuous loss in length of anterior residual bone.

bone loss in a manner not sufficiently considered by the doctor and the patient. The doctor should inform the patient that a denture replaces more bone and soft tissue than teeth, and every 5 years a reline or new denture is suggested to replace the additional bone loss by atrophy (Figure 1-16).

Preventive dentistry has traditionally emphasized methods to decrease tooth loss. No predictable therapy had been accepted by the profession to avoid the bone changes resulting from tooth loss. Today the profession must consider the loss of both teeth and bone. The loss of teeth causes remodeling and resorption of the surrounding alveolar bone and eventually leads to atrophic edentulous ridges. Although the patient often is not aware or informed of the potential consequences, over time consequences will occur. The rate and amount of bone loss may be influenced by such things as gender, hormones, metabolism, parafunction, and ill-fitting dentures. Yet almost 40% of denture wearers have been wearing an ill-fitting prosthesis for more

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

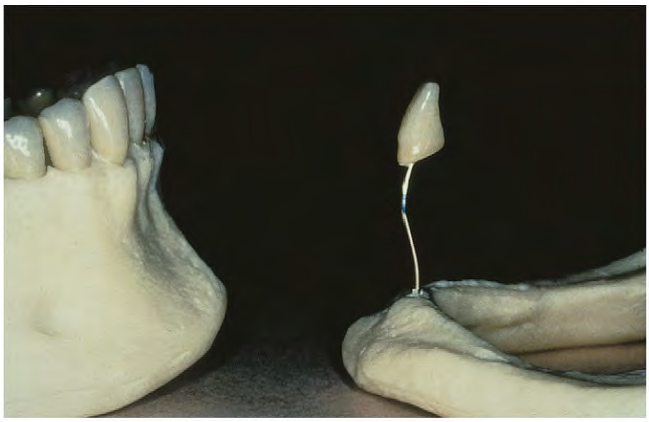

Figure 1-16 Loss of bone height in the mandible may be measured in inches and often is ignored. Such bone loss is often more significant than the bone loss (in millimeters) from periodontal disease. The patient should understand that a denture often replaces more bone than teeth to restore the proper dimensions of the face.

Figure 1-17 A patient with moderate to severe atrophy usually has the intraoral muscles above the residual ridge, including the floor of the mouth and the mentalis and buccinator muscles.

Box 1-3 Consequences of Bone Loss in Fully Edentulous Patients

- Decreased width of supporting bone
- Decreased height of supporting bone
- Prominent mylohyoid and internal oblique ridges with increased sore spots
- Progressive decrease in keratinized mucosa surface
- Prominent superior genial tubercles with sore spots and increased denture movement
- Muscle attachment near crest of ridge
- Elevation of prosthesis with contraction of mylohyoid and buccinator muscles serving as posterior support
- Forward movement of prosthesis from anatomical inclination (angulation of mandible with moderate to advanced bone loss)
- Thinning of mucosa, with sensitivity to abrasion
- Loss of basal bone
- Paresthesia from dehiscent mandibular neurovascular canal
- More active role of tongue in mastication
- Effect of bone loss on esthetic appearance of lower third of face
- Increased risk of mandibular body fracture from advanced bone loss
- Loss of anterior ridge and nasal spine, causing increased denture movement and sore spots during function

than 10 years.[67] Patients wearing dentures day and night place greater forces on the hard and soft tissues, which accelerates bone loss. Nonetheless, 80% of dentures are worn both day and night.[68]

Atrophic edentulous ridges are associated with anatomical problems that often impair the predictable results of traditional dental therapy (Figure 1-17). Several of these anatomical problems are listed in Box 1-3. The loss of bone first causes decreased bone width. The remaining narrow residual ridge often causes discomfort when the thin overlying tissues are loaded under a soft tissue–borne removable prosthesis. The continued atrophy of the posterior mandible eventually causes prominent mylohyoid and internal oblique ridges covered by thin, movable, unattached mucosa. The anterior residual alveolar process also continues to resorb, and the superior genial tubercles (which are 20 mm below the crest of bone when teeth are present) eventually become the most superior aspect of the anterior mandibular ridge. There is little to prevent the prosthesis from moving forward against the lower lip during function or speech. This condition is further compromised by the vertical movement of the distal aspect of the prosthesis during contraction of the mylohyoid and buccinator muscles and the anterior incline of the atrophic mandible compared with that of the maxilla.[69]

Loss of bone in the maxilla or mandible is not limited to alveolar bone; portions of the basal bone may be resorbed also (Figure 1-18), especially in the posterior aspect of the mandible where severe resorption may result in more than 80% bone loss.[66] The contents of the mandibular canal or mental foramen eventually become dehiscent and serve as part of the support area of the prosthesis.[70] As a result, acute pain and transient to permanent paresthesia of the areas supplied by the mandibular nerve are possible. The body of the mandible also is at increased risk of fracture, even under very-low-impact forces (Figure 1-19). The mandibular fracture causes the jaw to shift to one side and makes stabilization and an esthetic result most difficult to obtain during treatment of the fracture.

The complete anterior ridge and even the nasal spine may be resorbed in the maxilla, causing pain and an increase in maxillary denture movement during function.[67] Masticatory forces generated by short facial types (brachiocephalics) can be three to four times that of long facial types (dolichocephalics). Short facial–

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

A B

Figure 1-18 **A,** Lateral cephalogram of a patient demonstrates the restored vertical dimension of occlusion with a denture. However, because of the advanced basal bone loss in the mandible, the superior genial tubercles are positioned above the residual anterior ridge. The body of the mandible is only a few millimeters thick, and the mandibular canal is completely dehiscent (one body is superimposed on top of the other in this view). In the maxillary anterior ridge, only the nasal spine remains (not the original alveolar ridge), and the posterior maxillary bone is paper thin because of basal bone loss at the crest and the pneumatization of the maxillary sinus. **B,** A denture may restore the vertical dimension of the face, but the bone loss of the jaws can continue until the basal bone is paper thin in the maxilla and the mandible becomes the size of a toothpick (this is a different patient from the one in **A**).

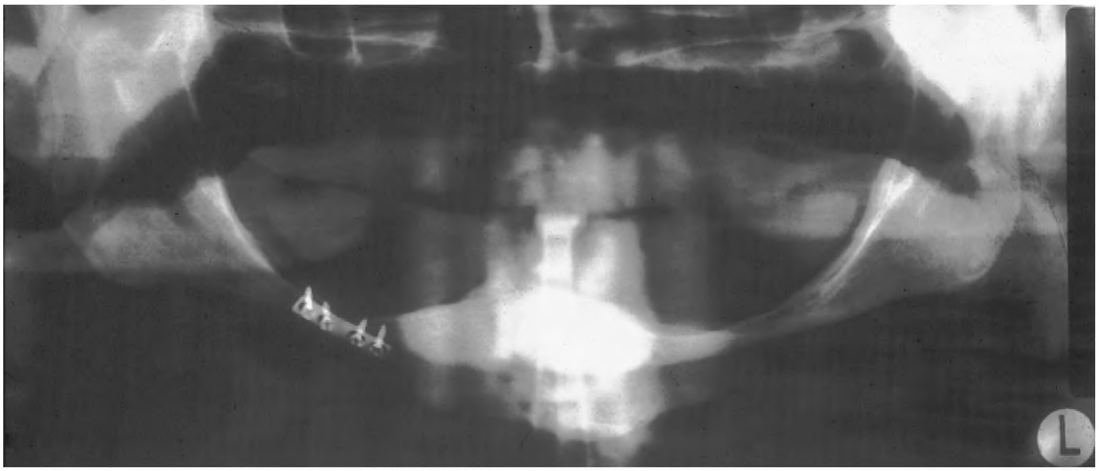

Figure 1-19 Resorption of an edentulous mandible may result in dehiscence of the mandibular canal and associated paresthesia. The patient may fear that a tumor is growing against the nerves. The body of the mandible may continue to resorb until minor trauma causes fracture (e.g., during mastication, the bump of a baby's head held closely to the face, or an accidental bump from the elbow).

type patients are at increased risk for developing severe atrophy[71,72] (see Box 1-3).

Many of these similar conditions exist in the partially edentulous patient wearing a removable soft tissue–borne prosthesis (Figure 1-20). In addition, the natural abutment teeth, on which direct and indirect retainers are designed, must submit to additional lateral forces. Because these teeth are often compromised by deficient periodontal support, many partial dentures are designed to minimize the forces applied to them. The result is an increase in mobility of the removable prosthesis and greater soft tissue support. These conditions protect the remaining teeth but accelerate the bone loss in the edentulous regions.[73]

Soft Tissue Consequences

As bone loses width, then height, then width and height again, the attached gingiva gradually decreases. A very thin attached tissue usually lies over the advanced atrophic mandible or is absent entirely. The increasing zones of unkeratinized gingiva are prone to abrasions caused by the overlaying prosthesis. In addition, unfavorable high muscle attachments and

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Figure 1-20 Panoramic radiograph demonstrates that more bone is maintained below the anterior periodontal diseased teeth compared with the basal bone loss and severe atrophy of the posterior edentulous segment. Wearing of a mandibular Class I removable partial denture has escalated the posterior bone loss.

Box 1-4 Soft Tissue Consequences of Edentulism

- Attached, keratinized gingiva is lost as bone is lost
- Unattached mucosa for denture support causes increased soft spots
- Thickness of tissue decreases with age, and systemic disease causes more sore spots for dentures
- Tongue increases in size, which decreases denture stability
- Tongue has more active role in mastication, which decreases denture stability
- Decreased neuromuscular control of jaw in the elderly

hypermobile tissue often complicate the situation. The thickness of the mucosa on the atrophic ridge is also related to the presence of systemic disease and the physiologic changes that accompany aging. Conditions such as hypertension, diabetes, anemia, and nutritional disorders have a deleterious effect on the vascular supply and soft tissue quality under removable prostheses. These disorders result in a decreased oxygen tension to the basal cells of the epithelium. Surface cell loss occurs at the same rate, but the cell formation at the basal layer is slowed. As a result, thickness of the surface tissues gradually decreases. Therefore, sore spots and uncomfortable removable prostheses result.

The tongue of the patient with edentulous ridges often enlarges to accommodate the increase in space formerly occupied by teeth. At the same time, it is used to limit the movements of the removable prostheses, and takes a more active role in the mastication process. As a result, the removable prosthesis decreases in stability. The decrease in neuromuscular control, often associated with aging, further compounds the problems of traditional removable prosthodontics. The ability to wear a denture successfully may be largely a learned, skilled performance. The aged patient who recently became edentulous may lack the motor skills needed to adjust to the new conditions (Box 1-4).

Esthetic Consequences

The facial changes that naturally occur in relation to the aging process can be accelerated and potentiated by the loss of teeth. Several esthetic consequences result from the loss of alveolar bone (Figures 1-21, 1-22). A decrease in facial height from a collapsed vertical dimension causes several facial changes. The loss of labiomental angle and deepening of vertical lines in the area create a harsh appearance. As the vertical dimension progressively decreases, the occlusion evolves toward a pseudo Class III malocclusion. As a result, the chin rotates forward and creates a prognathic facial appearance (Figure 1-23). These conditions result in a decrease in the horizontal labial angle at the corner of the lips; the patient appears unhappy when the mouth is at rest. Short facial types suffer higher bite forces, greater bone loss, and more dramatic facial changes with edentulism compared with others.

A thinning of the vermillion border of the lips results from the poor lip support provided by the prosthesis and the loss of muscle tone; its retruded position is related to the loss of premaxilla ridge and the loss of tonicity of the muscles involved in facial

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

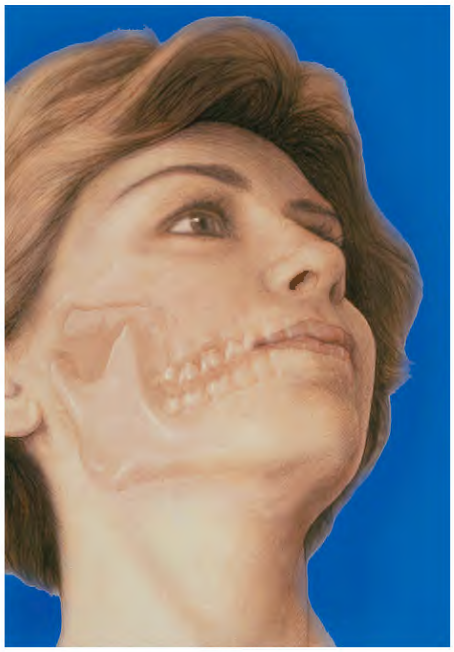

Figure 1-21 Esthetics of the inferior third of the face are related to the position of the teeth and include the muscles that attach to the bone.

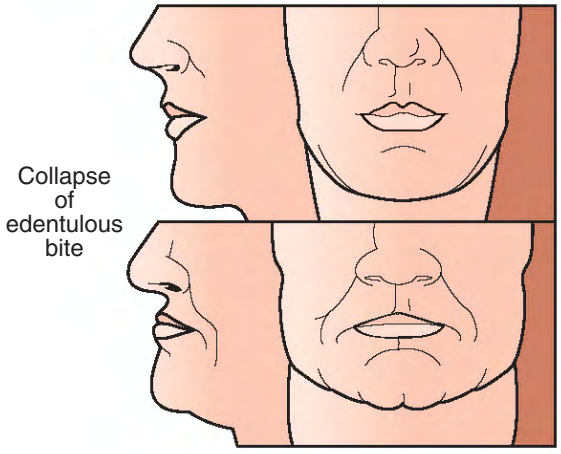

Figure 1-22 A patient often wears a denture for more than 15 years. The loss of bone height during this time is associated with many extraoral facial changes. The loss of vertical dimension results in many changes, including closed bite, a mandible that rotates forward, a receding maxilla, reverse smile line, increased number and depth of lines in the face, more acute angle between the nose and the face, loss of vermillion border in the lips, jowls, and witch's chin from loss of muscle attachment.

expression. In a study of 179 white patients at different stages of jaw atrophy, the collapse of the lips and circumoral musculature were evaluated by Sutton et al. The contraction of the orbicularis oris and buccinator muscles in the patient with moderate to advanced bone atrophy displaces the modiolus and muscles of facial expression medially and posteriorly. As a result, a narrowing of the commissure, inversion of the lips, and hollowing of the cheeks were very characteristic findings[74] (Figure 1-24). Women often use one of two

Figure 1-23 Loss of bone height can lead to a closed bite with rotation of the chin anterior to the tip of the nose.

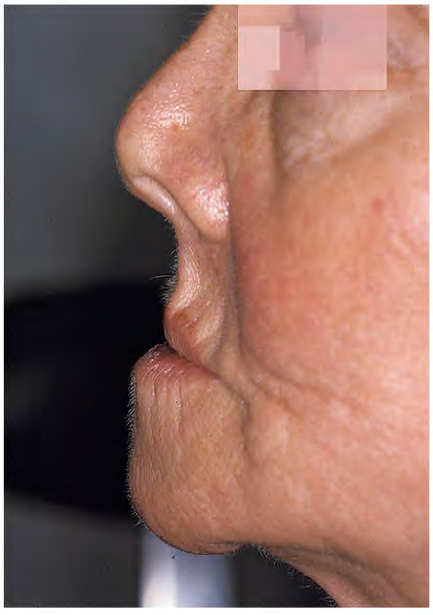

Figure 1-24 This patient has severe bone loss in the maxilla and mandible. Although she is wearing her 15-year-old dentures, the facial changes are significant. The loss of muscle attachments lead to ptosis of the chin (witch's chin), loss of vermillion border (lipstick is applied to the skin), reverse lip line (decrease in horizontal angles), increased vertical lines in the face and lips, increased lip angle under the nose, and a lack of body in the masseter and buccinator muscles.

techniques to hide this cosmetically undesirable appearance: either no lipstick and minimal makeup, so that little attention is brought to this area of the face; or lipstick drawn on the skin over the vermilion border to give the appearance of fuller lips. A deepening of the nasolabial groove and an increase in the depth of other vertical lines in the upper lip are related to normal

A B

Figure 1-25 **A,** Panoramic radiograph of a 68-year-old female. The maxillary arch has severe atrophy and almost complete basal bone loss, including most of the nasal spine. Implants were inserted in the anterior mandible 15 years before this film. The anterior bone has been maintained. The posterior mandible has continued to resorb, and the mandibular canal is dehiscent on one side. **B,** Profile view. Note the maxillary bone loss effect: the lack of vermillion border of the lip, deep labial folds, and the columella-philtrum angle. Yet the lower lip has a normal vermillion border and the muscles to the lower jaw are still attached, providing a normal contour.

Box 1-5 Esthetic Consequences of Bone Loss

- Decreased facial height
- Loss of labiomental angle
- Deepening of vertical lines in lip and face
- Chin rotates forward—gives a prognathic appearance
- Decreased horizontal labial angle of lip—makes patient look unhappy
- Loss of tone in muscles of facial expression
- Thinning of vermillion border of the lips from loss of muscle tone
- Deepening of nasolabial groove
- Increase in columella-philtrum angle
- Increased length of maxillary lip, so less teeth show at rest and smiling—ages the smile
- Ptosis of buccinator muscle attachment—leads to jowls at side of face
- Ptosis of mentalis muscle attachment—leads to "witch's chin"

aging but are accelerated with bone loss. This usually is accompanied by an increase in the columella-philtrum angle. This can make the nose appear larger than if the lip had more support (Figure 1-25). Men often grow a moustache to minimize this effect. The maxillary lip naturally becomes longer with age as a result of gravity and loss of muscle tone, resulting in less of the anterior teeth shown when the lip is at rest. This has a tendency to "age" the smile, because the younger the patient, the more the teeth show in relation to the upper lip at rest or when smiling. Loss of muscle tone is accelerated in the edentulous patient, and the lengthening of the lip occurs at a younger age.

The attachments of the mentalis and buccinator muscles to the body and symphysis of the mandible also are affected by bone atrophy. The tissue sags, producing "jowls" or a "witch's chin." This effect is cumulative because of the loss in muscle tone with the loss of teeth, the associated decrease in bite force, and the loss of bone in the regions where the muscles used to attach.

Patients are unaware that these hard and soft tissue changes are from the loss of teeth. Among denture wearers, 39% have been wearing the same prosthesis for more than 10 years.[66] The profession is unable to evaluate patients unless they return yearly. Therefore the consequences of tooth loss must be explained to the partially or completely edentulous patient during the early phases of treatment (Box 1-5).

DECREASED PERFORMANCE OF COMPLETE DENTURES

The difference in maximum occlusal forces recorded in a person with natural teeth and one who is completely edentulous is dramatic. In the first molar region of a dentate person, the average force has been measured at 150 to 250 psi.[75] A patient who grinds or clenches the teeth may exert a force that approaches 1000 psi. The maximum occlusal force in the edentulous patient is reduced to less than 50 psi. The longer patients are

Box 1-6 Negative Effects of Removable Prostheses

- Bite force is decreased from 200 psi to 50 psi
- 15-year denture wearers have reduced bite force to 6 psi
- Masticatory efficiency is decreased
- More drugs are necessary to treat gastrointestinal disorders
- The life span may be decreased
- Food selection is limited
- Healthy food intake is decreased

Box 1-7 Problems with Removable Partial Dentures

- Low survival rate—60% at 4 years
- 35% survival rate at 10 years
- Repair of abutment teeth rate—60% at 5 years and 80% at 10 years
- Increased mobility, plaque, bleeding upon probing, and caries of abutment teeth
- 44% abutment tooth loss within 10 years
- Accelerated bone loss in edentulous region if wearing removable partial denture

edentulous, the less force they are able to generate. Patients wearing complete dentures for more than 15 years may have a maximum occlusal force of 5.6 psi.[76]

As a result of decreased occlusal force and the instability of the denture, masticatory efficiency also decreases with tooth loss. Within the same 15-year time frame, 90% of the food chewed with natural teeth fits through a No. 12 sieve; this is reduced to 58% in the patient wearing complete dentures.[77] The tenfold decrease in force and the 40% decrease in efficiency affects the patient's ability to chew. In persons with dentures, 29% are able to eat only soft or mashed foods[78]; 50% avoid many foods; and 17% claim they eat more efficiently without the prosthesis.[79] A study of 367 denture wearers (158 men and 209 women) found that 47% exhibited a low masticatory performance.[79] Lower intakes of fruits, vegetables, and vitamin A by women were noted in this group. These patients took significantly more drugs (37%), compared with those with superior masticatory ability (20%); 28% were taking medications for gastrointestinal disorders. The reduced consumption of high-fiber foods could induce gastrointestinal problems in edentulous patients with deficient masticatory performance. In addition, the coarser bolus may impair proper digestive and nutrient extraction functions.[80]

The literature includes several reports suggesting that a compromised dental function causes poor swallowing and masticatory performance, which in turn may influence systemic changes favoring illness, debilitation, and shortened life expectancy[81-86] (Box 1-6).

In a study evaluating the ability to eat fruit, vegetables, and other dietary fiber in edentulous subjects, 10% claimed difficulty, and blood tests demonstrated reduced levels of plasma ascorbate and plasma retinol compared with dentate subjects. These two blood tests are correlated to an increased risk of dermatologic and visual problems in aging adults.[87]

In a study, the masticatory performance and efficiency in denture wearers were compared with dentate individuals.[88] This report noted that when appropriate connections were made for different performance norms and levels, the chewing efficiency of a denture wearer was less than one sixth of a person with teeth.

Several reports in the literature correlate a patient's health and life span to dental health.[89-93] Poor chewing ability may be a cause of involuntary weight loss in old age, with an increase in mortality.[94] In contrast, persons with a substantial number of missing teeth were more likely to be obese.[89]After conventional risk factors for strokes and heart attacks were accounted for, there was a significant relationship between dental disease and cardiovascular disease, the latter still remaining as the major cause of death.[92-96] It is logical to assume that restoring the stomatognathic system of these patients to a more normal function may indeed enhance the quality and length of their lives.[89,96-98]

NEGATIVE CONSEQUENCES OF REMOVABLE PARTIAL DENTURES

Removable soft tissue–borne partial dentures have one of the lowest patient acceptance rates in dentistry. Half the patients with a removable partial denture chew better without the device. A 44-year Scandinavian study revealed that only 80% of patients were wearing such prostheses after 1 year. The number further decreased to only 60% of the free-end partial dentures worn by the patients after 4 years.[99,100]

A 5-year survival rate of partial dentures based on tolerance and use of the prosthesis was approximately 60% for distal extension prostheses. This was reduced to 35% at 10 years.[101-103] In another study, few partial dentures survived more than 6 years.[104] Although one of five U.S. adults has had a removable prosthesis of some type, 60% reported at least one problem with it (Box 1-7).[50]

Reports of removable partial dentures indicate the health of the remaining dentition and surrounding oral tissues often deteriorates.[90,99,105] In a study that evaluated the need for repair of an abutment tooth as the indicator of failure, the survival rate of conventional removable partial dentures was 40% at 5 years and 20% at 10 years.[101] Those patients wearing the partial dentures often exhibit greater mobility of the abutment teeth, greater plaque retention, increased bleeding upon

Box 1-8 Psychological Effects of Tooth Loss

- Range from minimal to neuroticism
- Romantic situations affected (especially in new relationship)
- "Oral invalids" unable to wear dentures
- 88% claim some difficulty with speech, and 25% claim significant problems
- More than $200 million each year spent on denture adhesive to decrease embarrassment
- Dissatisfaction with appearance, low self-esteem
- Avoidance of social contact

probing, higher incidence of caries, speech inhibition, taste inhibition, and noncompliance of use.[102-105] A report by Shugars et al. found abutment tooth loss for a removable partial denture may be as high as 23% within 5 years and 38% within 8 years.[30] Aquilino et al. reported a 44% abutment tooth loss within 10 years for a removable partial denture (see Box 1-7).[106] In addition, it should be noted those patients wearing the removable device accelerate bone loss in the soft tissue support regions. Therefore, alternative therapies that improve oral conditions and maintain bone are often warranted.

PSYCHOLOGICAL ASPECTS OF TOOTH LOSS

The psychological effects of total edentulism are complex and varied, and range from very minimal to a state of neuroticism (Box 1-8). Although complete dentures are able to satisfy the esthetic needs of many patients, there are those who feel their social life is significantly affected.[107,108] They are concerned with kissing and romantic situations, especially if a new partner in a relationship is unaware of their oral handicap. Fiske et al., in a study of interviews with edentulous subjects, found tooth loss was comparable to the death of a friend or loss of other important parts of a body in causing a reduction of self-confidence ending in a feeling of shame or bereavement.[107]

One dental survey of edentulous patients found 66% were dissatisfied with their mandibular complete dentures. Primary reasons were discomfort and lack of retention causing pain and discomfort.[109] Past dental health surveys indicate that only 80% of the edentulous population are able to wear both removable prostheses all the time.[90,110] Some patients wear only one prosthesis, usually the maxillary; others are able to wear their dentures for short periods only. In addition, approximately 7% of patients are not able to wear their dentures at all and become dental cripples or "oral invalids." They rarely leave their home environment and when they feel forced to venture out, the thought of meeting and talking to people when not wearing their teeth is unsettling.

A report of 104 completely edentulous patients seeking treatment was performed by Misch.[79] Of the patients studied, 88% claimed difficulty with speech, with one fourth having great difficulty. As a consequence, it is easy to correlate the reported increase with concern relative to social activities. Awareness of movement of the mandibular denture was cited by 62.5% of these patients, although the maxillary prosthesis stayed in place most of the time at almost the same percentage. Mandibular discomfort was listed with equal frequency as movement (63.5%), and surprisingly, 16.5% of the patients stated they never wear the mandibular denture. In comparison, the maxillary denture was uncomfortable half as often (32.6%), and only 0.9% were seldom able to wear the prosthesis. Function was the fourth most common problem reported by these 104 denture wearers. Half the patients avoided many foods, and 17% claimed they were able to masticate more effectively without the prostheses. The psychological effects of the inability to eat in public can be correlated with these findings. Other reports agree that the major motivating factors for patients to undergo treatment were related to the difficulties with eating, denture fit, and discomfort.

The psychological need of the edentulous patient is expressed in many forms. For example, in 1970, Britons used approximately 88 tons of denture adhesive.[111] In 1982, more than 5 million Americans used denture adhesives (Ruskin Denture Research Associates: AIM study, unpublished data, 1982), and a report shows that in the United States, more than $200 million is spent each year on denture adhesives, representing 55 million units sold.[112] The patient is willing to accept the unpleasant taste, need for recurring application, inconsistent denture fit, embarrassing circumstances, and continued expense for the sole benefit of increased retention of the prosthesis. Clearly the lack of retention and psychological risk of embarrassment in the denture wearer with removable prostheses is a concern the dental profession must address.

ADVANTAGES OF IMPLANT-SUPPORTED PROSTHESES

The use of dental implants to provide support for prostheses offers many advantages, compared with the use of removable soft tissue–borne restorations (Box 1-9). A primary reason to consider dental implants to replace missing teeth is the maintenance of alveolar bone (Figure 1-26). The dental implant placed into the bone serves both as an anchor for the prosthetic device and as one of the better preventive maintenance procedures in dentistry. Stress and strain may be applied to the bone surrounding the implant. As a result, the decrease in trabeculation of bone that occurs after

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Box 1-9 Advantages of Implant-Supported Prostheses

- Maintain bone
- Restore and maintain occlusal vertical dimension
- Maintain facial esthetics (muscle tone)
- Improve esthetics (teeth positioned for appearance versus decreasing denture movement)
- Improve phonetics
- Improve occlusion
- Improve/regain oral proprioception (occlusal awareness)
- Increase prosthesis success
- Improve masticatory performance/maintain muscles of mastication and facial expression
- Reduce size of prosthesis (eliminate palate, flanges)
- Provide fixed versus removable prostheses
- Improve stability and retention of removable prostheses
- Increase survival times of prostheses
- No need to alter adjacent teeth
- More permanent replacement
- Improve psychological health

tooth extraction is reversed. There is an increase in bone trabeculae and density when the dental implant is inserted and functioning. The overall volume of bone is also maintained with a dental implant. Even grafts of iliac bone to the jaws, which usually resorb without dental implant insertion within 5 years, are instead stimulated and maintain overall bone volume and implant integration. An endosteal implant can maintain bone width and height as long as the implant remains healthy.[113] As with a tooth, periimplant bone loss may be measured in tenths of a millimeter and may represent a more than twentyfold decrease in lost structure, compared with the resorption that occurs with removable prostheses.

Figure 1-26 Bone loss in the edentulous patient may be dramatically stopped by using implants to support the prosthesis.

The benefit of bone maintenance is especially noteworthy in the maxillary edentulous arch. Rather than using implants only in the edentulous mandibular arch, because the main mechanical denture problems are in this arch, the maxillary arch should also be addressed. Once implant prostheses are placed to support and retain the mandibular restoration, the bone in the maxillary region continues to be lost and eventually the patient may complain of loss of retention and inability of the maxillary denture to function.[114] The loss of facial esthetics is most often first noted in the maxillary arch, with the loss of vermillion border of the lip, increased length of the maxilla lip, and lack of facial bone support. Implants should be used to treat the continued bone loss and prevent the later complications found in the maxillary arch (Figures 1-27 to 1-31).

A mandibular denture often moves when the mylohyoid and buccinator muscles contract during speech or

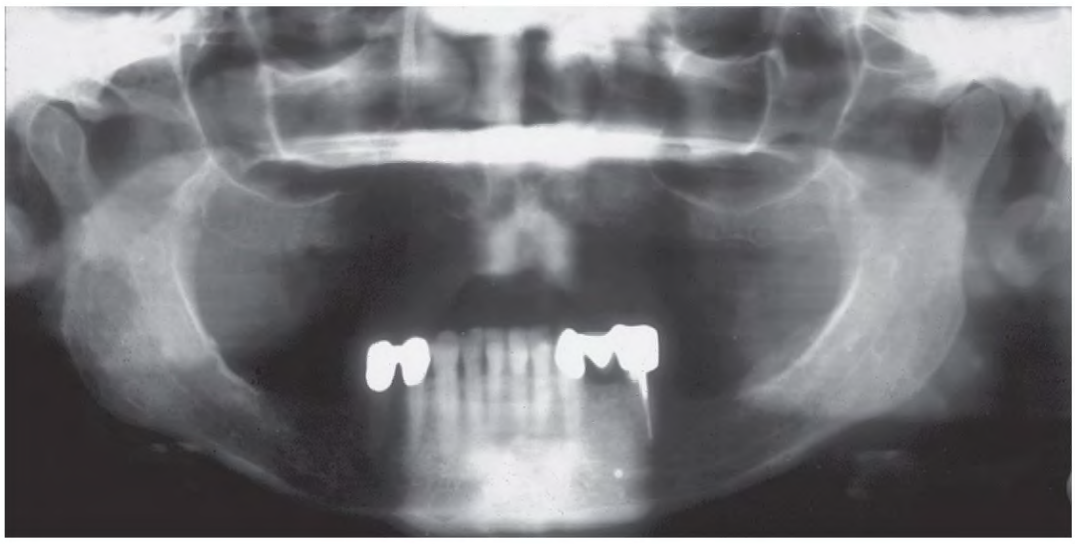

Figure 1-27 A panoramic radiograph of an edentulous maxillary arch with moderate sinuses and a resorbed anterior maxilla.

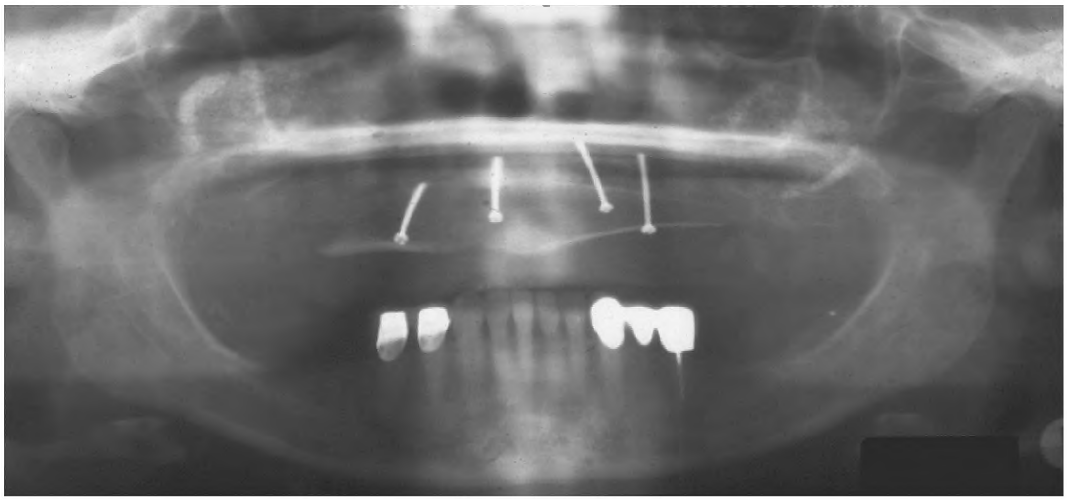

Figure 1-28 An iliac crest bone graft was inserted into the maxilla, and bilateral sinus grafts were also made to the posterior regions.

Figure 1-29 Maxillary implants were inserted after the graft in Figure 1-28 matured, and a maxillary fixed prosthesis was fabricated.

mastication. The teeth are often positioned for denture stability rather than where natural teeth usually reside. With implants, the teeth may be positioned to enhance esthetics and phonetics rather than in the neutral zones dictated by traditional denture techniques to improve the stability of a prosthesis.

The features of the inferior third of the face are closely related to the supporting skeleton. When vertical bone is lost, the dentures only act as "oral wigs" to improve the contours of the face. The dentures become bulkier as the bone resorbs, making it more difficult to control function, stability, and retention. With implant-supported prostheses, the vertical dimension may be restored, similar to natural teeth. In addition, the implant-supported prosthesis allows a cantilever of anterior teeth for ideal soft tissue and lip contour and improved appearance in all facial planes. This happens without the instability that usually occurs when an anterior cantilever is incorporated in a traditional denture. The facial profile may be enhanced for the long term with implants, rather than deteriorating over the years, as can occur with traditional dentures.

Occlusion is difficult to establish and stabilize with a completely soft-tissue–supported prosthesis. Because the mandibular prosthesis may move as much as 10 mm or more during function,[115,116] proper occlusal contacts occur by chance, not by design. But an implant-supported restoration is stable. The patient can more consistently return to centric-relation occlusion rather than adopt variable positions dictated by the prosthesis' instability. Proprioception is awareness of a structure in time and place. The receptors in the periodontal membrane of the natural tooth help determine its occlusal position. Although endosteal implants do not have a periodontal membrane, they provide greater occlusal awareness than complete dentures. Patients

with natural teeth can perceive a difference of 20 µm between the teeth, whereas implant patients can determine a 50-µm differences with rigid implant bridges, compared with 100 microns in those with complete dentures (either one or two).[117]

As a result of improved occlusal awareness, the patient functions in a more consistent range of occlusion. With an implant-supported prosthesis, the direction of the occlusal loads is controlled by the restoring dentist. Horizontal forces on removable prostheses accelerate bone loss, decrease prosthesis stability, and increase soft tissue abrasions. Therefore the decrease in horizontal forces that are applied to implant restorations improves the local parameters and helps preserve the underlying soft and hard tissues.

In a randomized clinical trial by Kapur et al., the implant group of patients demonstrated a higher level of eating enjoyment and improvement of speech, chewing ability, comfort, denture security, and overall satisfaction.[118] The ability to eat several different foods among complete denture versus mandibular overdenture patients was evaluated by Awad and Feine. The implant overdenture was superior for eating not only harder foods, such as carrots and apples, but also softer foods, such as bread and cheese.[119] Geertman et al. evaluated complete denture wearers with severely resorbed mandibles before and after mandibular implant overdentures. The ability to eat hard or tough foods significantly improved.[120,121]

Researchers at McGill University evaluated blood levels of patients who had complete dentures and 30 maxillary dentures and mandibular implant prostheses 6 months after treatment. Within this rather short period, implant patients had higher B_{12} hemoglobin (related to iron increase) and albumin levels (related to nutrition). These patients also had greater body fat in their shoulders and arms, with decreased body fat in their waists.[122]

The success rate of implant prostheses varies, depending on a host of factors that change for each patient. However, compared with traditional methods of tooth replacement, the implant prosthesis offers increased longevity, improved function, bone preservation, and better psychological results. According to 10-year survival surveys of fixed prostheses on natural teeth, decay is indicated as the most frequent reason for replacement; survival rates are approximately 75%.[31] In the partially edentulous patient, independent tooth replacement with implants may preserve intact adjacent natural teeth as abutments, further limiting complications such as decay or endodontic therapy, which are the most common causes of fixed prosthesis failure. A major advantage of the implant-supported prosthesis is that the abutments cannot decay and never require endodontics. The implant and related prosthesis can attain a 10-year survival of more than 90%.

The maximum occlusal force of a traditional denture wearer ranges from 5 to 50 lb. Patients with an implant-supported fixed prosthesis may increase their maximum bite force by 85% within 2 months after the completion of treatment. After 3 years, the mean force may reach more than 300%, compared with pretreatment values. As a result, an implant prosthesis wearer may demonstrate a force similar to that of a patient with a fixed restoration supported by natural teeth. Chewing efficiency with an implant prosthesis is greatly improved, compared with that of a soft tissue–borne restoration. The masticatory performance of dentures, overdentures, and natural dentition was evaluated by Rissin et al.[77] The traditional denture showed a 30% decrease in chewing efficiency; other reports indicate a denture wearer has less than 60% of the function of people with natural teeth. The supported overdenture loses only 10% of chewing efficiency compared with natural teeth. These findings are similar with implant-supported overdentures. In addition, rigid, implant-supported fixed bridges may function the same as natural teeth. Beneficial effects such as a decrease in fat, cholesterol, and the carbohydrate food groups have been reported, as well as significant improvement in eating enjoyment and social life.[123-131]

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

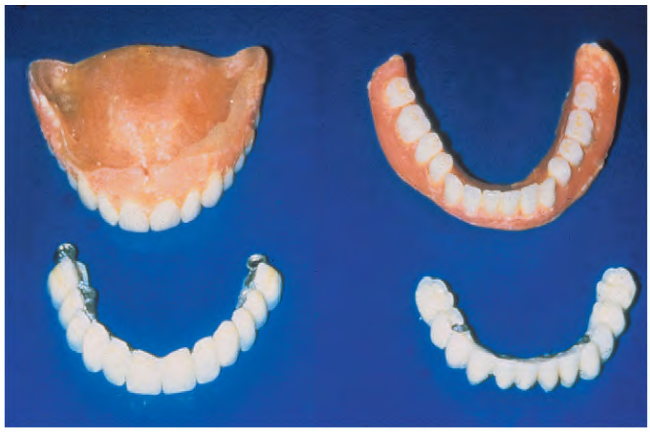

Figure 1-32 Implant prostheses can maintain bone and reduce the bulk of the soft tissue–borne prostheses.

Stability and retention of an implant-supported prosthesis are great improvements over soft tissue–borne dentures (Figure 1-32). Mechanical means of implant retention are far superior to the soft tissue retention provided by dentures or adhesives and cause fewer associated problems. The implant support of the final prosthesis is variable, depending on the number and position of implants; yet all treatment options demonstrate significant improvement.

Phonetics may be impaired by the instability of a conventional denture. The buccinator and mylohyoid muscles may flex and propel the posterior portion of the denture upward, causing clicking, regardless of the vertical dimension.[116] As a result, a patient in whom the vertical dimension already has collapsed 10 to 20 mm may still produce clicking sounds during speech. Often the tongue of the denture wearer is flattened in the posterior areas to hold the denture in position. The anterior mandibular muscles of facial expression may be tightened to prevent the mandibular prosthesis from sliding forward. The implant prosthesis is stable and retentive and does not require these oral manipulations. The implant restoration allows reduced flanges or palates of the prostheses. This is of special benefit to the new denture wearer, who often reports discomfort with the bulk of the restoration. The extended soft tissue coverage also affects the taste of food, and the soft tissue may be tender in the extended regions. The palate of a maxillary prosthesis may cause gagging in some patients, which can be eliminated in an implant-supported overdenture.

Patients treated with implant-supported prostheses judge their overall psychological health as improved by 80% compared with their previous state while wearing traditional, removable prosthodontic devices. They perceived the implant-supported prosthesis as an integral part of their body.[120,132-136] For example, Raghoebar et al. evaluated 90 edentulous patients in a randomized multicenter study. Five years after treatment, a validated questionnaire targeted patient esthetic satisfaction, retention, comfort, and the ability to speak and eat with either a complete mandibular denture, complete mandibular denture with vestibuloplasty, or mandibular two-implant overdenture. Implant overdentures had significantly higher ratings, whereas no significant difference was found between the two complete-denture groups.[135] Geertman et al. reported similar results comparing chewing ability of conventional complete dentures with mandibular implant overdentures.[120,121]

SUMMARY

The goal of modern dentistry is to return patients to oral health in a predictable fashion. The partial and complete edentulous patient may be unable to recover normal function, esthetics, comfort, or speech with a traditional removable prosthesis. The patient's function when wearing a denture may be reduced to one sixth of that level formerly experienced with natural dentition; however, an implant prosthesis may return the function to near-normal limits. The esthetics of the edentulous patient are affected as a result of muscle and bone atrophy. Continued bone resorption leads to irreversible facial changes. An implant prosthesis allows normal muscle function, and the implant stimulates the bone and maintains its dimension in a manner similar to healthy natural teeth. As a result, the facial features are not compromised by lack of support as often required for removable prostheses. In addition, implant-supported restorations are positioned in relation to esthetics, function, and speech, not in neutral zones of soft tissue support. The soft tissues of the edentulous patients are tender from the effects of thinning mucosa, decreased salivary flow, and unstable or unretentive prostheses. The implant-retained restoration does not require soft tissue support and improves oral comfort. Speech is often compromised with soft tissue–borne prostheses because the tongue and perioral musculature may be compromised to limit the movement of the mandibular prosthesis. The implant prosthesis is stable and retentive without the efforts of the musculature.

Implant prostheses often offer a more predictable treatment course than traditional restorations. Thus the profession and the public are becoming increasingly aware of this dental discipline. Manufacturers' sales have increased from a few million dollars to more than several hundred million dollars. Almost every professional journal now publishes refereed reports on dental implants. All U.S. dental schools now teach implant dentistry to all interfacing specialties. Implant dentistry has finally been accepted by organized dentistry. The current trend to expand the use of implant dentistry will continue until every restorative practice uses this modality for abutment support of both fixed and removable prostheses on a regular basis as the primary option for all tooth replacement.[137]

Chapter 2

Generic Root Form Component Terminology

Carl E. Misch

An endosteal implant is an alloplastic material surgically inserted into a residual bony ridge, primarily as a prosthodontic foundation.[1] The prefix *endo* means "within," and *osteal* means "bone."[2] The major subcategory of endosteal implants covered in this text are root form implants. The term *endosseous* is also used in the literature, and because the term *osseous* also indicates bone, either term is acceptable. However, *endosteal*, *periosteal*, and *transosteal* are preferred. Many endosteal implant designs have been used in the past, including tapered pegs, pin shapes, and plate forms.[3,4] Today, an endosteal implant in the shape of a tooth root is the design most often used in the restoration of partial or complete edentulous patients.

The desire has always been to replace missing teeth with something similar to the root of a tooth. Implant dentistry is the second oldest discipline in dentistry (oral surgery [exodontia] is the oldest). Root form implant history dates back thousands of years and includes civilizations such as the ancient Chinese who, 4000 years ago, carved bamboo sticks in the shape of pegs and drove them into the bone for fixed tooth replacement. The Egyptians, 2000 years ago, used precious metals with a similar peg design. A skull was found in Europe with a ferrous metal tooth inserted into a skull with a tooth peg design that dated back to the time of Christ. Incas from Central America took pieces of sea shells and, similar to the ancient Chinese, tapped them into the bone to replace missing teeth[5] (Figure 2-1). In other words, history shows that it has always made sense to replace a tooth with an implant in the approximate shape of a tooth. In reality, if the lay public were given a choice to replace a missing tooth with an implant or to grind down several adjacent teeth and connect them with a prosthesis to replace a missing tooth and then attempt to make the adjacent teeth look similar to the condition prior to their preparation, the implant would be the obvious choice.

Maggiolo introduced the more recent history of implant dentistry in 1809 with use of gold in the shape of a tooth root.[6] In 1887, Harris reported the use of teeth made of porcelain into which lead-coated platinum posts were fitted.[7] Many materials were tested, and in the early 1900s, Lambotte fabricated implants of aluminum, silver, brass, red copper, magnesium, gold, and soft steel plated with gold and nickel.[8] He identified the corrosion of several of these metals in body tissues related to electrolytic action. The first root form design that differed significantly from the shape of a tooth root was the Greenfield latticed-cage design in 1909, made of iridoplatinum.[9] This was also the first two-piece implant, which separated the abutment from the endosteal implant body at the initial placement. The surgery was designed to use a calibrated trephine bur to maintain an inner core of bone within the implant body. The implant crown was connected to the implant body with an antirotational internal attachment after several weeks. Reports indicate this implant had a modicum of success. Seventy-five years later, this implant design was reintroduced by ITI in Europe and later by Core-Vent in the United States.[10,11]

Surgical cobalt chromium molybdenum alloy was introduced to oral implantology in 1938 by Strock (Boston, Mass.) when he replaced a single maxillary left incisor tooth[12] with a root form, one-piece implant

Figure 2-1 This mandible, dated AD 600, was found in Honduras. This jaw shows three carved, implanted incisors made from carved sea shells. Calculus formation on these three implants indicate this was not a burial ceremony, but a fixed, functional, and esthetic tooth replacement.

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

that lasted more than 15 years. A direct bone-implant interface to titanium was initially called *bone fusing* and was first reported in 1940 by Bothe and coworkers.[13] In 1946, Strock designed the first titanium, two-piece screw implant that was initially inserted without the permucosal post. The abutment post and individual crown were added after complete healing.[14] The desired implant interface described by Strock was a direct bone-implant connection, which was called *ankylosis.* The first submerged implant placed by Strock was still functioning 40 years later[15] (Figure 2-2).

Brånemark began extensive experimental studies in 1952 on the microscopic circulation of bone marrow healing. These studies led to a dental implant application in the early 1960s in which a 10-year implant integration was established in dogs without significant adverse reactions to hard or soft tissues. Implant clinical studies in humans with the Brånemark philosophy began in 1965, were followed for 10 years, and were reported in 1977.[16] The term *osseointegration* (rather than *bone fusing* or *ankylosis*) was defined by Brånemark as a direct contact of living bone with the surface of an implant at the light microscopic level of magnification.[17] The terms *bone fusing, ankylosis,* and *osseointegration* may be interchangeable and may address the microscopic bone-implant interface. The percentage of direct bone-implant contact was not initially addressed and has been found to be highly variable. Today, the term *osseointegration* has become common in the implant discipline and describes not only a microscopic condition, but also the clinical condition of rigid fixation. *Rigid fixation* is a clinical term that implies no observable movement of the implant when a force of 1 to 500 g is applied. The prefix *osteo* (e.g., *osteo*blast, *osteo*tomy) also is widely used by the profession. Rigid fixation is the clinical result of a direct bone interface but has also been reported with a fibrous tissue interface.[18]

The osseointegration concepts of Brånemark have been promoted more than those of any other person in recent history. The documentation of past clinical case studies, research of surgery and bone physiology, healing of soft and hard tissues, and restorative applications from Brånemark's laboratory were unprecedented. Adell et al. published the Brånemark 15-year clinical case series report in 1981 on the use of implants in completely edentulous jaws.[19] Approximately 90% of the reported anterior mandibular implants that were in the mouths of patients after the first year of loading were still in function 5 to 12 years later. Lower survival rates were observed in the anterior maxilla. In the initial Brånemark clinical reports, no implants were inserted into the posterior regions of the mouth, and all reported prostheses were fixed restorations.

The use of dental implants in the treatment of complete and partial edentulism has become an integral treatment modality in restorative dentistry.[20-22] The 1988 National Institutes of Health consensus panel on

Figure 2-2 The patient shown here received a two-stage endosteal implant (invented by Strock in 1948) to replace a maxillary lateral incisor. The patient presented in 1986 with the implant still in function 38 years later.

dental implants recognized that restorative procedures using implants differ from those of traditional dentistry and stressed the necessity for advanced education.[22] During the past 15 years, implant dentistry has become a routine method to replace teeth in a restorative practice.

Many practitioners are taught the use of a specific manufacturer's implant system, rather than the theory and comprehensive practice of implant dentistry. The increasing number of manufacturers entering the field use trade names for their implant components (often unique to a particular system), and such names have proliferated to the point of creating confusion. Several different terms or abbreviations now exist that describe similar basic components.[23-28]

To make conditions worse, in the team approach to implant treatment, the widening referral base often requires that the restoring practitioner be knowledgeable regarding many implant systems. With the required knowledge of multiple systems and the lack of uniformity in component names, communication is hampered among manufacturers, dentists, staff, laboratory technicians, students, and researchers. In addition, the incorporation of implant dentistry into the curriculum of most predoctoral and postdoctoral programs further emphasizes the need for standardization of terms and components in implant dentistry.[29]

GENERIC PROSTHETIC COMPONENT TERMINOLOGY

A generic language for endosteal implants was developed by Misch and Misch in 1992.[30] The order in which it is presented follows the chronology of insertion to restoration. In formulating the terminology, five commonly used implant systems in the United States were referenced. Fifteen years later, the dramatic evolution of the U.S. implant market has resulted in changes in nearly

t.me/highdent www.highdentlab.com instagram.com/high_dent

Figure 2-3 Implant body designs generally relate to three different categories: cylinder implants *(top row)*, screw design implants *(middle row)*, or a combination *(bottom row)*, which usually are pressed into position and have a macro body design similar to a thread form. *(Courtesy Charles English.)*

all the implant lines and component designs. In 2000 the U.S. market alone had to choose from more than 1300 different implant designs and 1500 abutments in various materials, shapes, sizes, diameters, lengths, surfaces, and connections.[31] More than ever, a common language is needed. In pharmacology the variety of pharmaceutical components makes it impossible to list them all by proprietary names, but a list by category of drugs is useful. Likewise, implant components still can be classified into broad application categories, and the practitioner should be able to recognize a certain component category and know its indications and limitations.

This book incorporates a generic terminology, first introduced by Misch and Misch for endosteal implants, that blends a continuity and familiarity of many implant systems with established definitions from the terms of the *Illustrated Dictionary of Dentistry* and the glossaries from *Terms of The Academy of Prosthodontics, American Academy of Implant Dentistry,* and *International Congress of Oral Implantologists.*[1,2,32,33]

GENERIC IMPLANT BODY TERMINOLOGY

Root form implants are a category of endosteal implants designed to use a vertical column of bone, similar to the root of a natural tooth. Although many names have been applied, the 1988 National Institutes of Health consensus statement on dental implants and the American Academy of Implant Dentistry recognized the term *root form.*[1,22,33] The exponential growth of implant use over the last 20 years has been paralleled by an explosion of the implant manufacturing field.[34] There are currently more than 90 implant body designs available, offering countless combinations of design features: screws, baskets, plateaus, balls, cylinders, diameters, lengths, prosthetic connections, and surface conditions[35-54] (Figure 2-3).

The most common root form design combines a separate implant body and prosthodontic abutment to permit only the implant body placement during bone healing. A second procedure is required to attach the implant abutment. The design and surgical philosophy is to achieve clinical rigid fixation that corresponds to a microscopic direct bone-to-implant interface without intervening fibrous tissue occurring over any significant portion of the implant body before the prosthetic phase of the procedure. Over the years, three different surgical approaches have been used for the two-piece implant systems: one stage, two stage, and immediate restoration (loading) (Figure 2-4). The two-stage surgical process places the implant body below the soft tissue, until the initial bone healing has occurred. During a

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

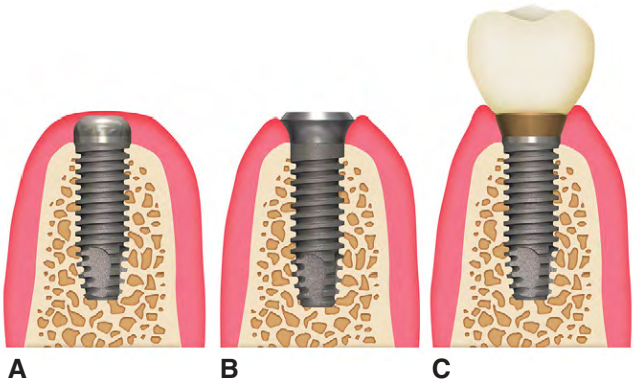

Figure 2-4 There are three different surgical approaches for two-piece implant systems: **(A)** two stage (healing submerged, then uncovery surgery), **(B)** one stage (implant with permucosal healing, no uncovery surgery), and **(C)** immediate restoration (restoration placed at the time of the surgical placement).

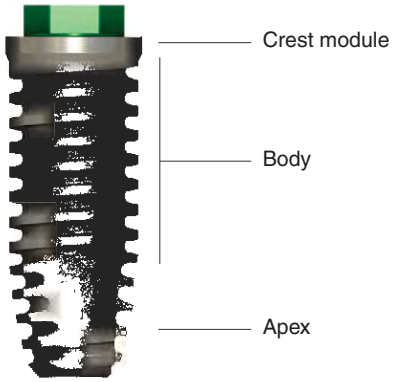

Figure 2-5 An implant body is the portion of the dental implant that is designed to be placed into the bone to anchor prosthetic components. The implant body has a crest module, a body, and an apex.

second-stage surgery, the soft tissues are reflected to attach a permucosal element or abutment. During a one-stage surgical approach, the implant body and the permucosal abutment above the soft tissue are both placed until initial bone maturation has occurred. The abutment of the implant then replaces the permucosal element without the need for a secondary soft tissue surgery.

The immediate restoration approach places the implant body and the prosthetic abutment at the initial surgery. A restoration is then attached to the abutment (out of occlusal contacts in partially edentulous patients) at the appointment.

An implant body especially designed for one surgical method may also be selected. For example, a permucosal element may already be attached to the implant body by the manufacturer to facilitate a one-stage surgical approach. An implant body also may have a prosthetic abutment, which may be part of the implant body, for the one-piece implant to be inserted and restored at the initial surgery. This was the original concept first introduced by Strock in the 1930s.[12]

There are three primary types of root form body endosteal implants based on design; cylinder, screw, or combination.[30]

Cylinder (press-fit) root form implants depend on a coating or surface condition to provide microscopic retention to the bone. Most often the surface is either coated with a rough material (e.g., hydroxyapatite, titanium plasma spray) or a macro retentive design (e.g., sintered balls). Cylinder implants are usually pushed or tapped into a prepared bone site. They can be a paralleled wall cylinder or a tapered implant design. Screw root forms are threaded into a slightly smaller prepared bone site and have the macroscopic retentive elements of a thread for initial bone fixation. They may be machined, textured, or coated. There are three basic screw-thread geometries: V-thread, buttress (or reverse buttress) thread, and power (square) thread designs. Threaded implants are primarily available in a parallel cylinder or tapered cylinder design. Micro or macro thread features, variable thread pitch, depth, and angle, as well as self-tapping features, can be combined to create a myriad of implant designs. Combination root forms have macroscopic features from both the cylinder and screw root forms. The combination root form designs also may benefit from microscopic retention to bone through varied surface treatments (machined, textured, and the addition of coatings).[55-68] Root forms also have been described by their means of insertion, healing, surgical requirements, surface characteristics, and interface.[28,69,70]

IMPLANT BODY REGIONS

The implant body may be divided into a crest module (cervical geometry), a body, and an apex (Figure 2-5). Each section of an implant has features that are of benefit in the surgical or prosthetic application of the implant.

Implant Body

An implant body is primarily designed for either surgical ease or prosthetic loading to the implant bone interface. Years ago, the implant body was the primary design feature. A round implant permits round surgical drills to prepare the bone. A smooth-walled cylinder implant allows the implant to be pressed or tapped into position, similar to a nail into a piece of wood. A tapered cylinder fits into the top of the osteotomy for further ease of placement.

A cylinder implant design system offers the advantage of ease of placement, even in difficult access locations. The cover screw of the implant also may be attached to the implant before implant placement. For example, in the very soft D4 bone of the posterior regions of the

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

maxilla, the surgeon must rotate a threaded implant design into place. Very soft bone may strip during a threaded implant insertion. This may result in lack of initial fixation, and the implant will not be rigid. A tapered cylinder implant may be pressed by hand into soft bone and can be initially fixated more easily. The speed of implant rotation during insertion and the amount of apical force in implant insertion in soft bone are less relevant for a press-fit cylinder. The cylinder system also presents some benefits for the single-tooth implant application, especially if adjacent to teeth with tall clinical crowns. Thread extenders are needed for the screw implant placement in these situations, as well as additional tools to insert the cover screw of the implant. In dense bone, cylinder systems also are easier and faster to place because bone tapping is not required.

Most cylinder implants are essentially smooth-sided and bullet-shaped implants that require a bioactive or increased surface area coating for retention in the bone. When these materials are placed on an implant, the surface area of bone contact increases more than 30%. The greater the functional surface area of the bone implant contact, the better the support system for the prosthesis.

A solid screw implant body design is the most commonly reported in the literature. A solid screw body is defined as an implant of a circular cross section without penetrating any vents or holes. A number of manufacturers provide this design (e.g., Nobel Biocare, Biomet, Zimmer, ITI, BioHorizons, LifeCore, Bio-Lok). The thread may be V-shaped, buttress, reverse buttress, or square (power thread) in design. The V-shaped threaded screw has the longest history of clinical use.[16,17] The most common outer thread diameter is 3.75 mm, with a 0.38-mm thread depth, and a 0.6-mm thread pitch (distance). The various body lengths usually range from 7 to 16 mm, although lengths from 5 mm to 56 mm are available. Similar body designs are offered in a variety of diameters (narrow, standard, wide) to respond to the mechanical, esthetic, and anatomical requirements in different areas of the mouth.[31,71]

A solid screw implant body permits the osteotomy and placement of the implant in dense cortical bone as well as in fine trabecular bone. The surgery may be easily modified to accommodate both extremes in bone density. The solid screw permits the implant removal at the time of surgery if placement is not ideal. It also permits implant removal at the Stage II surgery if angulation or crestal bony contours are not deemed adequate for long-term prosthesis success. The solid screw implant body may be machined or roughened to increase marginally the functional surface area or to take advantage of biochemical properties related to the surface coating (e.g., bone bonding or bone growth factors).

A threaded implant body is primarily designed to increase the bone-implant surface area and to decrease the stresses at the interface during occlusal loading. The functional surface area of a threaded implant is greater than a cylinder implant by a minimum of 30% and may exceed 500%, depending on the thread geometry. This increase in functional implant surface area decreases the stress imposed on the implant-bone interface and is directly related to the thread geometry.

Crest Module

The crest module of an implant body is that portion designed to retain the prosthetic component in a one-piece or two-piece implant system. It also represents the transition zone from the implant body design to the transosteal region of the implant at the crest of the ridge. The abutment connection area usually has a platform on which the abutment is seated; the platform offers physical resistance to axial occlusal loads. An antirotation feature also is included on the platform (external hex) or extends within the implant body (internal hex, octagon, Morse taper or cone screw, internal grooves or cam tube, and pin slots). The implant body has a design to transfer stress/strain to the bone during occlusal loads (e.g., threads or large spheres), whereas the crest module often is designed to reduce bacterial invasion. (e.g., smoother to impair plaque retention if crestal bone loss occurs). Its smoother dimension varies greatly from one system to another (0.5 to 5 mm). When the crest module is smooth, polished metal, it is often called a *cervical collar*.

A high-precision fit of the external or internal anti-rotational component (flat to flat dimension) is paramount to the stability of the implant body/abutment connection.[31,71-74] The prosthetic connection to the crest module is received by slip-fit or friction-fit with a butt or bevel joint. All prosthetic connections aim at providing a precise mating of the two components with minimal tolerance.

Another antirotational feature of an implant body may be flat sides or grooves along the body or apical region of the implant body. When bone grows against the flat or groove regions, the bone is placed in compression with rotational loads. The apical end of each implant should be flat rather than pointed. This allows for the entire length of the implant to incorporate design features that maximize desired strain profiles. Additionally, if an opposing cortical plate is perforated, a sharp, V-shaped apex may irritate or inflame the soft tissues if any movement occurs (e.g., the inferior border of the mandible).

IMPLANT SURGERY

At the time of insertion of a two-stage implant body (stage I surgery), a first-stage cover screw is placed into the top of the implant to prevent bone, soft tissue, or

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

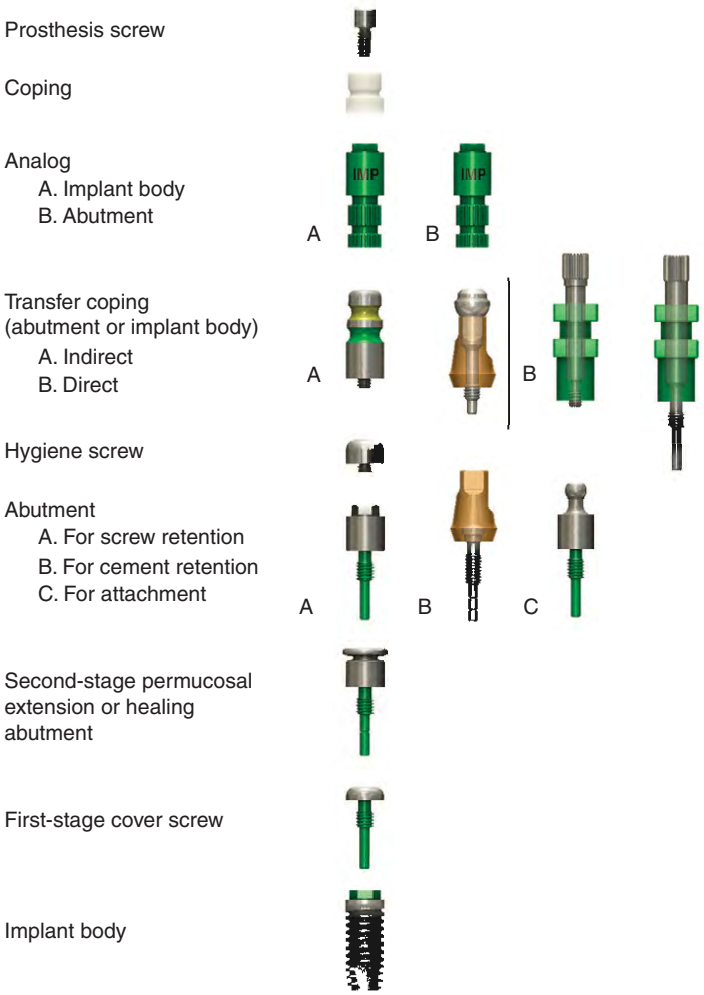

Figure 2-6 Implant components frequently have terms that are different for each company, but a generic language exists that applies to any product. This language permits improved communication between referring doctors and laboratories, which often must be familiar with several different systems.

debris from invading the abutment connection area during healing (Figure 2-6).

After a prescribed healing period sufficient to allow a supporting bone interface to develop, a second-stage procedure may be performed to expose the two-stage implant or to attach a transepithelial portion.[32] This transepithelial portion is termed a *permucosal extension* because it extends the implant above the soft tissue and results in the development of a permucosal seal around the implant. This implant component has also been called a *healing abutment* because stage II uncovery surgery often uses this device for initial soft tissue healing (Figure 2-7).

In the case of a one-stage procedure, the surgeon may have placed the permucosal extension at the time of implant insertion or may have selected an implant body design with a cervical collar of sufficient height to be supragingival. In the case of immediate load, the permucosal healing abutment may not be used at all if a temporary prosthesis is delivered on the day of surgery or may be used until the suture removal appointment and the temporary teeth delivery. The permucosal extension is available in multiple heights to accommodate soft tissue variations. It also can be straight, flared, or anatomical to assist in the initial contour of the soft tissue healing.

Prosthetic Attachments

The abutment is the portion of the implant that supports or retains a prosthesis or implant superstructure.[32] A *superstructure* is defined as a metal framework that attaches to the implant abutment(s) and provides either retention for a removable prosthesis[1] (e.g., a cast bar retaining an overdenture with attachments) or the framework for a fixed prosthesis. Three main categories of implant abutments are described, according to the method by which the prosthesis or superstructure is retained to the abutment: (1) an abutment for screw retention uses a screw to retain the prosthesis or superstructure (Figure 2-8, *A*), (2) an abutment for cement retention uses dental cement to retain the prosthesis or superstructure (Figure 2-8, *B*), and (3) an abutment for attachment uses an attachment device to retain a removable prosthesis (such as an O-ring attachment) (Figure 2-8, *C*). The abutment for cement/

Figure 2-7 **A,** The permucosal extension (PME) attaches to the implant body and allows the soft tissue to heal and mature around the future implant abutment. The PME may be the same size as the crest module of the implant body *(left)* or slightly larger *(right)* and helps develop the emergence contour of the implant crown. **B,** An intraoral view of eight second-stage permucosal extensions that were inserted into the implant bodies.

screw/attachment may be screwed or cemented into the implant body, but this aspect is not delineated within the generic terminology.

Each of the three abutment types may be further classified as straight or angled abutments, describing the axial relationship between the implant body and the abutment. An abutment for screw retention uses a hygiene cover screw placed over the abutment to prevent debris and calculus from invading the internally threaded portion of the abutment retention during prosthesis fabrication between prosthetic appointments.

The lack of abutment design of a decade ago has been replaced by a variety of options. The expansion of implant dentistry, its applications for esthetic dentistry, and the creativity of manufacturers in this very competitive market is responsible for the explosion of implant abutment styles available today (Figure 2-9). In the abutment for cement category, the doctor may choose from one- and two-piece abutments; UCLA type (plastic castable, machined/plastic castable, gold sleeve castable); two-piece esthetic; two-piece anatomical; two-piece shoulder; preangled (several angulations); or

C

Figure 2-8 **A,** An abutment for screw retention is used for a screw-retained bar or fixed prosthesis. **B,** Abutments for cement retention may be one piece *(far left)* or two pieces, which are retained by a separate abutment screw. **C,** Abutments for attachment are used for removable prostheses that are implant retained. These may be used for complete dentures and partial dentures. *(**A,** Courtesy BioHorizons, Birmingham, Ala.)*

ceramic, Zirconia, or computer-assisted custom designs. The abutment for screw category also has been enlarged with one- and two-piece overdenture abutments of different contours and heights.

Many manufacturers classify the prosthesis as *fixed* whenever cement retains the prostheses, *fixed/removable* when screws retain a fixed prosthesis, and *removable* when the restoration is removed by the patient. This description implies that only screw-retained prostheses may be removed. This is not an accurate description, because a fixed, cemented prosthesis also may be

t.me/highdent www.highdentlab.com instagram.com/high_dent

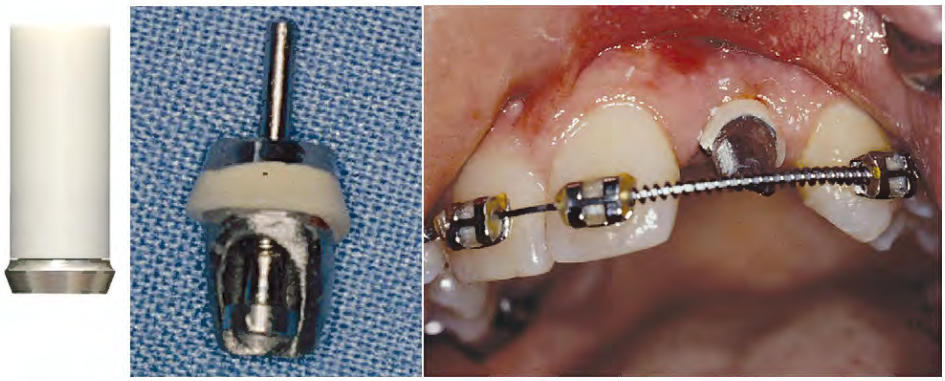

Figure 2-9 **A,** A custom abutment can be fabricated to address specific angulation or esthetic requirements. **B,** On a custom abutment, porcelain may be built between the crown margin and the abutment-to-implant position. This buildup allows the crown margin to be above the bone, yet the subgingival region has pink or tooth-colored porcelain and a customized shape to improve esthetics. **C,** A custom abutment with tooth-colored ceramic and ideal emergence profile from the implant body. If the tissue shrinks in the future, the crown will appear longer, but the titanium color of the abutment will not be visible.

removed by the dentist (especially when a temporary cement is used). The generic language in this chapter separates prostheses into either fixed or removable in a method similar to traditional prosthetics.

Prosthesis Fabrication

An impression is necessary to transfer the position and design of the implant or abutment to a master cast for prosthesis fabrication. A transfer coping is used in traditional prosthetics to position a die in an impression[32] (Figure 2-10). Most implant manufacturers use the terms *transfer* and *coping* to describe the component used for the final impression. Therefore a transfer coping is used to position an analog in an impression and is defined by the portion of the implant it transfers to the master cast, either the implant body transfer coping or the abutment transfer coping.

Two basic implant restorative techniques are used to make a master impression, and each uses a different design transfer coping, based on the transfer technique performed. An indirect transfer coping uses an impression material requiring elastic properties.[32] The indirect transfer coping is screwed into the abutment or implant body and remains in place when a traditional "closed tray" impression is set and removed from the mouth. The indirect transfer coping is usually slightly tapered to allow ease in removal of the impression and often has flat sides or smooth undercuts to facilitate reorientation in the impression after it is removed.

A direct transfer coping usually consists of a hollow transfer component, often square, and a long central screw to secure it to the abutment or implant body and may be used as a pick-up impression coping. An "open tray" impression tray is used to permit direct access to the long central screw securing the indirect transfer coping. After the impression material is set, the direct transfer coping screw is unthreaded to allow removal of the impression from the mouth. Direct transfer copings take advantage of impression materials having rigid properties and eliminate the error of permanent deformation because they remain within the impression until the master model is poured and separated (Figure 2-11).

Laboratory Fabrication

An *analog* is defined as something that is analogous or similar to something else.[32] An implant analog is used in the fabrication of the master cast to replicate the retentive portion of the implant body or abutment (implant body analog, implant abutment analog). After the master impression is obtained, the corresponding analog (e.g., implant body, abutment for screw) is attached to the transfer coping and the assembly is poured in stone to fabricate the master cast (Figure 2-12).

A prosthetic coping is a thin covering,[32] usually designed to fit the implant abutment for screw retention. It serves as the connection between the abutment and the prosthesis or superstructure. A prefabricated coping usually is a metal component machined precisely to fit the abutment. A castable coping usually is a plastic pattern cast in the same metal as the superstructure or prosthesis. A screw-retained prosthesis or superstructure is secured to the implant body or abutment with a prosthetic screw.

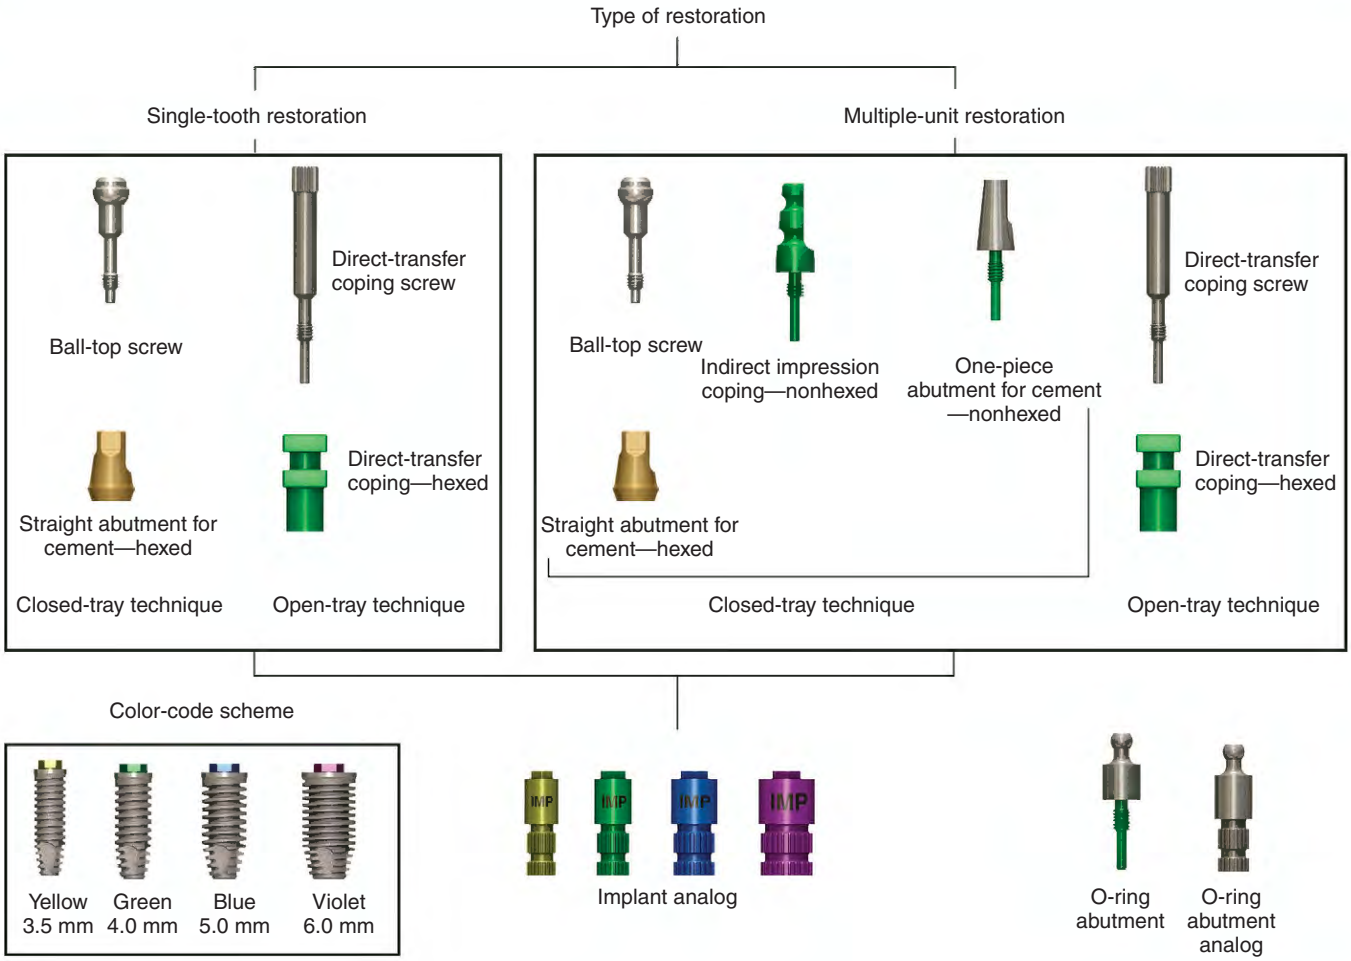

Figure 2-10 An indirect transfer *(far left and center)* is inserted into an implant body or abutment for screw retention, and a closed tray impression is made. The impression is removed, and the transfers are connected to an analog and reinserted into the impression. A direct impression transfer *(far right)* uses an open tray to make the impression. The direct transfer coping screw must be unthreaded before the impression is removed from the mouth. *(Courtesy BioHorizons, Birmingham, Ala.)*

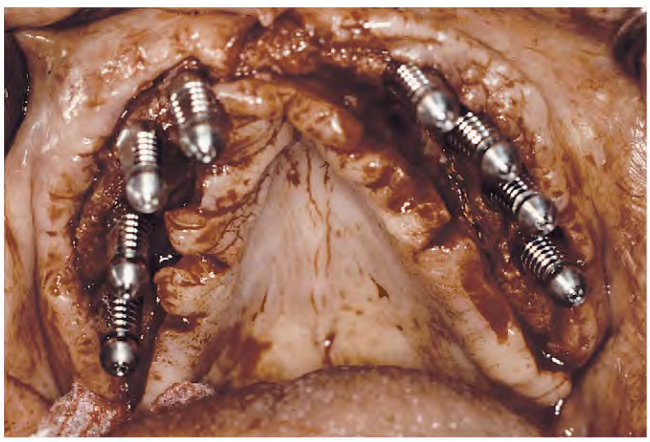

Figure 2-11 These eight maxillary implants are connected to two-piece indirect impression transfers, which engage the hexagon of the implant platform. A closed-tray impression is made, and the indirect transfer copings are unthreaded from the implant bodies, connected to implant body analogs, and reinserted into the impression before pouring of the cast.

SUMMARY

A generic terminology has been developed to facilitate communication among implant team members. Regardless of the implant system used, the generic term is descriptive of the function of the component, rather than its proprietary name. The surgery phase of treatment most often uses an implant body with a first-stage cover screw. The second-stage surgery removes the first-stage cover screw and inserts a permucosal extension. The restoring dentist removes the permucosal extension and places the abutment or makes an implant body impression.

The implant body impression may use a direct or indirect technique. The laboratory uses analogs to fabricate the prosthesis. The prosthesis is most often cement retained in partially edentulous patients and uses an abutment for cement retention. Regardless of the implant system selected, the staff and laboratory should be familiar with generic, descriptive terminology.

C

Figure 2-12 **A,** Analogs may represent an abutment for screw retention, an implant body *(left)*, or an abutment for attachment *(right)*. **B,** An indirect closed-tray impression in a "customized" impression tray, which also relates the incisal edge of the patient to the laboratory technician. The indirect impression transfers have been attached to implant body analogs and reinserted into the closed-tray impression. **C,** The impression in **B** is mounted against the opposing arch (with a bite registration not pictured). In this particular system the indirect transfer coping may be a one- or two-piece component. A one-piece component does not engage the hexagon and does not transfer the position of the antirotational hexagon from the mouth to the model. The two-piece indirect transfer does allow the transfer. The laboratory can remove the indirect transfer copings, insert the abutments for cement retention, and prepare them before making a transition prosthesis. Some dentists also will make a metal casting for the final restoration on this model.

Chapter 3

Diagnostic Imaging and Techniques

Randolph R. Resnik, Louis T. Kircos, Carl E. Misch

Diagnostic imaging and techniques help develop and implement a cohesive and comprehensive treatment plan for the implant team and the patient. The implant team requires the services or functions of a number of professionals and may include the referring dentist, laboratory technician, prosthodontist, periodontist, oral surgeon, implantologist, anesthesiologist, radiologist, hygienist, and staff. Information acquired from the patient's medical and dental history, including clinical examination, laboratory tests, diagnostic casts, diagnostic wax-up, and diagnostic imaging, plays a role in developing the patient's treatment plan and objectives.

IMAGING OBJECTIVES

The objectives of diagnostic imaging depend on a number of factors, including the amount and type of information required and the period of the treatment rendered. The decision of when to image along with which imaging modality to use depends on the integration of these factors and can be organized into three phases.

Phase 1

Phase 1 is termed *presurgical implant imaging* and involves all past radiologic examinations and new radiologic examinations chosen to assist the implant team in determining the patient's final and comprehensive treatment plan. The objectives of this phase of imaging include all necessary surgical and prosthetic information to determine the quantity, quality, and angulations of bone; the relationship of critical structures to the prospective implant sites; and the presence or absence of disease at the proposed surgery sites.

Phase 2

Phase 2 is termed *surgical and intraoperative implant imaging* and is focused on assisting in the surgical and prosthetic intervention of the patient. The objectives of this phase of imaging are to evaluate the surgery sites during and immediately after surgery, assist in the optimal position and orientation of dental implants, evaluate the healing and integration phase of implant surgery, and ensure that abutment position and prosthesis fabrication are correct.

Phase 3

Phase 3 is termed *postprosthetic implant imaging*. This phase commences just after the prosthesis placement and continues as long as the implants remain in the jaws. The objectives of this phase of imaging are to evaluate the long-term maintenance of implant rigid fixation and function, including the crestal bone levels around each implant, and to evaluate the implant complex.

IMAGING MODALITIES

The decision to image the patient is based on the patient's clinical needs. After a decision has been made to obtain images, the imaging modality is used that yields the necessary diagnostic information related to the patient's clinical needs and results in the least radiologic risk. The opinion of a radiologist may be required for more complex modalities or for situations in which the attending dentist is less experienced.

Maximizing the ratio of benefit to risk for imaging examinations is a fundamental tenet of radiology. Examinations known to produce this result are not necessarily the examinations that cost the least, are in proximity to the dentist, or produce the lowest radiation exposure.[1-3] However, they enable the dentist to provide the proper care or treatment for the patient.

Many imaging modalities have been reported as useful for dental implant imaging, including devices recently developed specifically for dental implant imaging (Box 3-1).[4,5]

These imaging modalities can be described as analog or digital and two- or three-dimensional. Most dentists are more familiar with analog two-dimensional imaging (see Box 3-1). Analog imaging modalities are two-

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

Box 3-1 Types of Imaging Modalities

- Periapical radiography (analog)
- Panoramic radiography (analog)
- Occlusal radiography (analog)
- Cephalometric radiography (analog)
- Tomographic radiography
- Computed tomography (three-dimensional)
- Magnetic resonance imaging (three-dimensional)
- Interactive computed tomography (three-dimensional)

dimensional systems that use radiograph film or intensifying screens as the image receptors. The image quality of these systems is characterized by resolution/modulation transfer function, contrast/H and D curve, noise/Weiner spectrum, and sensitivity.[6] The clinical performance of these imaging systems is gauged by receiver operator characteristics.[7,8]

Digital images also can be produced with each imaging modality (see Box 3-1). A digital two-dimensional image is described by an image matrix that has individual picture elements called *pixels*. A digital image is described by its width and height and pixels (i.e., 512×512). For larger digital images (i.e., $1.2\ M \times 1.2\ M$, where *M* is megapixels), the image is alternatively described as a 1.5-M image. Each picture element, or pixel, has a discrete digital value that describes the image intensity at that particular point. The value of a pixel element is described by a scale, which may be as low as 8 bits (256 values) or as high as 12 bits (4096 values) for black-and-white imaging systems, or 36 bits (65 billion values) for color imaging systems.[9-11] Black-and-white digital images are displayed optimally on a dedicated black-and-white monitor. Generally, 8 bits or 256 levels can be displayed effectively on a monitor.

A digital three-dimensional image is described by an image matrix that has individual image/picture elements called *voxels*. A digital three-dimensional image is described not only by its width and height and pixels (i.e., 512×512) but also by its depth/thickness. An imaging volume or three-dimensional characterization of the patient is produced by contiguous images, which produce a three-dimensional structure of volume elements (i.e., computed tomography [CT], magnetic resonance imaging [MRI], and interactive computed tomography [ICT]). Each volume element has a value that describes its intensity level. Typically, three-dimensional modalities have an intensity scale of 12 bits or 4096 values. Box 3-1 identifies the three-dimensional imaging modalities.

PRESURGICAL IMAGING (PHASE 1)

In the field of oral implantology, there exist numerous radiographic imaging modalities available for the presurgical assessment of the dental implant patients. In the past, intraoral radiographs along with panoramic images were used as the sole determinants of implant diagnosis and treatment planning. With the advancement of radiographic technology, various three-dimensional imaging systems are now available to the dental profession allowing the implant team an infinite amount of diagnostic information.

The goal of presurgical radiographic evaluation is to assess the available bone quality and quantity, angulation of bone, selection of potential implant sites, and to verify absence of pathology. However, there exists no ideal radiographic imaging technique in the field of oral implantology that would be acceptable for all patients. All imaging techniques in the field of dentistry have inherent advantages and disadvantages and have been shown to exhibit false-negative and false-positive images.[12-14]

When selecting a radiographic modality for preoperative assessment, a careful examination of the available imaging options should be evaluated for selection as per the patient's needs. In dental and medical radiology, a recommended principle when selecting the appropriate radiographic modality is based on radiation dosage. The "as low as reasonably achievable" (ALARA) principle should always be adhered to that states that the diagnostic imaging technique selected should include the lowest possible radiation dose to the patient. However, patient care and treatment planning should not be jeopardized in response to radiation dose. Studies have shown that an overwhelming number (90%) of dentists prescribe panoramic images as the sole determinant for implant treatment planning.[15,16] In comparison, less than 10% prescribe conventional or CT. On the other hand, the American Academy of Oral and Maxillofacial Radiology guidelines state that all implant site evaluations should be evaluated with a three-dimensional imaging technique such as conventional or computerized tomography.[17]

This phase of implant imaging is intended to evaluate the current status of the patient's teeth and jaws and to develop and refine the patient's treatment plan. Evaluation of the patient by members of the dental implant team is accomplished with a review of the patient's history, a thorough clinical examination, and a review of the patient's radiologic examinations. At this point, the dentist should be able to rule out dental or bone disease and establish a tentative clinical objective that meets the patient's functional and esthetic needs. If the dentist cannot rule out dental or bone disease, further clinical or radiologic examination is necessary.

The global objective of this phase of treatment is to develop and implement a treatment plan for the patient that enables restoration of the patient's function and esthetics by the accurate and strategic placement of dental implants. The patient's functional and esthetic needs can be transformed physically into a three-dimensional diagnostic template, which enables the implant team to identify the specific sites of prospective implant surgery

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Box 3-2 Objectives of Preprosthetic Imaging

- Identify disease
- Determine bone quality
- Determine bone quantity
- Determine implant position
- Determine implant orientation

Box 3-3 Periapical Radiographic Images

Advantages

- Low radiation dose
- Minimal magnification with proper alignment and positioning
- High resolution
- Inexpensive

Limitations

- Distortion and magnification
- Minimal site evaluation
- Difficulty in film placement
- Technique sensitive
- Lack of cross-sectional imaging

Indications

- Evaluation of small edentulous spaces
- Alignment and orientation during surgery
- Recall/maintenance evaluation

in the imaging examinations. The specific objectives of preprosthetic imaging listed in Box 3-2.

All the modalities identified in Box 3-1 have been used in the first diagnostic phase of treatment.[4,5] However, dental implant cases are inherently three-dimensional problems relating to the final prosthetics, occlusion, and function of the patient's three-dimensional anatomy. A three-dimensional treatment plan ideally identifies at each prospective implant site the amount of bone width, the ideal position and orientation of each implant, its optimal length and diameter, the presence and amount of cortical bone on the crest, the degree of mineralization of trabecular bone, and the position or relationship of critical structures to the proposed implant sites. Thus the modalities of choice for presurgical implant treatment planning provide high-resolution and dimensionally accurate three-dimensional information about the patient at the proposed implant sites.

The imaging modalities listed in Box 3-1 can be subdivided into planar two-dimensional, quasi–three-dimensional, and three-dimensional imaging modalities. Planar imaging modalities include periapical, bite-wing, occlusal, and cephalometric imaging and are simply two-dimensional projections of the patient's anatomy. Thus the dentist cannot possibly develop a three-dimensional perspective of the patient's anatomy with a single image. However, with a number of cleverly oriented projections, development of some useful three-dimensional information is possible.

Quasi–three-dimensional imaging modalities include x-ray tomography and some cross-sectional panoramic imaging techniques. These techniques produce a number of closely spaced tomographic images, and the three-dimensional perspective of the patient's anatomy is developed by viewing each image and mentally filling in the gaps. Three-dimensional imaging techniques include CT and MRI and enable the dentist to view a volume of the patient's anatomy. These techniques are quantitatively accurate, and three-dimensional models of the patient's anatomy can be derived from the image data and used to produce stereotactic surgical guides and prosthetic frameworks.

PERIAPICAL RADIOGRAPHY

Periapical radiographs are images of a limited region of the mandibular or maxillary alveolus. Periapical radiographs are produced by placing the film intraorally parallel to the body of the alveolus with the central ray of the x-ray device perpendicular to the alveolus at the region of interest, producing a lateral view of the alveolus.[18] Periapical radiography provides a high-resolution planar image of a limited region of the jaws.[19] Number 2 size dental film provides a 25 × 40-mm view of the jaw with each image. Periapical radiographs provide a lateral view of the jaws and no cross-sectional information. Even with adjacent periapical radiographs made with limited oblique orientations, three-dimensional information is of little use for the implant imaging (Box 3-3).

Periapical radiographs may suffer from distortion and magnification. The most accurate radiographic technique used for periapical radiology is the paralleling technique that necessitates placing the film or sensor parallel to the long axis of the implant, tooth, or osseous structure in question. These principles in positioning will allow for an intraoral image with minimal distortion and magnification. If improper positioning or the bisecting angle technique is used, vertical and horizontal measurements may be distorted and magnified.

The long cone paralleling technique eliminates distortion and limits magnification to less than 10%. Millimeter radiopaque grids, sometimes used in endodontics, may be superimposed over the film before it is exposed, but are of little quantitative value and provide misleading information because they lie on the film and obfuscate the underlying anatomy and do not compensate for magnification.

Image shape distortion occurs when unequal magnification of the object exists. This will occur when the total area in question (alveolar bone, implant) does not

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

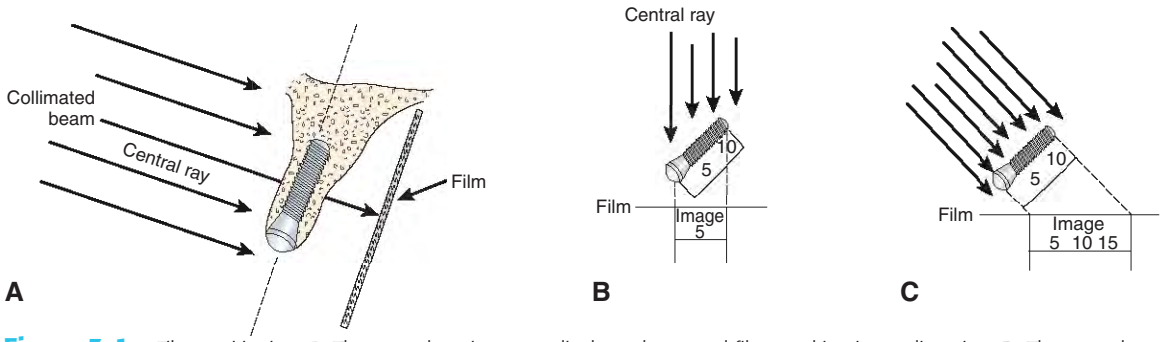

Figure 3-1 Film positioning. **A,** The central ray is perpendicular to bone and film resulting in no distortion. **B,** The central ray is perpendicular to film but not to the implant which will result in foreshortening. **C,** The central ray is perpendicular to the object but not the film and will result in elongation.

have the same focal spot-to-object distance. When the x-ray beam is perpendicular to the object, but the object is not parallel to the film, foreshortening will occur. If the x-ray beam is oriented perpendicular to the object but not the film, elongation will occur (Figure 3-1). These basic and important concepts will help minimize distortion and magnification when using intraoral radiographs.[20]

Image magnification may be assessed by placing a known-dimension radiographic marker (e.g., 5-mm ball bearing) at the crestal region of the desired implant location. When the marker is elongated, so is the implant site. For example, a ball bearing radiographic measurement of 8 mm relates to a 60% magnification. Therefore the image below the ball bearing may represent a 60% magnification of dimension.

The opposing landmark of available bone in implant dentistry is beyond lingual muscle attachments in the mandible or beyond the palatal vault in the maxilla. As such, the image most often must be foreshortened to visualize the opposing cortical plate. As a result, the actual available bone height may be difficult to determine.

The bone density at the crest is also a factor to evaluate crestal bone loss with radiographic indexes. In D4 bone, no cortical plate is present on the crest, and fine trabecular bone is primarily present. Burnout effects are common when standard kilovolt and milliampere settings are used, making crestal bone loss evaluation with digital intraoral systems of benefit in these situations.[21-23]

The dense cortical plates on the lateral aspect of the mandible and palatal aspect of the maxilla make bone quality difficult to assess with a periapical radiograph. In fact, a 40% change in trabecular bone density is necessary before a difference may be observed in the anterior mandible.

In terms of the objectives of presurgical imaging, periapical radiography is:

- A useful high-yield modality for ruling out local bone or dental disease
- Of limited value in determining quantity because the image is magnified, may be distorted, and does not depict the third dimension of bone width
- Of limited value in determining bone density or mineralization (the lateral cortical plates prevent accurate interpretation and cannot differentiate subtle trabecular bone changes)
- Of value in identifying critical structures but of little use in depicting the spatial relationship between the structures and the proposed implant site

In the preprosthetic phase, these films most often are used for single-tooth implants in regions of abundant bone width.

DIGITAL RADIOGRAPHY

One of the most recent significant advances in dental radiology is the advent of digital technology that has allowed numerous limitations of conventional intraoral radiography to be reduced. The advantages of digital radiography and the uses in oral implantology are well documented.[24,25] With the use of digital radiography, implant surgical procedures and prosthetics have been simplified with increased efficiency.

Digital radiology is an imaging process wherein the film is replaced by a sensor that collects the data. The analog information received is then interpreted by specialized software, and an image is formulated on a computer monitor. The resultant image can be modified in various ways, such as gray scale, brightness, contrast, and inversion. Color images may be formed to enhance the digital image for better evaluation. Computerized software programs (i.e., DexisImplant) are now available that allow for calibration of magnified images, thus ensuring accurate measurements (Figure 3-2).

When compared with conventional radiographs, the most current digital systems have significantly less radiation[26,27] with superior resolution.[25] However, with respect to oral implantology, the most significant advan-

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Figure 3-2 Digital radiographic system that includes digital sensor and computer. *(Courtesy Dexis, LLC.)*

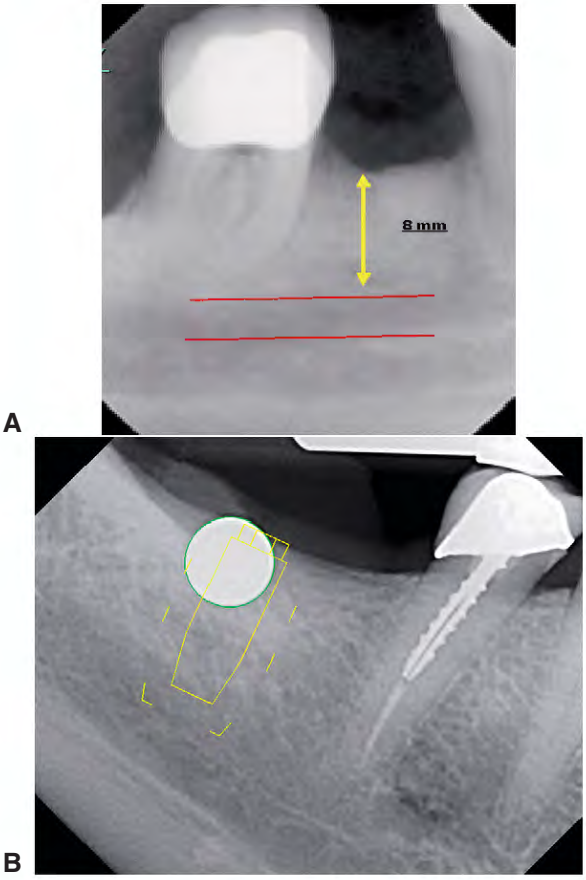

Figure 3-3 **A,** Direct measurements of vital structures may be made directly on the calibrated digital images. Studies have shown that on plain film intraoral radiographs, more than 50% of the time the mandibular canal and mental foramen are indistinguishable. However, this limitation has been drastically reduced with the advent of digital imaging. **B,** Image magnification can be determined by imaging a known-diameter radiographic marker, and the appropriate size implant (adjusted for magnification) may then be selected and placed into the edentulous area.

tage of digital radiography is the instantaneous speed in which images are formed that is highly useful during surgical placement of implants and the prosthetic verification of component placement (Figure 3-3).

Table 3-1 Comparison of Film versus Digital-Based Images

	FILM	DIGITAL
Image	Analog	Analog → Digital
Cost	Film, chemicals	Up-front
Radiation	High	50%-90% less
Viewing	Delayed	Immediate
Resolution	14-18 Ln/mm	12-20 Ln/mm
Grayscale	16 shades	256 shades
Film	Thin, flexible	Thin, cord
Enhancement	Unchangeable	Wide range
Storage	Chart	Computer

From Park ET, Williamson GF: Digital radiography: an overview, *J Contemp Dent Pract* 3:1-13, 2002.

Box 3-4 Occlusal Radiographic Images

Advantages
- Evaluation for pathology

Limitations
- Does not reveal true buccolingual width in mandible
- Difficulty in positioning

Indications
- None

A disadvantage of digital radiography is the size and thickness of the sensor and the position of the connecting cord. These features make the positioning of the sensor more difficult in some sites such as those adjacent to tori or a tapered arch form in the region of the canines (Table 3-1).[28]

OCCLUSAL RADIOGRAPHY

Occlusal radiographs are planar radiographs produced by placing the film intraorally parallel to the occlusal plane with the central x-ray beam perpendicular to the film for the mandibular image and oblique (usually 45 degrees) to the film for the maxillary image. Occlusal radiography produces high-resolution planar images of the body of the mandible or the maxilla.[19] Maxillary occlusal radiographs are inherently oblique and so distorted that they are of no quantitative use for implant dentistry for determining the geometry or the degree of mineralization of the implant site. In addition, critical structures such as the maxillary sinus, nasal cavity, and nasal palatine canal are demonstrated, but the spatial relationship to the implant site generally is lost with this projection (Box 3-4).

Because the mandibular occlusal radiograph is an orthogonal projection, it is a less-distorted projection

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

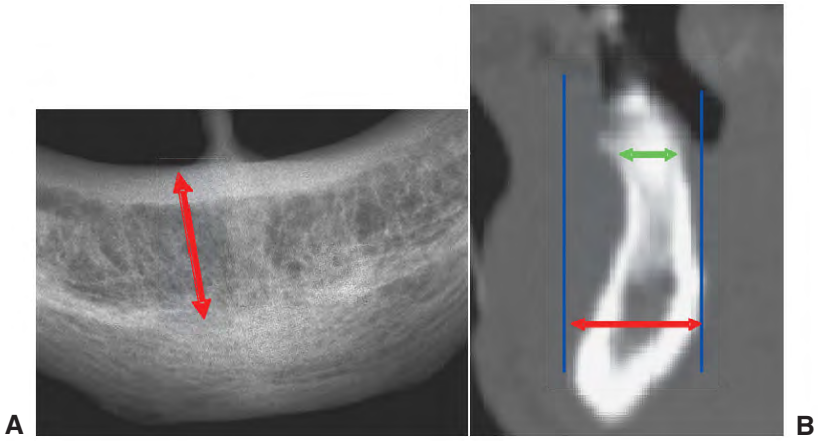

Figure 3-4 **A,** Occlusal radiographs have been postulated to show the width of bone in the anterior region. **B,** However, occlusal radiographs actually show the widest buccolingual distance *(red arrows)* not in the same plane. Actual width of bone *(green arrow).*

than the maxillary occlusal radiograph. However, the mandibular alveolus generally flares anteriorly and demonstrates a lingual inclination posteriorly, producing an oblique and distorted image of the mandibular alveolus, which is of little use in implant dentistry. In addition, the mandibular occlusal radiograph shows the widest width of bone (i.e., the symphysis) versus the width at the crest, which is where diagnostic information is needed most (Figure 3-4). The degree of mineralization of trabecular bone is not determined from this projection, and the spatial relationship between critical structures, such as the mandibular canal and the mental foramen, and the proposed implant site is lost with this projection. As a result, occlusal radiographs rarely are indicated for diagnostic presurgical phases in implant dentistry.

CEPHALOMETRIC RADIOGRAPHY

Cephalometric radiographs are oriented planar radiographs of the skull. The skull is oriented to the x-ray device and the image receptor using a cephalometer, which physically fixes the position of the skull with projections into the external auditory canal. The geometry of cephalometric imaging devices results in a 10% magnification of the image with a 60-inch focal object and a 6-inch object-to-film distance.[19]

A lateral cephalometric radiograph is produced with the patient's midsagittal plane oriented parallel to the image receptor. This radiograph demonstrates a cross-sectional image of the alveolus of the mandible and the maxilla in the midsagittal plane.[21] With a slight rotation of the cephalometer, a cross-sectional image of the mandible or maxilla can be demonstrated in the lateral incisor or in the canine regions. Unlike panoramic or periapical images, the cross-sectional view of the alveolus demonstrates the spatial relationship between occlusion and esthetics with the length, width,

Figure 3-5 A limited projection of the mandibular symphysis region is useful for preoperative evaluation of the symphysis.

angulation, and geometry of the alveolus and is more accurate for bone quantity determinations. Implants often must be positioned in the anterior regions adjacent to the lingual plate.

The lateral cephalometric radiograph is useful because it demonstrates the geometry of the alveolus in the mid-anterior region and the relationship of the lingual plate to the patient's skeletal anatomy (Figures 3-5 and 3-6; Box 3-5). The width of bone in the symphysis region and the relationship between the buccal cortex and the roots of the anterior teeth also may be determined before harvesting this bone for ridge augmentation. Together with regional periapical radiographs, quantitative spatial information is available to demonstrate the geometry of

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

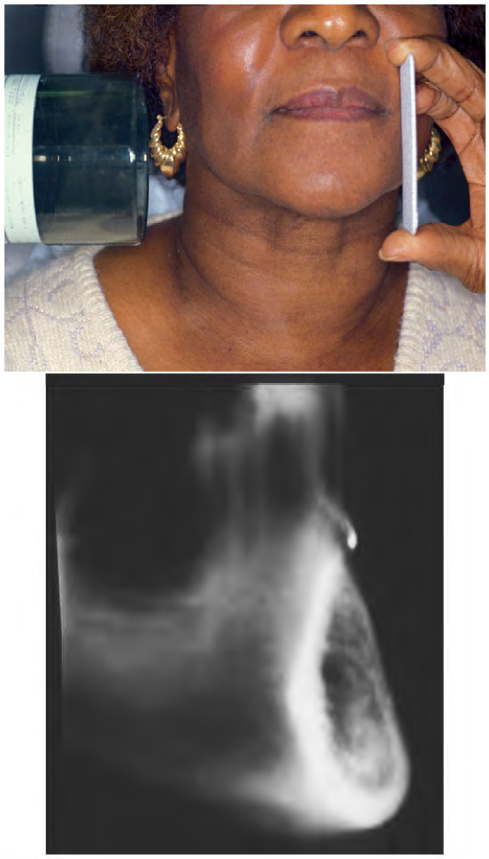

Figure 3-6 **A,** An alternative technique to the standard lateral cephalometric unit is the use of an occlusal film (size 2) held by the patient using a standard intraoral radiographic unit. **B,** Resultant image.

Box 3-5 Lateral Cephalometric Images

Advantages

- Height/width in anterior region
- Low magnification
- Skeletal relationship
- Crown-implant ratio (anterior)
- Tooth position in prosthesis
- Evaluation of the quantity of bone in anterior region prior to symphysis grafting

Limitations

- Availability
- Image information limited to midline
- Reduced resolution and sharpness
- Technique sensitive

Indications

- Used in combination with other radiographic techniques for anterior implants
- Symphysis bone graft evaluation

the implant site and the spatial relationship between the implant site and critical structures such as the floor of the nasal cavity, the anterior recess of the maxillary sinus, and the nasal palatine canal. The lateral cephalometric view also can help evaluate a loss of vertical dimension, skeletal arch interrelationship, anterior crown/implant ratio, soft tissue profile, anterior tooth position in the prosthesis, and resultant moment of forces. As a result, cephalometric radiographs are a useful tool for the development of an implant treatment plan, especially for the completely edentulous patient. However, this technique is not useful for demonstrating bone quality and only demonstrates a cross-sectional image of the alveolus where the central rays of the x-ray device are tangent to the alveolus.

Disadvantages of cephalometric radiographs include cross-sectional information limited to the midline area and difficulty in cephalometric machine accessibility. Any non-midline structure is superimposed on the contralateral side. This radiographic technique is operator technique sensitive and, if improperly positioned, will result in a distorted view. Because lateral cephalometric radiographs use intensifying screens, resolution and sharpness is compromised in comparison to intraoral radiographic techniques.

PANORAMIC RADIOGRAPHY

Panoramic radiography is a curved plane tomographic radiographic technique used to depict the body of the mandible, the maxilla, and the lower half of the maxillary sinuses in a single image. This modality is probably the most used diagnostic modality in implant dentistry. However, for quantitative presurgical implant imaging, panoramic radiography is not the most diagnostic. This radiographic technique produces an image of a section of the jaws of variable thickness and magnification. The image receptor traditionally has been radiograph film but may be a digital storage phosphor plate or a digital charge–coupled device receptor.[23,29,30] Nonetheless, panoramic images offer many advantages (Box 3-6).

The significant limitations of panoramic radiographs can be classified into two categories: (1) distortions inherent in the panoramic system and (2) errors in patient positioning. Panoramic radiography is characterized by a single image of the jaws that demonstrates vertical and horizontal magnification, along with a tomographic section thickness that varies according to the anatomical position. The x-ray source exposes the jaws from a negative angulation and produces a relatively constant vertical magnification of approximately 10%. The horizontal magnification is approximately 20% and variable depending on the anatomical location, the position of the patient and the focus object distance, and the relative location of the rotation center of the x-ray system. Clinical data have shown that nonuniform magnification may be in the range of 15% to 220%.[31-33] Structures of the jaws become magnified more as the object-film distance increases and the object–x-ray source distance decreases.

Advantages

- Easy identification of opposing landmarks
- Initial assessment of vertical height of bone
- Convenience, ease, and speed in performance in most dental offices
- Evaluation of gross anatomy of the jaws and any related pathologic findings*

Limitations

- Distortions inherent in the panoramic system
- Errors in patient positioning
- Does not demonstrate bone quality
- Misleading quantitate because of magnification and no third dimension
- No spatial relationship between structures

*Kircos LT: *Preprosthetic imaging in prospective,* Chicago, 1990, University of Chicago Press.

Structures that are located obliquely in relation to the implant receptor produce aspects of the structures that are magnified more when they are farther from the image receptor and less when they are closer to the image receptor.[34-36] Uniform magnification of structures produces images with distortion that cannot be compensated for in treatment planning. The posterior maxillary regions are generally the least distorted regions of a panoramic radiograph. The tomographic section thickness of panoramic radiography or trough of focus is thick, approximately 20 mm, in the posterior regions and thin, 6 mm, in the anterior region.[36]

Traditional panoramic radiography is a high-yield technique for demonstrating dental and bone disease. However, panoramic radiography does not demonstrate bone quality/mineralization, is misleading quantitatively because of magnification and because the third-dimension cross-sectional view is not demonstrated, and is of some use in demonstrating critical structures but of little use in depicting the spatial relationship between the structures and dimensional quantitation of the implant site. Because panoramic radiography is such a popular and widely available technique in dentistry, dentists have developed means to compensate for its shortcomings. Implant companies often market magnified overlays with a preset 25% magnification for evaluation of an implant size that are placed on a panoramic film for comparison with vital structure positions.

Because the concept of standardized magnification is impossible and unreliable, most clinical studies have observed the inaccuracies of direct measurements of panoramic radiographs[37,38] (Figure 3-7).

Inherent magnification is dependent upon patient positioning errors, which results in significant geometric distortion. With knowledge, most errors in patient positioning can be corrected (Table 3-2). However, in a given plane, horizontal distortion cannot be determined

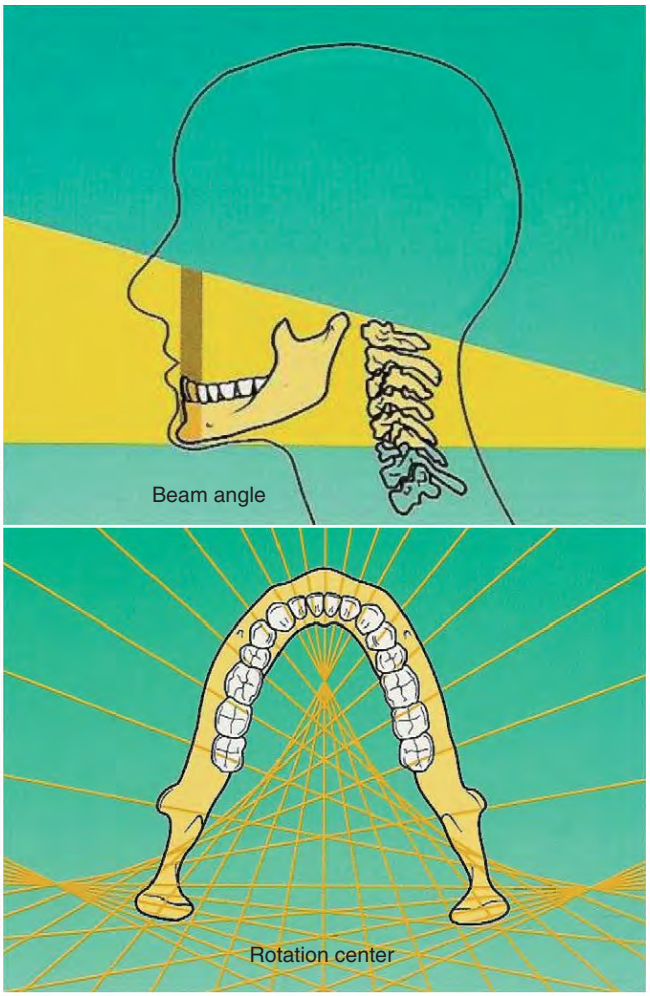

Figure 3-7 **A,** All panoramic beam angles are approximately at 8 degrees, which gives the image inherent magnification. **B,** Because of the curvature of the arch, panoramic machines have changing rotational centers.

and measurements are completely unreliable. The horizontal dimensions are affected by the rotation center of the beam that changes with relation to the object-film distance.[26]

The vertical dimensions are dependent upon the x-ray source as the focus with the amount of distortion determined by the distance of the patient's arch to the film. However, vertical magnification may be determined by imaging a known-diameter object close to the alveolar ridge. The magnification factor can be calculated at the given site by dividing the actual diameter of the object by the diameter measured on the radiographic image. Diagnostic templates that have 5-mm ball bearings or wires incorporated around the curvature of the dental arch and worn by the patient during the panoramic x-ray examination enable the dentist to determine the amounts of magnification in the radiograph (Figure 3-8). A technique for evaluating the panoramic radiograph for mandibular posterior implants and comparison with the clinical evaluation during surgery was developed by identifying the mental

Table 3-2 Common Panoramic Positioning Problems and Corrections

PROBLEM	CAUSE	CORRECTION
Blurred Magnified	Patient positioned too far posterior	Make sure anterior teeth are properly in holder
Blurred Narrow anterior region	Patient positioned too far anterior	Make sure anterior teeth are in holder
Exaggerated curve of Spee Anterior foreshortening Condyles not seen Spine forms "gazebo" effect	Patient chin tipped down too far	Correctly align ala-tragus
Flattened curve of Spee Hard palate superimposed	Patient chin tipped too far upward	Correctly align ala-tragus
Radiopaque shadow over anterior region	Patient slumped too far forward	Straighten neck
Ramus larger on one side Uneven pattern of blurring	Patient head rotated in machine	Patient midsaggital plane should be perpendicular to floor
Large radiolucency over maxilla	Patient tongue not in floor of mouth	Patient places tongue in roof of mouth, swallows

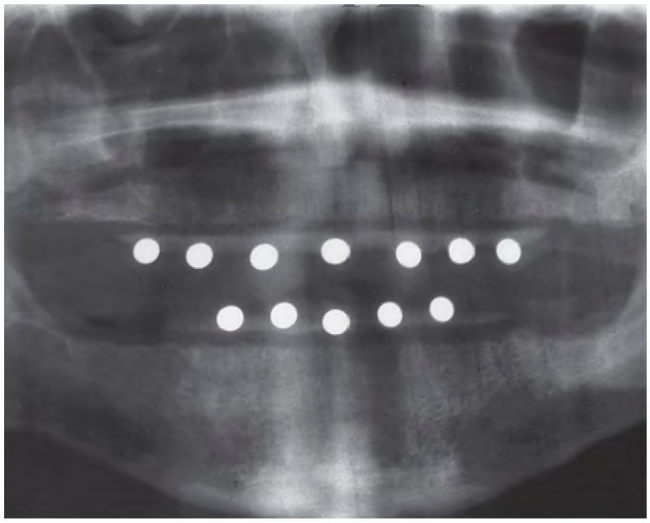

Figure 3-8 Panoramic radiograph with 5-mm ball bearings on the crest of a Division A mandible.

foramen and the posterior extent of the inferior alveolar canal.[39] However, studies have demonstrated that the mandibular foramen cannot be identified 30% of the time on the radiograph film and, when visible, may not be identified correctly.[40-43] The maxillary anterior edentulous region is generally oblique to the film and is often the most difficult area of a panoramic radiograph to evaluate because of the curvature of the alveolus and the inclination of the bone. The dimensions of inclined structures in panoramic radiographs are not reliable. Studies on panoramic x-ray units have demonstrated that objects in front of and behind the focal trough are blurred, magnified, reduced in size, or distorted to the extent of being unrecognizable.

Because the x-ray source comes from below the position of the mandible, the position of the mandibular canal in relation to the crest of the ridge is variable, depending on its buccolingual position in the mandibular body. In other words, when the canal runs lingual within the body, the position displayed on the film is more crestal compared with a nerve that is positioned more buccal, even though they are the same vertical distance from the crest of the ridge. As a result, the lingual-positioned canal may have enough vertical height to place an implant, but the panoramic film indicates inadequate height of bone.

A modification of the panoramic x-ray machine has been developed that has the capability of making a cross-sectional image of the jaws. These devices use limited-angle linear tomography (zonography) and a means for positioning the patient. The tomographic layer is approximately 5 mm. This technique enables the appreciation of spatial relationship between the critical structures and the implant site and quantification of the geometry of the implant site. The tomographic layers are thick and have adjacent structures that are blurred and superimposed on the image, limiting the usefulness of this technique for individual sites, especially in the anterior regions where the geometry of the alveolus changes rapidly. This technique is not useful for determining the differences in most bone densities or identifying disease at the implant site.

TOMOGRAPHY

Tomography is a generic term formed from the Greek words *tomo* (slice) and *graph* (picture) that was adopted in 1962 by the International Commission on Radiological Units and Measurements to describe all forms of body section radiography. Body section radiography is a special x-ray technique that enables visualization of a section of the patient's anatomy by blurring regions of the patient's anatomy above and below the section of interest.

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

Many ingenious tomographic methods and devices have been developed. However, the basic principle of tomography is that the x-ray tube and film are connected by a rigid bar called the *fulcrum bar*, which pivots on a point called the *fulcrum*. When the system is energized, the x-ray tube moves in one direction with the film plane moving in the opposite direction and the system pivoting about the fulcrum. The fulcrum remains stationary and defines the section of interest, or the tomographic layer. Different tomographic sections are produced by adjusting the position of the fulcrum or the position of the patient relative to the fulcrum in fixed geometry systems.[6]

Factors that affect tomographic quality are the amplitude and direction of tube travel. The greater the amplitude of tube travel, the thinner the tomographic section. Linear tomography is the simplest form of tomography in which the x-ray tube and film move in a straight line. This tomographic motion is one-dimensional and produces blurring of adjacent sections in one dimension, resulting in linear streak artifacts in the resulting image, which may obfuscate the section of interest. Complex-motion, high-quality tomography is described by two-dimensional motion of the tube and film and results in uniform blurring of the regions of the patient's anatomy adjacent to the tomographic motion. Circular, spiral, and hypocycloidal are tube motions used in complex tomography.

The diagnostic quality of the resulting tomographic image is determined by the type of tomographic motion, the section thickness, and the degree of magnification. The type of tomographic motion is probably the most important factor in tomographic quality. Hypocycloidal motion generally is accepted as the most effective blurring motion. Large-amplitude tube travel and 1-mm sections are preferred for high-contrast anatomical objects with geometry that changes in a short distance, such as the alveolus of the jaws. Magnification varies from 10% to 30%, with higher magnification generally producing higher-quality images. Dense structures such as teeth, exostoses, thick cortical plates, and dental materials/restorations are difficult to blur effectively when they are much more dense than the structures depicted in the tomographic section. Dense structures may persist in the tomographic image even though they are three or four times the tomographic layer thickness distant from the tomographic section and will serve to obfuscate the structures of interest in the tomographic section.

For dental implant patients, high-quality complex motion tomography demonstrates the alveolus and, taking magnification into consideration, enables quantification of the geometry of the alveolus.[44,45] This technique also enables determination of the spatial relationship between the critical structures and the implant site. Ideally, tomographic sections spaced every 1 or 2 mm enable evaluation of the implant site region and, with mental integration, enable appreciation of the quasi–three-dimensional appearance of the alveolus. The quantity of alveolar bone available for implant placement can be determined by compensating for magnification. Postimaging digitization of tomographic implant images enables use of a digital ruler to aid in the determination of alveolar bone for implant placement. Image enhancement can aid in identifying critical structures such as the inferior alveolar canal. Complex tomography is not particularly useful in determining bone quality or identifying dental and bone disease (Box 3-7).

Conventional tomograms will have a constant magnification that varies among different machines. Image magnification has been shown to be as much as 40% on some machines.[2] Additionally, this technique is very operator technique–sensitive with superimposition of structures outside of the plane of focus causing significant "blurring" of the image, making them very difficult to read (Figure 3-9). In addition, when looking for the position of a mandibular canal, a vascular space and the cross section of the canal appear similar, and a misinterpretation is possible. Studies have shown that more than 20% of tomographic images are undiagnostic.[46]

COMPUTED TOMOGRAPHY

The discovery and development of CT revolutionized medical imaging. CT is a digital and mathematical imaging technique that creates tomographic sections where the tomographic layer is not contaminated by blurred structures from adjacent anatomy. In addition, and probably most important, CT enables differentiation and quantification of soft and hard tissues. Thus for the first time in medical imaging, the radiologist could view hard and soft tissues on an image without performing

an invasive procedure on a patient, such as the injection of contrast media.

CT was invented by Hounsfield and was announced to the imaging world in 1972,[47] but it had its origins in mathematics (1917) and in astrophysics (1956). The first CT scanners appeared in medical imaging departments during the mid-1970s and were so successful that they largely replaced complex tomography by the early 1980s.

CT produces axial images of a patient's anatomy. Axial images are produced perpendicular to the long axis of the body. CT is a prospectively digital imaging technique. The x-ray source is attached rigidly to a fan-beam geometry detector array, which rotates 360 degrees around the patient and collects data. The image detector is gaseous or solid state, producing electronic signals that serve as input data for a dedicated computer. The computer processes the data using back-projection Fourier algorithm techniques first developed by Hounsfield to produce CT images. CT images are inherently three-dimensional digital images, typically 512×512 pixels with a thickness described by the slice spacing of the imaging technique. The individual element of the CT image is called a *voxel*, which has a value, referred to in Hounsfield units, that describes the density of the CT image at that point. Each voxel contains 12 bits of data and ranges from −1000 (air) to +3000 (enamel/dental materials) Hounsfield units. CT scanners are standardized at a Hounsfield value of 0 for water. The CT density scale is quantitative and meaningful in identifying and differentiating structures and tissues.

CT images are inherently three dimensional. Contiguous CT images describe a three-dimensional structure of voxels. The original imaging computer can create secondary images from almost any perspective by reprojecting or reformatting the original three-dimensional voxel data. When a secondary computer is used to perform reformatting or image processing of the original CT data, the system is referred to as a *workstation*.

The power and usefulness of CT for maxillofacial imaging and diagnosis were apparent as soon as high-resolution CT was introduced in the early 1980s. CT was used for imaging the temporomandibular joint, evaluating dental-bone lesions, assessing maxillofacial deformities, and preoperative and postoperative evaluation of the maxillofacial region.[48] CT provides a unique means of postimaging analysis of proposed surgery or implant sites by reformatting the image data to create tangential and cross-sectional tomographic images of the implant site. With current-generation CT scanners, reformatted images are characterized by a section thickness of 1 pixel (0.25 mm) and an in-plane resolution of 1 pixel by the scan spacing (0.5 to 1.5 mm), producing a geometric resolution similar to that of planar imaging. The density of structures within the image is absolute and quantitative and can be used to differentiate tissues in the region and characterize bone quality (Figure 3-10; Boxes 3-8 and 3-9).[10,11,49-55] CT enables the evaluation of proposed implant sites and provides diagnostic information that other imaging or combinations of imaging techniques cannot provide. The utility of CT for dental implant treatment planning[56-62] was evident, but the access to these imaging techniques was limited. Access to this diagnostic information required a radiologist to communicate with the referring doctors in detail about prospective surgery and then to sit at the imaging computer or a workstation for a considerable length of time to reformat the study, interpret the resulting images, and

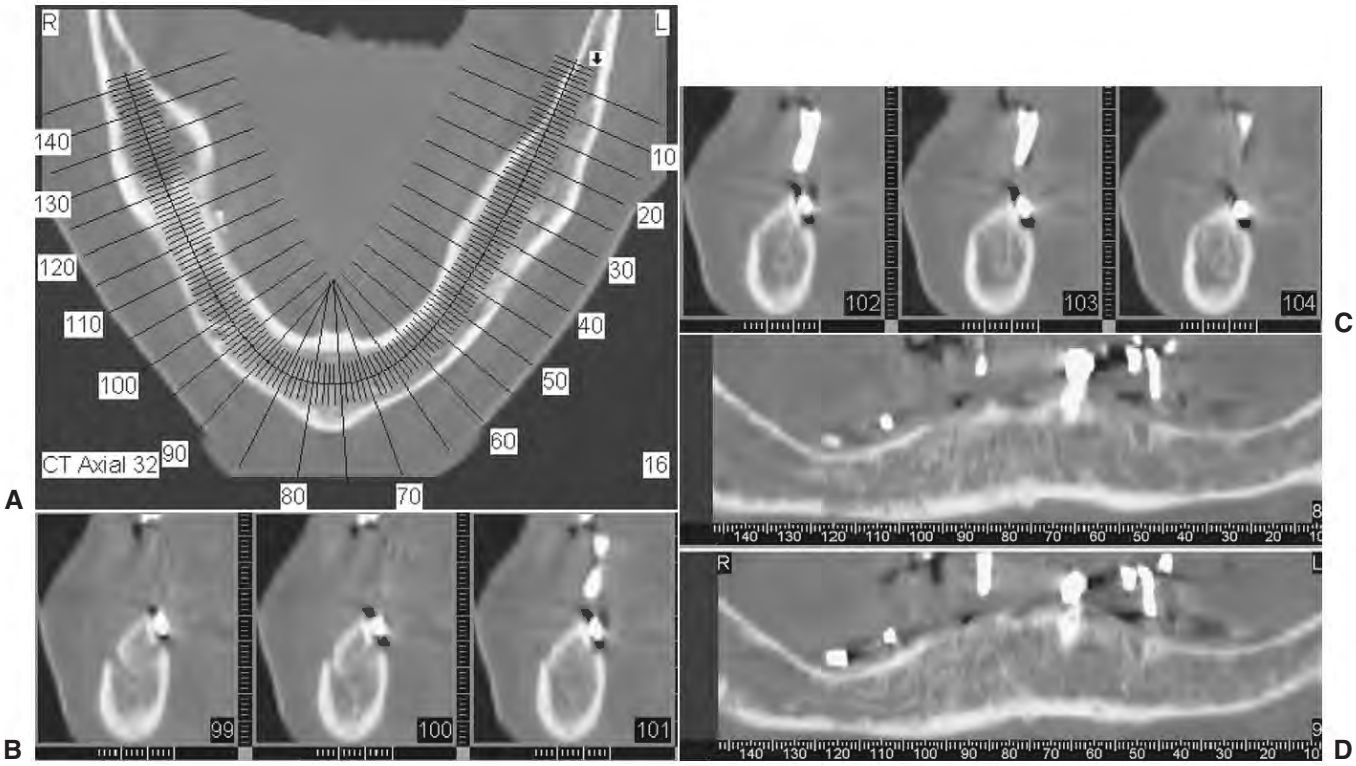

Figure 3-10 Programmed dental computed tomography. The radiologist identifies curvature of the mandible, which programs the computed tomography workstation to create reformatted cross-sectional and curved plane images. **A,** Axial view of mandibular alveolus with curvature of the mandible defined and location of the derived cross-sectional and curved plane images identified. **B, C,** Images 99 to 104 are cross-sectional images that are referenced to the axial and curved plane images. **D,** Images 8 and 9 are curved plane images that are referenced to the axial and cross-sectional images. Gutta-percha radiopaque cylinders identify prospective implant positions.

produce hard-copy images to send to the referring doctor. The advantages of this type of imaging were evident and the limitations of delivery clear, which spawned the development of a number of techniques referred to generically as *DentaScan imaging*.

DentaScan imaging provides programmed reformation, organization, and display of the imaging study[63-65] (see Figure 3-10). The radiologist or technologist simply indicates the curvature of the mandibular or maxillary arch, and the computer is programmed to generate referenced cross-sectional and tangential/panoramic images of the alveolus along with three-dimensional images of the arch. The cross-sectional and panoramic images are spaced 1 mm apart and enable accurate presurgical treatment planning.

Limitations of DentaScan imaging include images that may not be true to size and require compensation for magnification; determination of bone quality that requires use of the imaging computer or workstation; hard-copy DentaScan images that only include a limited range of the diagnostic grayscale of the study; and the tilt of the patient's head during the examination, which is critical because all the cross-sectional images are perpendicular to the axial imaging plane. This technique provides a wealth of diagnostic information that is accurate, detailed, and specific. Usually a diagnostic template is necessary to take full advantage of the technique. The diagnostic template enables the dentist to incorporate the three-dimensional treatment plan of the final prosthetic result into the imaging examination; evaluate the patient's anatomy relative to the proposed implant sites, esthetics, and occlusion; and record and transfer these findings to the patient at the time of surgery. CT enables identification of disease, determination of bone quantity, determination of bone quality, identification of critical structures at the proposed regions, and determination of the position and orientation of the dental implants. Thus CT is capable of determining all five of the radiologic objectives of presurgical implant imaging (Box 3-10; see Box 3-2).

Types of CT Scanners

Medical

In medical radiology departments, the CT scan is the most common diagnostic imaging modality to evaluate hard and soft tissues. Technology in medical CT imaging has advanced significantly since its introduction, and usage is increasing at a rate of 15% to 20% annually.[55] Advances in speed and image quality were apparent in the early 1990s with the advent of spiral/helical

CT scanners. However, since its introduction in 1998, multislice (multirow detector CT) has revolutionized the field of medical CT tomography. These CT scanning units are tomographic machines that are classified as 4-, 8-, 12-, 16-, 32-, and 64-slice machines. The number of slices corresponds to the number of times the x-ray beam rotates around the patient's head to acquire the CT data. The CT numbers, or Hounsfield units, are then reconstructed mathematically and formatted into images. However, because these images consist of a series of incremental images grouped together, CT spiral slices produce "average" reconstructed images based on multiple x-rays transversing the scanning area. With this reconstruction of images, a small gap between each slice is present, which contributes to an inherent error within medical scanners.

In the 1980s, cross-sectional reconstruction of the CT images dramatically improved the diagnosis and treatment planning in oral implantology. These reformatted images allowed three-dimensional evaluation of vital structures and related oral anatomy.[62-65] However, even though these advances enhanced diagnostic skills, there were inherent shortcomings to medical scanners used for dental purposes. Because medical scanners were not developed for dental reformatting, there existed inherent errors such as distortion, magnification, and positioning problems that led to inaccuracies when reformatted.[66] In addition, there existed no prosthetic information that could be gathered to predict the final prosthetic outcome. This was overcome with the advent of sophisticated scanning appliances, stereolithographic resin bone models,[67] interactive software, computer-generated surgical guides, and CT-based image-guided navigation systems, which allowed for ideal placement and prosthetic outcome to be established.

Although the clinical problems of medical scanners have been remedied, there still existed numerous disadvantages: radiation exposure and availability. The amount of radiation exposure of medical scans has been a controversial topic for many years and has been shown to be excessive and unnecessary. It has been postulated that radiation exposure for a scan involving the maxilla and mandible is equivalent to approximately 20 panoramic radiographs.[68] The availability, although dramatically improved over the years, is still a concern for practices in rural areas.

Cone Beam Volumetric Tomography

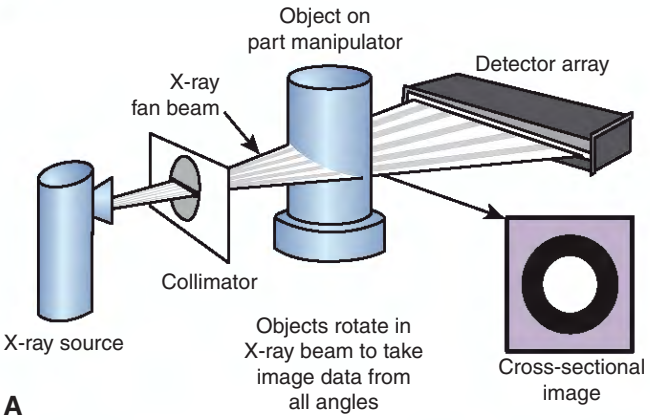
To overcome some of the disadvantages of conventional medical CT scanners, a new type of CT specific for dental applications has recently been developed.[69,70] This type of advanced tomography is termed *cone beam volumetric tomography* (CBVT). Because conventional CT is associated with such a high dose of radiation, this medical imaging technique has always been under significant criticism when used for implant treatment planning. However, with the advent of cone beam technology, the limitations of medical computerized tomography have been overcome.[71] Recently, with the U.S. Food and Drug Administration approval of cone beam technology, there are choices to provide more accurate diagnostic images along with a fraction of the radiation exposure, and adherence to the ALARA principle has been accomplished (Figure 3-11).[72] Scanners are made for "in-office" installation and use, which allows the doctor and patient the convenience of onsite scanning capabilities.

The first CBVT scanner approved for use in dentistry was the NewTom QR-DVT 9000 and most recently has been replaced by the NewTom 3G (Figure 3-12). Other brand names have also become readily available. The x-ray tube on these scanners rotates 360 degrees and will capture images of the maxilla and mandible in 36 seconds, in which only 5.6 seconds is needed for exposure. The positioning of patients is similar to medical scans in which the patient lies on a gurney with the head positioned in an open gantry. A scout film allows for proper positioning and calibrates for radiation dosage. The images recorded are placed onto a charge-coupled device chip with a matrix of 752×582 pixels[73] and are then converted into axial, sagittal, and coronal slices, and permit reformatting to view traditional radiographic images as well as three-dimensional soft tissue or osseous images (Figure 3-13).

Medical versus Cone Beam Technology Radiation Dosages. The average absorbed radiation dose from a CBVT scanner (NewTom 3G) is approximately 12.0 mSv (micro sieverts). This dose is equivalent to five D-speed dental x-rays or 25% of the radiation from a typical panoramic radiograph.[3] Additionally, medical scanners

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت



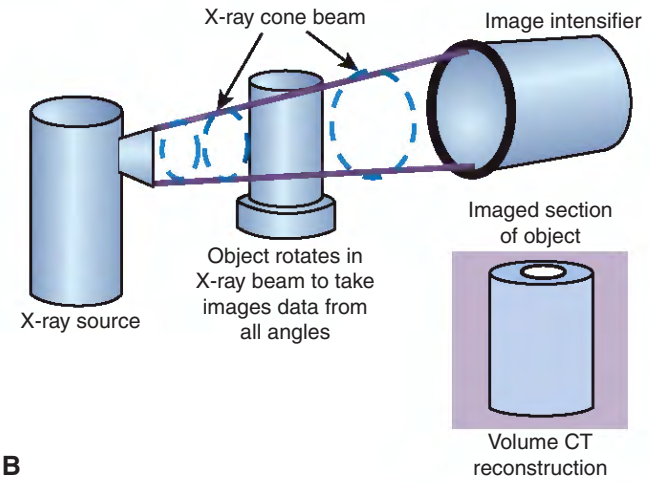


Figure 3-11 **A,** Conventional computed tomography (CT) scan uses a very narrow "fan beam" that rotates around the patient, acquiring one thin slice (image) with each revolution. Because of the numerous revolutions needed, radiation dose is increased. **B,** Cone beam volumetric tomography captures all data in one rotation, thus reducing radiation and avoiding distortion and errors in reformatting.

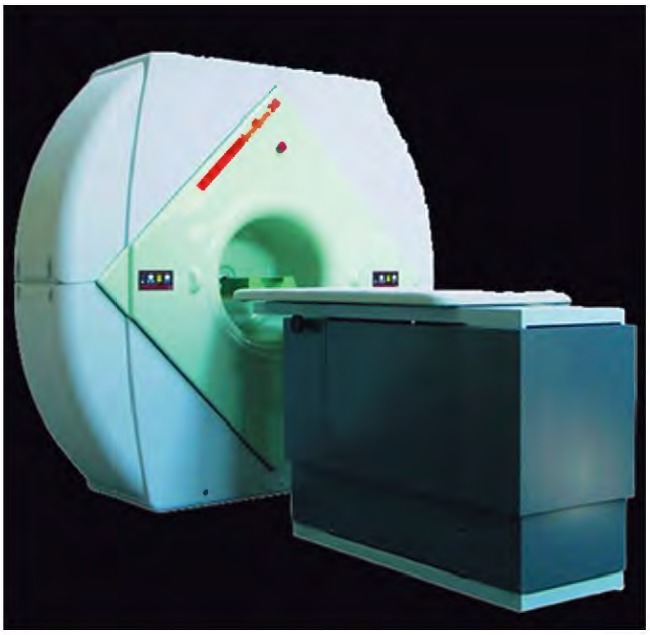

Figure 3-12 The NewTom 3G in-office cone beam computed tomography scanner. The scan is completed in just 36 seconds, with only 5.4 seconds of actual radiation exposure.

Table 3-3 Comparison of Medical Spiral Scanners and Cone Beam

	MEDICAL	CONE BEAM
Scanning time	Approximately 10 min	Approximately 36 sec
Radiation exposure	More	Less
Scan	Multiple slices	One rotation
Exposed field	One arch at a time	Both arches simultaneously
Scatter	More	Less
Positioning	Very technique sensitive	Not as critical

acquire images that use radiation doses of 40 to 60 times that of CBVT doses (Table 3-3).[3]

Image Acquisition of Medical versus Cone Beam Scanners. Medical CT scans produce images of transaxial planes by use of solid-state detectors and an x-ray source that rotates around the patient. When compared with a conventional dental x-ray that is a two-dimensional image of many planes superimposed on each other, the CT image has greater contrast with a reduction in spatial resolution.[74] These CT images are reconstructed mathematically from these incremental images that produce averaged reconstructed images. However, between each parallel slice exists a small "gap" that contributes to a built-in error within medical scanners. These gaps are adjusted within the software's algorithms that can result in errors of 1.0 to 1.5 mm.

Using CBVT avoids the errors in medical scanners by accumulating data from one 360-degree rotation around the patient's head. The algorithms on CBVT scanners are very predictable because they are void of any "gaps," thus eliminating distortion and magnification. Margins of error for CBVT are less than 0.1 mm. Numerous studies have shown cone beam technology to be more accurate than conventional medical CT.[75]

The advantages of CT images are numerous, with the magnification being almost 0% with no superimposition or overlapping of images and minimal distortion. The density of bone may also be assessed with all images being displayed as Hounsfield units. When comparing CT with other types of radiographic modalities, CT has been shown to be superior in identification of vital structures and calculation of distance measurements[76] (see Box 3-10).

INTERACTIVE COMPUTED TOMOGRAPHY

One of the most significant advances in CT is interactive ICT, which addresses many of the limitations of CT.[51,52,78,79] ICT is a technique that was developed to bridge the gap in information transfer between the radiologist and the practitioner. This technique enables the radiologist to transfer the imaging study to the practitioner as a computer file and enables the practitioner to view and interact with the imaging study on a personal computer. The dentist's computer becomes a diagnostic radiologic workstation with tools to measure the length and the width of the alveolus, measure bone quality, and change the window and level of the grayscale of the study to enhance the perception of critical structures. Axial, cross-sectional, and panoramic images and three-dimensional images are displayed and referenced so that the dentist can appreciate the same position or region within the patient's anatomy in each of the images. Regions of the patient's anatomy can be selected for display normally, with magnification, or with a number of grayscale depictions facilitating the appreciation of anatomy, structures, or disease.

An important feature of ICT is that the dentist and radiologist can perform electronic surgery (ES) by selecting and placing arbitrary-sized cylinders that simulate root form implants in the images. With an appropriately designed diagnostic template, ES can be performed to develop the patient's treatment plan electronically in three dimensions. Electronic implants can be placed at arbitrary positions and orientations with respect to each other, the alveolus, critical structures, and the prospective occlusion and esthetics. Electronic surgery and ICT enable the development of a three-dimensional treatment plan that is integrated with the patient's anatomy and can be visualized before surgery by members of the implant team and the patient for approval or modification. ICT enables the determination of bone quality adjacent to the prospective implant sites (Figures 3-14 to 3-16). With the number and size of implants accurately determined, along with the density of bone at the proposed implant sites, the dentist can

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

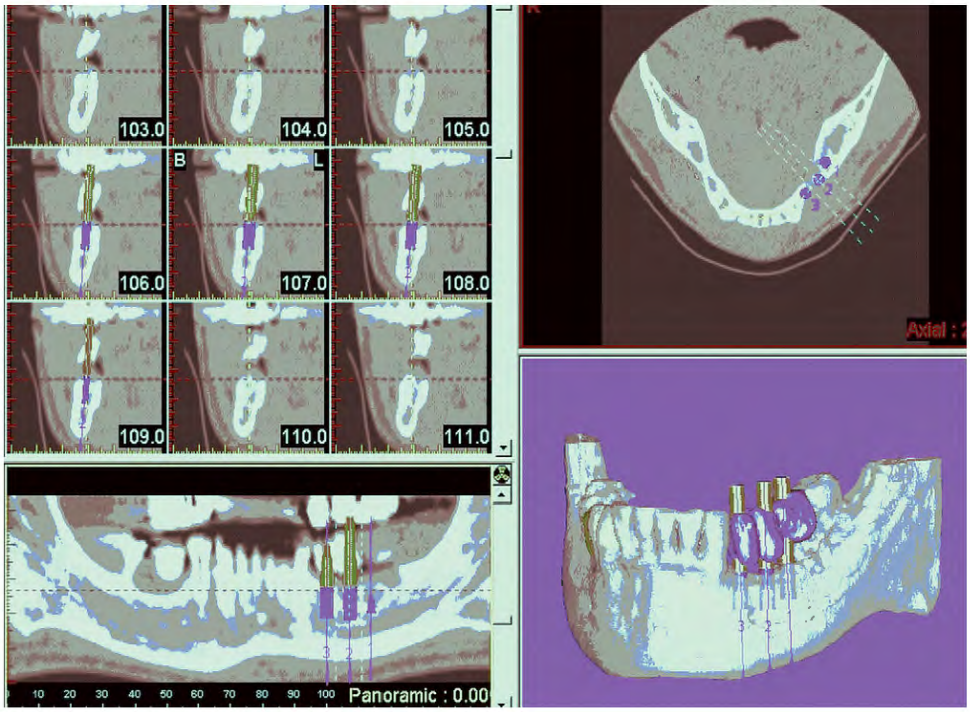

Figure 3-14 Reformatted computed tomography scan showing the interactive placement of implants in relation to the diagnostic wax-up fabricated radiopaque template. Note that each position is cross-referenced according to the tick marks.

determine the characteristics of the implants accurately before surgery.

The first step in the ICT process is the impressions for study casts. With the use of these casts, a diagnostic wax-up is completed according to the ideal position of missing teeth in question with emphasis on the final prosthesis. From the diagnostic wax-up, a radiopaque template is fabricated that the patient will wear during the scan. This diagnostic template will allow the transfer of the ideal positioning of the teeth that will be transferred into the radiographic examination.[79,80]

For conventional and CT, the positioning of the teeth is integrated into a scanning template by way of a radiopaque material. This can be accomplished by way of an acrylic template coated with barium sulfate, gutta percha markers, or radiopaque denture teeth.[81,82] These radiopaque templates may then be modified into use for surgical templates.

ICT is the most accurate imaging technique for implant imaging and surgery, but it some limitations. ES enables placement of electronic implants in the imaging study, but the refinement and exact relative orientation of the implant positions are difficult and cumbersome. For instance, three consecutive implants may require parallelism and interproximal spacing of 2.7 mm. The dentist may struggle in achieving the exact relative spacing and orientation with ES and ICT. Parallelism is difficult to appreciate in ICT using orthogonal rather than three-dimensional images. In this case, implant orientation must be deferred to the orientation developed in the diagnostic template rather than that from the images. After the treatment plan has been developed using ICT and ES and has been approved by the implant team and the patient, executing the plan may be difficult. The precision and accuracy of the treatment plan achieved using ICT and ES for the implant position, size, orientation, relative spacing, spatial relationship to the critical structures and proposed esthetics, and occlusion become a major challenge at the time of surgery. The treatment plan may require implant positions to an accuracy of a few tenths of a millimeter and orientation to a couple of degrees. Transfer of the plan to the patient at the time of surgery can be accomplished by simple visualization and comprehension by a skilled and experienced surgeon, using positions and orientations obtained from ICT and ES to convert the diagnostic template into a surgical template, or the production of a computer-generated, three-dimensional stereotactic surgical template from the digital ICT and ES data.

Surgical Guides

SurgiGuides (Materialise NV, Glen Burnie, Md.) are computer-generated drilling guides that are fabricated through the process of stereolithography. The SurgiGuide concept is based on the presurgical treatment planning using SimPlant software for ideal implant positioning. These successive diameter surgical osteotomy drill guides may be either bone-, teeth-, or mucosa-borne. SurgiGuides

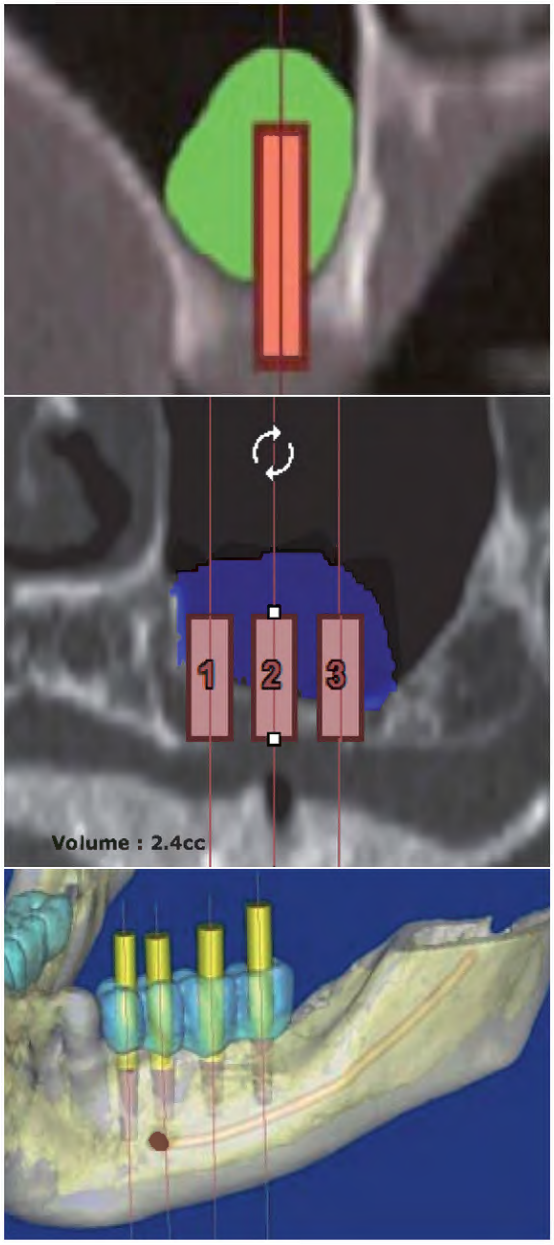

Figure 3-15 **A, B,** In areas where there is insufficient available bone such as the maxillary sinus, the amount of bone grafting needed may be determined. **C,** Implant placement in relation to the mandibular canal and mental foramen; all images are cross-referenced with each other. Three-dimensional analysis for the evaluation of proximity to vital structures may be generated from the same computed tomography images.

have metal cylindrical tubes that correspond to the number of desired osteotomy preparations and specific drill diameters. The diameter of the drilling tube is usually 0.2 mm larger than the corresponding drill, thus making angle deviation highly unlikely.

Clinical data and studies have shown that these computer-aided stereolithographic surgical guides have shown that implant placement is improved and that these guides allow precise translation of a predetermined treatment plan directly to the surgical field (see Chapter 13).[83,84]

CT-Based Surgical Guidance Templates and Navigation Systems

Advanced technology has introduced guidance systems to facilitate dental implant placement procedures during surgery (see Chapter 13). These systems allow the transfer of the presurgical plan to the patient, thus indicating when there is deviation from the predetermined drilling parameters. Therefore the depth and trajectory of the drilling sequence is made to the exact location of the preplanned position.

Numerous clinical studies and case reports have substantiated the use of the CT-based dental imaging with surgical guidance templates. The authors of these studies have shown enhanced accuracy and precision of the surgical procedure that facilitates surgery in anatomical locations.[85,86]

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is a CT imaging technique that produces images of thin slices of tissue with excellent spatial resolution. This imaging modality developed by Lauterbur in 1972[87] uses a combination of magnetic fields that generate images of tissues in the body without the use of ionizing radiation.[88] MRI allows complete flexibility in the positioning and angulation of image sections and can reproduce multiple slices simultaneously. Digital MRI images are characterized by voxels with an in-plane resolution measured in pixels (512×512) and millimeters and a section thickness measured in millimeters (2 to 3 mm) for high-resolution imaging acquisitions. The image sequences used to obtain magnetic resonance images can be varied to obtain fat, water, or balanced imaging of the patient's anatomy. The images created by MRI are the result of signals generated by hydrogen protons in water or fat such that cortical bone will appear black (radiolucent) or as having no signal. Cancellous bone will generate a signal and will appear white because it contains fatty marrow. Metal restorations will not produce scattering and thus will appear as black images. Therefore MRI has been shown to be less prone to artifacts from dental restorations, prostheses, and dental implants than CT scans.[89] As with CT, MRI is a quantitatively accurate technique with exact tomographic sections and no distortion.[90]

Numerous authors have suggested the use of MRI for dental implant evaluation and treatment planning.[91,92] Additionally, vital structures are easily viewed, such as the inferior alveolar canal and the maxillary sinus. In cases where the inferior alveolar canal cannot be differentiated by conventional or computed tomography, MRI would be a viable alternative as the trabecular bone is easily differentiated with the inferior alveolar canal. In cases of nerve impairment or infection (osteo-

myelitis), MRI may be used because of added advantages including differentiation of soft tissue with respect to CT. Studies have shown that the geometric accuracy of the mandibular nerve with MRI is comparable to CT and is an accurate imaging method for dental implant treatment planning.[93]

MRI may be used in implant imaging as a secondary imaging technique when primary imaging techniques such as complex tomography, CT, or ICT fail (Box 3-11).[92,94] Complex tomography fails to differentiate the inferior alveolar canal in 60% of implant cases, and CT fails to differentiate the inferior alveolar canal in about 2% of implant cases. Failure to differentiate the inferior alveolar canal may be caused by osteoporotic trabecular bone and poorly corticated inferior alveolar canal. MRI visualizes the fat in trabecular bone and differentiates the inferior alveolar canal and neurovascular bundle from the adjacent trabecular bone. Double-scout MRI protocols[90] with volume and oriented cross-sectional imaging of the mandible produce orthogonal quantitative contiguous images of the proposed implant sites. Oriented MRI of the posterior mandible is dimensionally quantitative and enables spatial differentiation between critical structures and the proposed implant site. However, there exist numerous disadvantages for the use of MRI for implant dentistry. MRI is not useful in characterizing bone mineralization or as a high-yield technique for identifying bone or dental disease. No commercially

Box 3-11 Magnetic Resonance Imaging

Advantages

- No radiation
- Vital structures are easily seen (inferior alveolar canal, maxillary sinus)

Limitations

- Cost
- Technique sensitive
- No reformatting software
- Availability
- Nonsignal for cortical bone

Uses

- Evaluation of vital structures when computed tomography is not conclusive
- Evaluation of infection (osteomyelitis)

available reformatting programs are available to use as reference points. Additional disadvantages are listed (see Box 3-11).

RADIOGRAPHIC IMAGING OF VITAL STRUCTURES IN ORAL IMPLANTOLOGY

Mental Foramen and Mandibular Canal

When evaluating the posterior mandible for implants, the position of the mandibular canal and mental foramen must be identified to avoid trauma to the inferior alveolar nerve. In implant dentistry, two-dimensional radiographs such as periapical and panoramic images are still used routinely as the sole determinate of osseous measurements with respect to these vital structures. However, these imaging views have numerous disadvantages with the lack of buccolingual identification as the most significant. When evaluating distances around these anatomical structures with two-dimensional radiographs, positioning has a significant impact on the intraoral imaging of vital structures.[95] Because of the curvature of the mandible, great care must be given to the angulation of the x-ray beam for intraoral radiography. The x-ray beam must be perpendicular to the tangent of the area in question between the foramen and the most anterior tooth. If the image is taken from a mesio-oblique orientation, measurements will be foreshortened and if the orientation is from a distal-oblique, measurements will appear to be elongated (Figure 3-17).

When evaluating the correct position of the mental foramen using two-dimensional radiographs, care must be taken to evaluate the position of the actual foramen. Studies have shown that on some two-dimensional radiographs, there exists lack of identification because of too large of a radiographic density.[42] This study states that mental foramina are easily seen on light radiographs; however, as the density increases above 2.8, the foramina area becomes less apparent. Other studies show lack of identification because of a lack of cortical bone around the mandibular canal. When evaluating the mental foramen on periapical radiographs, studies have shown that on 50% of periapical radiographs, the mental foramen is not visible.[96] Many studies including dry skull evaluations conclude that the mental foramen is absent in approximately 12% of panoramic radiographs.[42]

In summary, the location of the mental foramen on periapical and panoramic radiographs are inaccurate. It has been shown that even though the mental foramen can be seen on Panorex more consistently than periapical radiographs, the radiograph position of this structure is dependent on the mandibular positioning in the panoramic unit. Additionally, the radiograph landmark depicted on these panoramic radiographs as the mental foramen is not the true foramen, however, represents a portion of the mental canal as it leaves the mandibular canal. In edentulous mandibles, the risk of error increases considerably where there is increased resorption of the alveolar crest.

Numerous studies have shown that the most accurate means of identification is with conventional and computerized tomography (Figure 3-18). The most accurate means of viewing the mandibular canal and mental foramen is with three-dimensional radiography. These images may be altered in contrast, brightness, and grayscale to help depict these structures. Therefore CT has been shown to be the most accurate and is highly recommended when exact location and measurements are needed for the inferior alveolar canal and mental foramen.[14,61,89]

When the inferior alveolar canal or mental foramen is not seen on a radiograph, usually superimposition

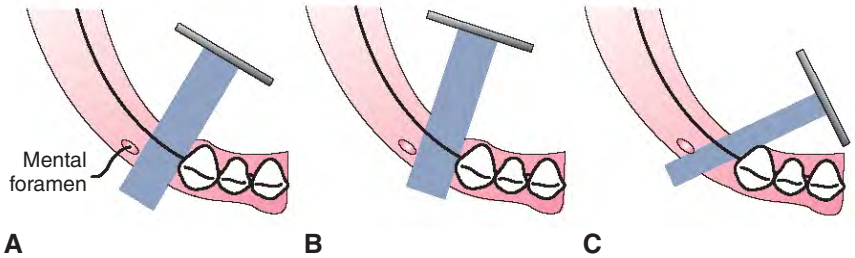

Figure 3-17 To have an accurate measurement between a tooth and a vital structure (mental foramen), a correct horizontal angulation of the x-ray beam is essential. **(A)** Correct, **(B)** improper positioning resulting in too large of a distance, and **(C)** improper positioning resulting in too small of a distance.

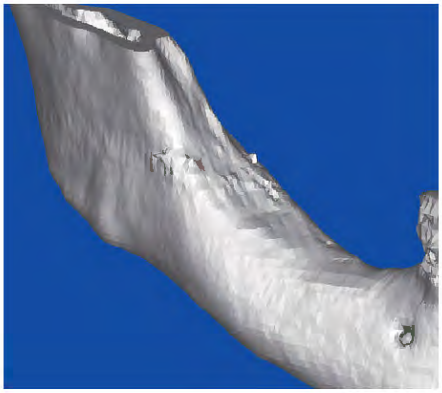

Figure 3-20 The more prominent the external oblique ridge, the better candidate for the ramus as a donor site. This can be best illustrated on a three-dimensional reformatted computed tomography image allowing 360-degree evaluation of the ramus area.

of structures on the contralateral side or lack of cortical bone around the canal is the cause.[97] Studies have shown that in cases where the canal or foramen cannot be seen, tilting the patient's head approximately 5 degrees downward in reference to the Frankfort horizontal plane allows these anatomical structures to be seen in 91% of radiographs.[98]

Mandibular Lingual Concavities

When relying on two-dimensional radiographs for evaluation of the amount of bone for implant placement, significant complications may occur because of overestimation of bone. When advanced atrophy in the posterior mandible is present, lingual concavities may be present (Figure 3-19). Even though there exists adequate bone on two-dimensional radiographs, this may be misleading. A study by Quirynen[99] showed a 2.4% prevalence of concavities with average depths of 6 mm (±2.6 mm). Within these concavities or submandibular gland fossa, branches of the facial artery may be present. Overestimation of the amount of bone may lead to perforation of the lingual plate when drilling the osteotomy. This may result in lingual bleeding problems that may even be life-threatening.[100-103] When assessment of the posterior mandible is needed, cross-sectional tomography is recommended.

Mandibular Ramus (Donor Site for Autogenous Grafting)

The mandibular ramus area has become a very popular donor site for autogenous onlay bone grafting. This area of the mandibular jaw is extremely variable in the amount of bone present. Standard radiographs for preassessment include panoramic images in which the location of the external oblique and the mandibular canal should be noted. However, two-dimensional evaluation of this area can be very difficult to use for adequate assessment of the amount of host bone present. A more accurate representation is the use of tomography, preferably computerized tomography. Accurate measurements may be made along with the use of three-dimensional bone models depicting the exact anatomy present (Figure 3-20).

Mandibular Symphysis

The mandibular symphysis area is a very critical anatomical area for oral implantology. Not only is this region a common position for implants in mandibular edentulous patients, it is also used as a donor site for autogenous grafting. When two-dimensional images are used, inherent errors may occur because of lingual concavities. It is not uncommon to overestimate the height of available bone in the anterior region on panoramic radiographs. For this reason, an imaging technique that will depict the true bucco-lingual amount of bone is recommended. Radiographs including lateral cephalometric and conventional CT, may be used (Figure 3-21).

Maxillary Sinus

Today, no radiographic modality gives more information of the paranasal sinuses than CT, which is the gold standard for viewing the osseous structures and evaluating pathology in the sinuses. This type of radiography provides much more detailed information regarding prevalence and position of septa,[104] maxillary sinus anatomy, and detection of sinus pathology in comparison with plain film imaging.

RECOMMENDED PRESURGICAL TREATMENT PLANNING

In the past, panoramic radiology was the gold standard for dental implant treatment planning. Along with periapical radiographs, these imaging techniques have many shortcomings that have previously been discussed. The most significant drawback to these radiographs is that they are two-dimensional. For more complex cases or when accurate representation and location of vital structures is needed, CT should be integrated into the pretreatment imaging process.

With CT technology and interactive software, treatment planning has become a very accurate modality for dental implant surgery. Because optimal placement of dental implants can be challenging, special interactive software along with computer-generated templates have been developed to assist the implant surgeon in accurate positioning. From this information and evaluation of all imaging modalities available in implant dentistry, pretreatment imaging evaluation is recommended, as illustrated in Box 3-12.

INTRAOPERATIVE IMAGING

The use of surgical imaging has dramatically changed the way that surgical implantology is completed (Boxes 3-13 and 3-14). In the past, the disadvantage of periapical radiography perioperatively has been time inefficiency. To verify positioning and location of an osteotomy site or for identification of a vital structure, processing of standard radiograph film can take up to 6 minutes. Because of this, practitioners rarely verified positioning

Note perpendicular orientation of x-ray beam as all threads are seen without distortion.

of anatomical structures during surgery. With new digital radiography technology, instantaneous images are achieved, allowing for multiple images to be completed in a fraction of the time. Additional advantages of digital intraoperative imaging include manipulation of images, calibration, accurate measurements and positioning, and maintenance of aseptic protocol (Figures 3-22 and 3-23).

Immediate Postsurgical Imaging

A plain film radiograph (periapical or panoramic) should be taken postsurgically so that a baseline image may be used to evaluate against future films (Figure 3-24). Additional imaging tools may be used to evaluate a zone of safety around vital structures.

Abutment and Prosthetic Component Imaging

When evaluating for transfer impressions along with two-piece abutment component placement, radiographs should be taken to verify secure adaptation. Intraoral radiographs should be used because of their high geometric resolution to evaluate for any fit discrepancy. However, care must be taken so that the x-ray beam is directed at a right angle to the longitudinal axis of the implant. Even a slight angulation may allow a slight gap to be unnoticed. When positioning is difficult for periapical radiographs, bitewing or panoramic radiographs may be used (Figures 3-25 and 3-26).

Postprosthetic Imaging

There exists no conclusive scientific evidence that low-level ionizing radiation has a detrimental effect on bone metabolism and healing. However, radiographs should not be indiscriminately taken. Only when there is a need for additional information or a problem is identified should additional imaging be used. When investigating complications after implant placement, a panoramic radiograph is the most ideal imaging technique for multiple implants. If single implants or if more detailed information concerning an implant viewed on a Panorex is needed, periapical radiographs are the image of choice. A postprosthetic radiograph needs to be taken to act as a baseline for future evaluation of component fit verification and also for marginal bone level evaluation. Care must be taken to ensure that adequate fit of all components is made. In addition, the marginal bone level must be determined for future evaluation.

Recall and Maintenance Imaging

For the evaluation of implant success, immobility and radiographic evidence of bone adjacent to the implant

body are the two most accurate diagnostic aids in evaluating success. Follow-up or recall radiographs should be taken after 1 year of functional loading and yearly for the first 3 years.[105] Multiple studies have shown that, in the first year, marginal bone loss and a higher rate of failure are seen.

Evaluation of Alveolar Bone Changes

Radiographically, lack or loss of integration is usually indicated as a radiolucent line around the implant. However, false-negative diagnoses may be made when the soft tissue surrounding an implant is not wide enough to overcome the resolution of the radiographic modality used. Also, false-positive diagnoses may be

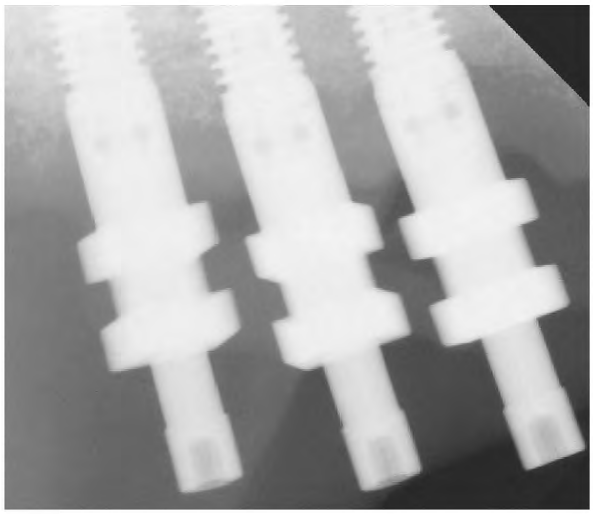

Figure 3-25 Verification of direct transfer coping placement before final impression. Note ideal angulation from thread alignment.

made when a "Mach band effect" results from an area of lower radiographic density adjacent to an area of high density (implant), which results in a more radiolucent area than is actually present.[106] However, studies have shown the possibility of the Mach band effect is significantly reduced with digital image processing. Additionally, digital radiography has been shown to have the advantage over conventional radiography with respect to "edge enhancement," which is the ability to detect space between the implant and the surrounding bone (Figure 3-27).[107] Because of the variability of operator-controlled problems, a strict quality assurance protocol should be used to maintain ideal image quality over time. Proper positioning along with documentation of kVp and mA settings should be documented for future reference.

Periapical Radiographs

In recall radiographic examinations, the marginal bone level is compared with the immediate postprosthetic films. Therefore radiographs similar in geometry, density, and contrast are paramount. To ensure accuracy, standardized periapical radiographs are essential.[108] However, reproducing positioning is very difficult. Numerous film-holding devices have been documented that attach to the implant, abutment, or prosthesis to standardize image geometry.[109-112] When proper projections are achieved, implant threads on both sides of the implant are clearly seen. If the threads are not clearly seen in the radiographs, modification of the beam angle needs to be made. If diffuse threads are present on the right side of the implant, then the beam angle was positioned too much in the superior direction. If the threads are diffuse on the left side, then the beam angle was from an inferior angulation (Figure 3-28). With digital enhanced radiographs, numerous techniques have been postulated to measure bone levels around implants.

t.me/highdent www.highdentlab.com instagram.com/high_dent

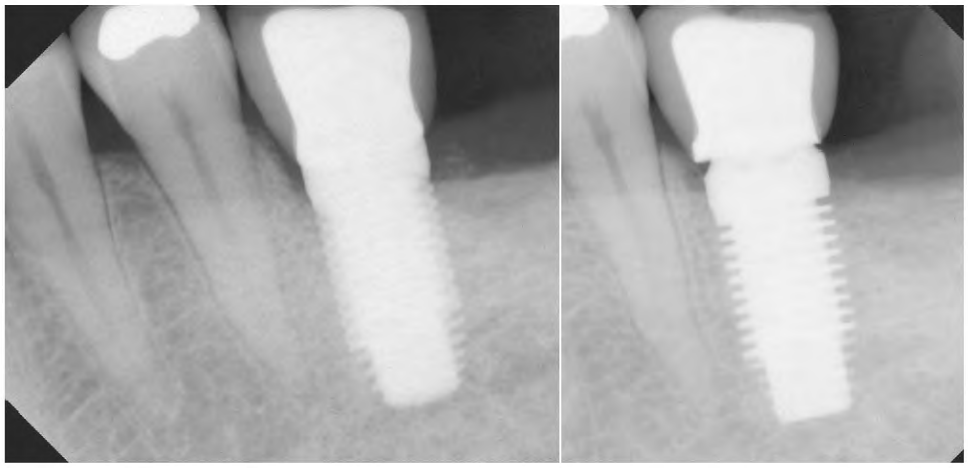

Figure 3-26 Seating of final prosthesis. **A,** Poor x-ray angulation showing a false-negative or complete seating of the prosthesis. Note the diffuse threads. **B,** A corrected angulation image exposes the seating problem.

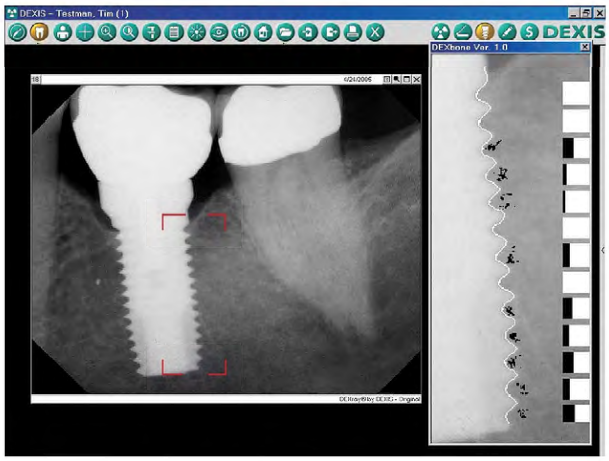

Figure 3-27 Specialized digital image modification programs (e.g., DexBone, Dexis) allow viewing of any subtle changes in bone density around the implant interface.

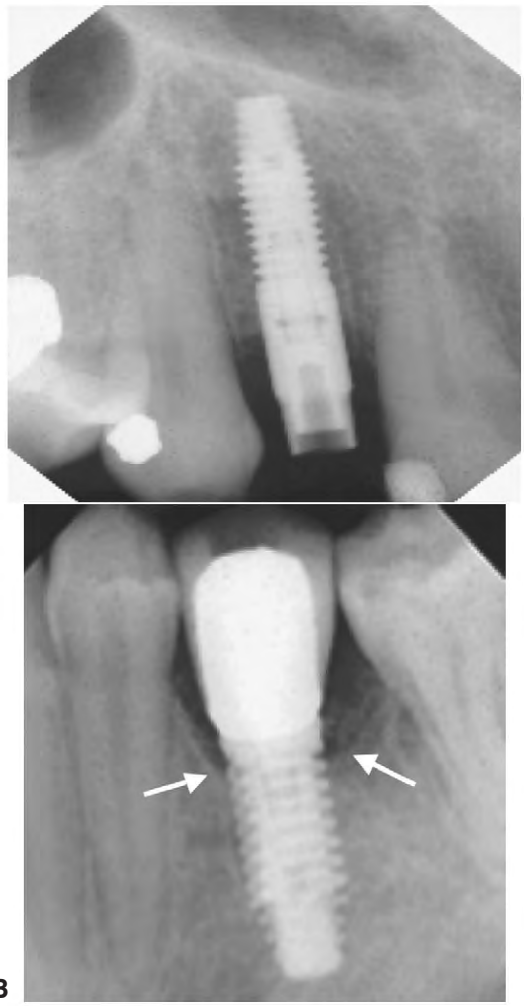

Figure 3-28 Alveolar bone level evaluation. **A,** Ideal positioning showing ideal thread orientation. **B,** Improper angulation showing diffuse thread orientation.

Computer-assisted measurements, rulers, calipers, and suprabony thread evaluation have been shown to have highly reproducible results.[113,114]

Bitewing Radiographs

In cases where the x-ray source cannot be positioned perpendicular to the implant because of oral anatomy or existing prosthesis, horizontal or vertical bitewings may be taken to evaluate the crestal bone area. With this projection, the central beam is perpendicular to the implant and alveolus and the object-film distance is relatively small, and very minor distortions are present. The only limitation of bitewing radiographs is that the apical portion cannot be seen.

Subtraction Radiography

Conventional radiographs are of limited value if minimal alveolar bone changes occur; therefore techniques have been developed to standardize the projection geometry of radiographs for evaluation. This technique, termed *digital subtraction radiography,* allows two radiographs taken at different times to be superimposed on one another, resulting in an image that exhibits the differences in the bone level.[115-117]

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Subtraction radiography requires the use of the same positioning and imaging technique between the two radiographs with respect to the x-ray source, patient and film position, exposure, and processing variables. After the images are subtracted, a subtraction image will be left that depicts the osseous changes between the radiographs.[118] This technique has been shown to be more accurate in accessing bone mineralization and volume changes in comparison to viewing original single radiographs. With the advent of in-office digital radiography systems, specialized software allows for digital radiography to be accomplished rather easily.

Panoramic Radiographs

Panoramic radiographs usually are not used routinely for evaluation of osseous bone levels and recall examinations. Because panoramic radiographs use intensifying screens, resolution is not as good as with intraoral radiographs. However, when film positioning or when multiple implants need to be evaluated, panoramic radiography is the imaging technique of choice.

Computed Tomography

Two-dimensional radiographs (periapical, panoramic) have limitations in that they give no buccolingual information about the present condition of alveolar bone. CT does allow three-dimensional information about the osseous status around an implant. Resolution and scattering has always been a problem in evaluation of implants; however, with the advent of cone beam technology, this is greatly improved.

CT can be of great benefit in the evaluation of sinus augmentation graft prognosis. With the advantage of bone density evaluation using Hounsfield units, important information on bone maturation may be determined. Also, this radiographic modality is the image of choice for evaluation of sinus infection or postsurgical sinusitis complications (Figure 3-29).

FABRICATION OF DIAGNOSTIC TEMPLATES

The purpose of diagnostic radiographic templates is to incorporate the patient's proposed treatment plan into the radiographic examination.[79-82] This practice requires the development of a tentative treatment plan before the imaging procedure. Ideally, mounted diagnostic casts, a diagnostic wax-up, agreement between the practitioners on the number and location of proposed dental implants, and prior authorization of the proposed treatment by the patient make the diagnostic template a useful tool and many times the determining factor in the final treatment plan of the patient. The preprosthetic imaging procedure enables evaluation of the proposed implant site at the ideal position and orientation identified by radiographic markers incorporated into the template.

Computed Tomography

The precision of CT enables use of a complex and precise diagnostic template. Although CT can identify the available bone height and width accurately for a dental implant at a proposed implant site, the exact position and orientation of the implant, which many times determine the actual length and diameter of the implant, often are dictated by the prosthesis. As such, a diagnostic template used during imaging is most beneficial. The surfaces of the proposed restorations and the exact position and orientation of each dental implant should be incorporated into the diagnostic CT template. Designs for diagnostic CT templates have evolved from a simple vacuform reproduction of the wax-up to one produced from a processed acrylic reproduction of the diagnostic wax-up and to more sophisticated types fabricated with specifically designed radiopaque denture teeth.[81,82] The processed acrylic template may be modified by coating the proposed restorations with a thin film of barium sulfate and filling a hole drilled through the occlusal surface of the restoration with gutta-percha. The surfaces of the proposed restoration then become radiopaque in the CT examination, and the position and orientation of the proposed implant may be identified by the radiopaque plug of gutta-percha within the proposed restoration.

The vacuform template has a number of variations. Another design involves coating the proposed restorations with a thin film of barium sulfate. Although the proposed restoration becomes evident in the CT examination, the ideal position and orientation of the proposed implant is not identified by this design. Another design involves filling the proposed restoration sites in the vacuform of the diagnostic wax-up with a blend of 10% barium sulfate and 90% cold-cure acrylic. This results in a radiopaque tooth appearance of the proposed restorations in the CT examination, which matches the density of enamel and dentin of natural teeth but does not identify the exact position and orientation of the proposed implant sites. The next design modifies the previous design by drilling a 2-mm hole through the occlusal surface of the proposed restoration at the ideal position and orientation of the proposed implant site with a twist drill. This procedure results in a natural toothlike appearance to the proposed restoration in the CT examination in which all the surfaces of the restoration are evident along with a 2-mm radiolucent channel through the restoration, which precisely identifies the position and orientation of the proposed implant.[81]

Recently, radiopaque teeth specifically designed for the fabrication of diagnostic templates for fixed and removable implant-supported restorations have been introduced. The radiopaque material (barium sulfate) is an integral component of the CT scan tooth (66% to 67%) (Figure 3-30) (Ivoclar, Orthotac, Schaan, Liechtenstein).

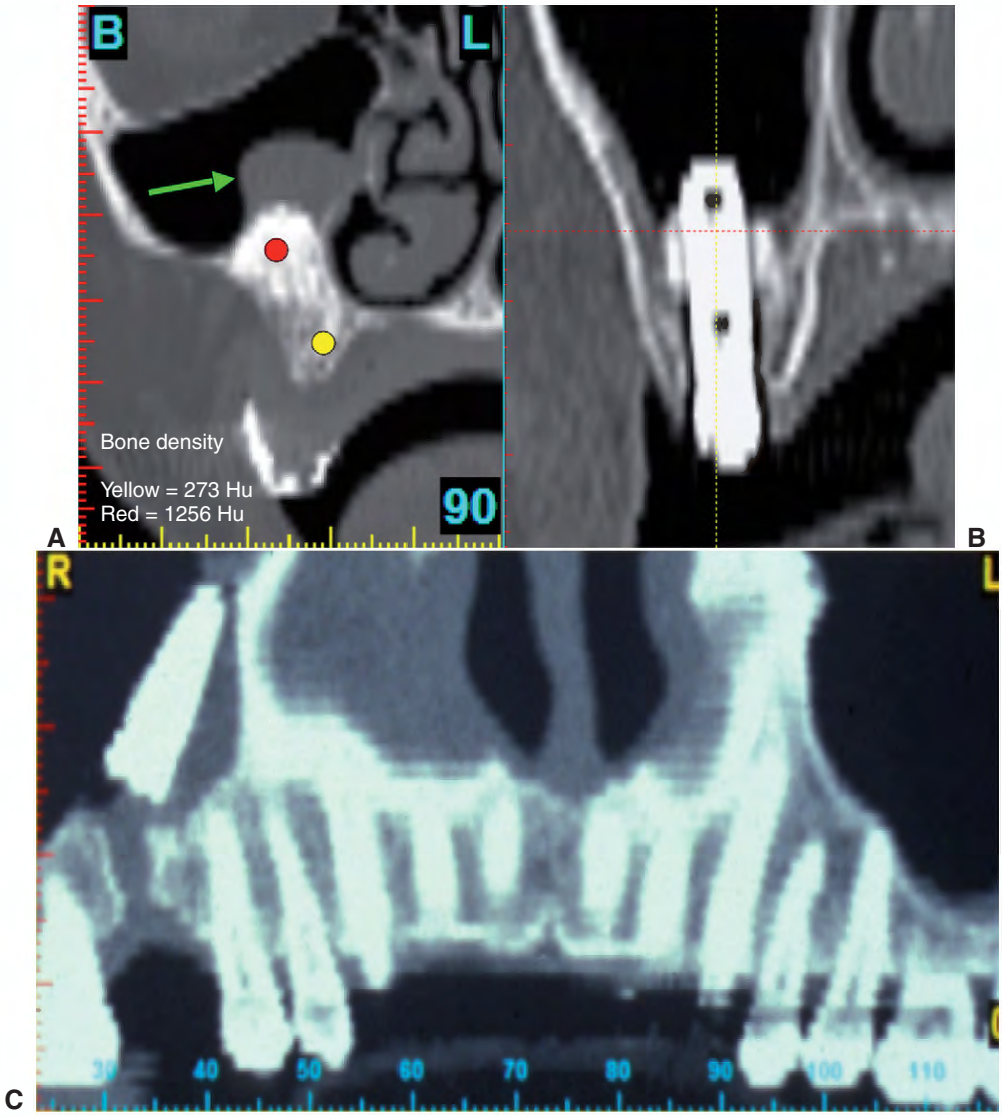

Figure 3-29 **A,** Post-sinus graft computed tomography (CT) scan showing differences in bone density of graft material (red = 1268 Hounsfield units, yellow = 273 Hounsfield units), and illustrating a post-sinus graft cyst blocking the ostium. **B,** CT image of failing implant with a lack of bone at implant interface. **C,** CT image of implant migration in the maxillary sinus.

The advantages of prefabricated teeth are that they are time saving, are placed easily, provide consistently high radiopacity, have molds corresponding to prosthetic teeth used in the final restoration, and are bonded easily with the template-based material. The diagnostic template then can be modified into a surgical template.[59]

Tomography

Diagnostic templates for tomography examinations are generally less precise than those required in CT examinations. The diagnostic information available from tomography examinations is not as detailed or as precise as that available from CT examinations. The simplest tomography template is produced by obtaining a vacuform of the patient's diagnostic cast with 3-mm ball bearings placed at the proposed implant positions. A number of tomograms of the implant region are produced with the implant site identified by the one in which the ball bearing is in sharp focus. The ball bearings additionally can serve as a measure of the magnification of the imaging system, although the magnification of most tomographic imaging systems is fixed and known. Templates that incorporate metal cylinders or tubes at the proposed implant sites also enable evaluation of tomograms for the orientation along with the position of the proposed implant. The diagnostic template used in CT examinations, which is produced from a vacuform of the patient's diagnostic cast with barium coating of the proposed restoration and orthodontic wires to indicate the position and orientation of the proposed implant, also can be used for tomography and provides the most diagnostic information of the templates described.

IMPLANT IMAGING IN PERSPECTIVE

The purpose of implant imaging is to assist the implant team in restoring the patient's occlusion and function by providing accurate and reliable diagnostic information on the patient's anatomy at the proposed implant sites. CT and ICT fulfill more of the objectives of preprosthetic imaging than periapical radiography, cephalometric radiography, panoramic radiography, and tomography. CT and ICT determine the absolute bone quantity, bone quality, and the relationship to critical structures at a level of precision considerably greater than that of tomography, periapical radiology, or panoramic radiology. For instance, bone quantity determination to an accuracy of ±1 mm occurs in about 95% of cases that use CT and only 30% of cases that use panoramic radiology. Furthermore, for mandibular cases, the inferior alveolar canal cannot be identified in more than 30% of cases that use periapical, panoramic, or tomographic techniques, whereas CT can identify the inferior alveolar canal in almost 100% of cases. With the use of ICT and ES, the implant team can determine bone quality directly at the prospective implant sites and develop an electronic three-dimensional treatment plan that can be converted into a stereotactic surgical guide to assist in executing the treatment plan at surgery. For surgical imaging, periapical or digital periapical radiography should be considered the modality of choice. Although digital periapical radiography offers many convenient alternatives to periapical film, neither modality appears to have a significant diagnostic advantage. However, temporal digital SR offers a considerable diagnostic advantage over periapical radiography for determining changes in bone volume or mineralization for post-prosthetic implant imaging. Unfortunately, SR is not conveniently available in general clinical practice, making periapical radiography the modality of choice for post-prosthetic imaging except in acute cases of implant failure, paresthesia, or infection, whereas CT has several advantages.

Chapter 4

Stress Treatment Theorem for Implant Dentistry

Carl E. Misch

Dentistry is a unique aspect of medicine, blending science and art form. Some aspects of the dental field emphasize the art form, as in dental esthetics, which deals with tooth color and shape to enhance a patient's smile and overall appearance. However, the primary reason the term *doctor* is applied to the dental profession is because of the dental sciences. These may be separated into a biological component and a biomechanical component. For general dentists, the biological aspects of oral health are emphasized. Common complications related to the natural dentition are primarily of biological origins, with periodontal diseases, caries, and endodontic problems as examples.[1-4]

A combination of biological and biomechanical factors is responsible for the failure of tooth-supported fixed prostheses. The four most common complications for three-unit fixed prostheses are (1) caries, (2) endodontic problems, (3) unretained prosthesis, and (4) porcelain fracture.[5,6] The biological complications occur with greater frequency (11% to 22%), compared with the biomechanical (7% to 10%), but both aspects should be understood by the clinician.

Implant dentistry always involves the replacement of teeth. When implant complications are reported, the vast majority of problems are related to the implant sciences, rather than esthetics.[7] But, unlike natural teeth, the biological aspects of implant dentistry have relatively few complications. For example, the development of a direct bone-implant interface is largely biological. Most recent reports indicate the surgical phase of implants form a successful interface more than 95% of the time, regardless of the implant system used.[7] Hence, the biological aspect of the field is very predictable.

The most common implant-related complications are biomechanical problems that occur after the implant is loaded. A literature review focusing on implant failure indicated these problems primarily occur within 18 months of initial implant loading. These early implant loading failures occur most often in the softest bone types (16% failure) or the shortest implant lengths (17% failure). These two failure groups are typically caused by biomechanical factors. Soft bone is too weak for the occlusal forces applied to the implants, or short implants have higher stresses at the bone-implant interface[8-20] (Figure 4-1).

The most common complications that do not lead to the failure of the implant are also biomechanical problems. Implant overdentures have problems of attachment fracture or complication (30%) and removable prosthesis fracture (12%). In implant-supported fixed prostheses, acrylic resin veneer fracture (22%), abutment or prosthetic screw loosening (7% to 10%), porcelain fracture (7%), and prosthesis metal fracture (3%) are examples of common complications.[7,15] In addition, implant components (2% to 4%) and even implant bodies may fracture (1% to 2%) (Box 4-1). In other words, mechanical complications far outnumber biological implant problems.[7,20]

Any complex engineering structure will fail at its "weakest link," and dental implant structures are no exception. A general concept in engineering is to determine the causes of complications and develop a system to reduce the conditions that cause the problems. The most common causes for implant-related complications

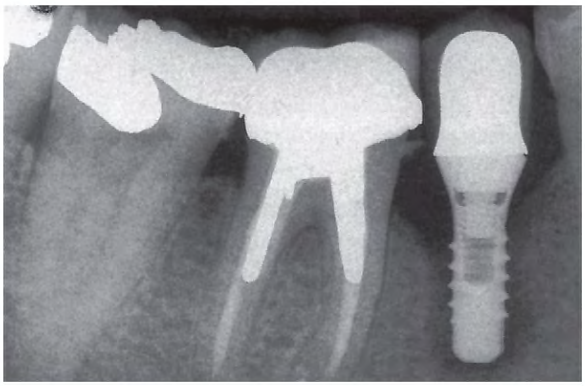

Figure 4-1 The majority of implant failures occur within 18 months after prosthetic loading and are related to short implants or implants placed in poor-quality bone.

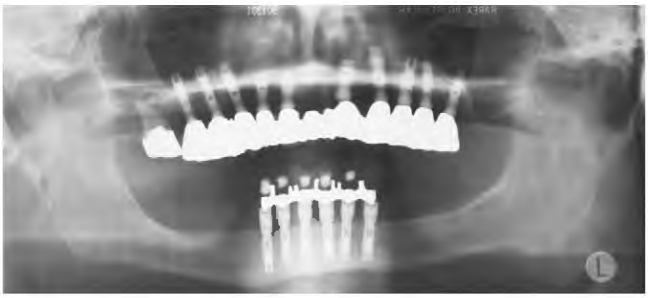

Figure 4-2 Excessive heat during osteotomy preparation can cause surgical failure of a healing implant.

Box 4-1 Stress Treatment Theorem: Biological versus Biomechanical

Biological	Biomechanical
Implant Failure	
Surgical failure	Early loading failure
Healing	Micromovement
Crestal Bone Loss	
Periosteal reflection	Cellular biomechanics
Osteotomy	Engineering
Autoimmune (bacteria)	Bone mechanics
Biological microgap	Animal studies
	Clinical reports
Prosthetic Complications: Mechanics	
Screw loosening	Attachment wear
Component fracture	Attachment fracture
Implant body fracture	Denture tooth fracture
Acrylic veneer/porcelain fracture	Acrylic base fracture
Framework fracture	Opposing prosthesis fracture

are centered around stress. Thus, the overall treatment plan should (1) assess the greatest force factors in the system and (2) establish mechanisms to protect the overall implant-bone-prosthetic system.

SURGICAL FAILURE

There are many reasons for the failure of an implant to integrate initially with the bone. The primary causes of failure relate to excessive heat during the preparation of the osteotomy or excessive pressure at the implant-bone interface at the time of implant insertion[21] (Figure 4-2). The excessive pressure at implant insertion is observed most often with tapered screw-type body designs. The insertion torque force on a tapered screw implant design may place excessive forces on the bone, which leads to resorption and implant failure.

An additional cause of surgical failure is micromovement of the implant while the developing interface is established (Figure 4-3). A fractured arm is immobilized to prevent movement at the fracture site to decrease

Figure 4-3 Micromovement of a developing bone-implant interface may cause fibrous tissue to form around an implant rather than a bone-implant interface. Excessive stresses to an implant may cause overload and failure. This implant had occlusal overload, which resulted in fibrous tissue formation around the implant *(From Isidor F: Loss of osseointegration caused by occlusal load of oral implants: a clinical and radiographic study in monkeys,* Clin Oral Implants Res *7:143-152, 1996.)*

the risk of a fibrous nonunion. Movement as little as 20 microns has been reported to cause a fibrous interface to form at the fracture site. Brunski observed a fibrous tissue interface development when a dental implant moved more than 100 microns during initial healing.[22] The original Brånemark protocol used a two-stage surgical approach.[23,24] One of the main reasons for this concept was to place the implant at or below the crestal bone region to decrease the risk of implant movement during initial bone healing. Schroeder also suggested an unloaded healing period on implants, although the implant was placed at or slightly above the gingival tissues.[25]

Occlusal forces applied to a removable prosthesis over a healing implant may also cause incision line opening of the soft tissue and delay soft tissue healing.[26] These occlusal forces may also affect the marginal bone around the developing implant site. Transferring these forces to an overlying soft tissue-borne prosthesis may cause micromovement of the implant-bone interface, whether the implant is healing below or above the gingival tissues. Stresses applied to a healing implant increase the risk of complications. On the other hand, multicenter clinical reports indicate an experienced surgeon may obtain rigid fixations after surgical placement 99% of the time.[27] The surgical component of implant failure is often the least risk associated with the overall implant treatment.

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

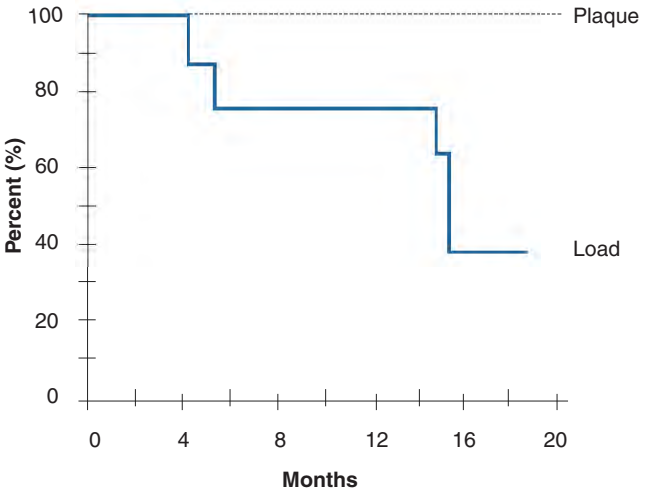

Figure 4-4 Premature occlusal contacts caused six of eight integrated implants to fail within 18 months. Strings in the sulcus and excessive plaque accumulation caused no failure during this period. *(From Isidor F: Loss of osseointegration caused by occlusal load of oral implants: a clinical and radiographic study in monkeys,* Clin Oral Implants Res *7:143-152, 1996.)*

Figure 4-5 The risk of screw loosening is greatest for single-implant crowns. To tighten the abutment screw, the implant crown may need to be cut off to gain access.

EARLY LOADING FAILURE

On occasion, an implant may fail shortly after it has initially "integrated" to the bone. Before failure, the implant appears to have rigid fixation, and all clinical indicators are within normal limits. However, once the implant is loaded, the implant becomes mobile within 6 to 18 months (see Figure 4-1). This has been called *early loading failure* by Misch and Jividen.[9] The cause of early loading failure is usually excessive stress for the bone-implant interface. Isidor allowed eight implants to integrate in monkey jaws.[28] Crowns were attached to the healed implants with excessive premature occlusal contacts. Over a 20-month period, six of eight implants failed (Figure 4-4). In these same animals, eight integrated implants with no occlusal loads had strings placed in the marginal gingiva to increase the amount of plaque retention. None of these implants failed over the following 20 months. The authors concluded that in this animal model, biomechanical occlusal stress was a greater risk factor for early implant failure than the biological component of bacterial plaque.[28,29]

Early loading failure is worse for the implant clinician than when a surgical failure occurs, because the patient may blame the restoring dentist. Although this is bad enough, in addition the restoring dentist spent two to five appointments restoring the implant and has a laboratory expense. Early loading failure is related to the amount of force applied to the prosthesis[8,22,30-33] and the density of the bone around the implants,[7,10-14,34] and it may affect 15% of implant restorations.[6-11] Early implant failure from biomechanical overload, as high as 40%, has been reported in the softest bone types.[13] No reports in the literature correlate such high incidence extreme with early implant failure rates related to the biological width-related complications observed in the field.

IMPACT OF OCCLUSAL OVERLOAD ON MECHANICAL COMPONENTS

Screw Loosening

Abutment screw loosening has been detected in an overall average of 6% of implant prostheses.[7] Single-tooth crowns exhibited the highest rate of 25% in early screw designs and concepts (and as high as 45%). Recent studies indicate this ratio has been reduced to an overall 8% average, with multiple-unit fixed prostheses at a 5% average and implant overdentures at 3% (Figure 4-5). The greater the stress applied to the prostheses (single tooth versus overdentures), the greater the risk of abutment screw loosening. Cantilevers also increase the risk of screw loosening, as they increase the forces in direct relationship to the length of the cantilever.[35] The greater the crown height attached to the abutment, the greater the force applied to the screw, and the greater the risk of screw loosening.

The height or depth of an antirotational component of the implant body also can affect the amount of the force applied to the abutment screw. The higher (or deeper) the hex height, the less stress applied to the screw and a corresponding lower risk for abutment screw loosening.[35,36] The platform dimension upon which the abutment is seated is even more important than the hex height dimension. Larger-diameter implants, with larger platform dimensions, reduce the forces applied to an abutment screw and change the arc of displacement of the abutment on the crest module. Screw loosening also may be decreased by a preload force with a torque wrench on the screw. Therefore, prosthetic methods to decrease stress to the abutment

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

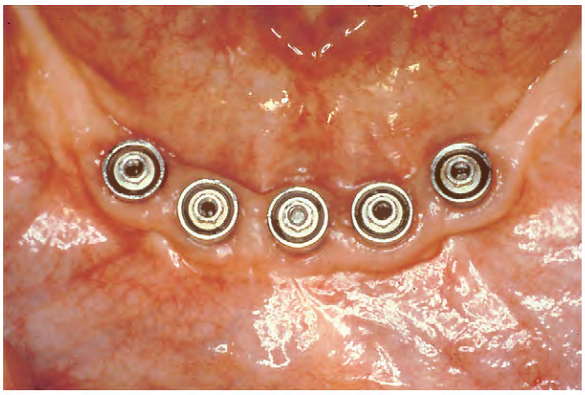

Figure 4-6 Prosthesis screw fracture has been observed for screw-retained fixed prostheses.

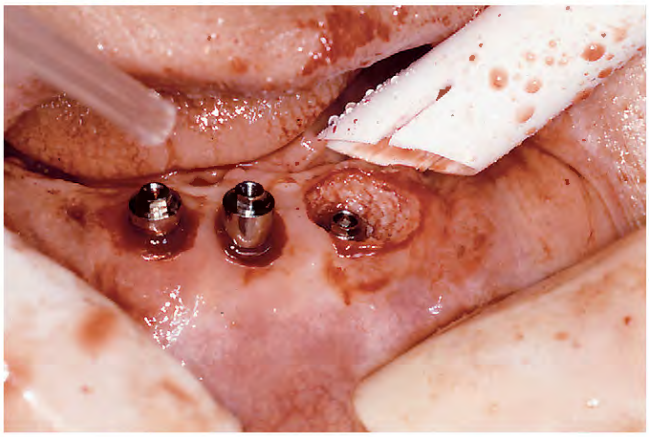

Figure 4-7 Abutment screw fracture occurs less often than prosthetic screw fracture, as they are larger in diameter.

screw or engineering approaches to decrease stress or increase thread tightening may be used to decrease the incidence of complications related to screw loosening.

Fatigue Fractures

Materials follow a fatigue curve, which is related to the number of cycles and the intensity of the force. There is a force so great that one cycle causes a fracture (e.g., karate blow to a piece of wood). However, if a lower force magnitude repeatedly hits an object, it will still fracture. The wire coat hanger that is bent does not break the first time, but repeated bends will fracture the material—not because the last bend was more forceful, but because of fatigue. Indeed, when the patient says he soaked his bread in coffee and then placed it in his mouth prior to the porcelain/abutment screw/cement seal/cantilevered prostheses fracture, it may have been "the straw that broke the camel's back."

Prosthesis screw fracture has been noted in both fixed partial and complete fixed prostheses, with a mean incidence of 4% and a range of 0% to 19%[7] (Figure 4-6). Abutment screws are usually larger in diameter and therefore fracture less often, with a mean incidence of 2% and a range of 0.2% to 8%

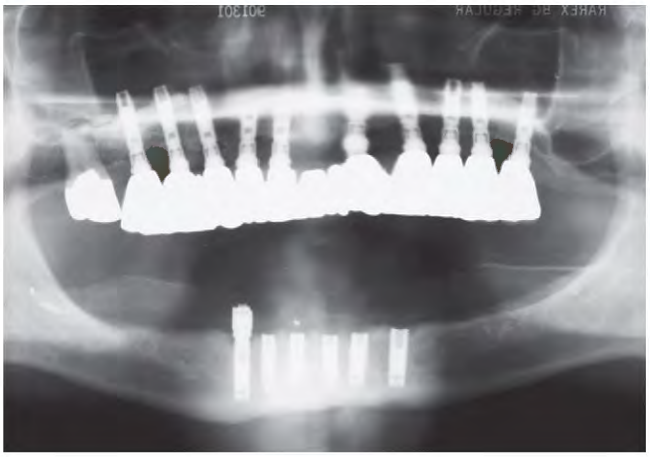

Figure 4-8 Metal framework fracture has been reported with an average of 3% with implant-fixed prostheses.

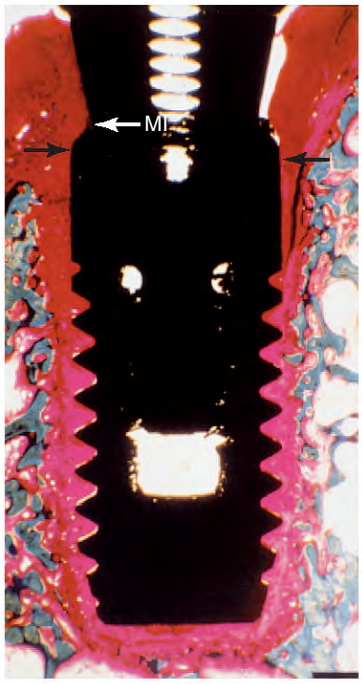

Figure 4-9 Implant body fracture may occur. It is most often related to parafunction and occurs with greater frequency for CP grade 1 titanium implants.

(Figure 4-7). Metal framework fractures also have been reported in an average of 3% of fixed complete and overdenture restorations, with a range of 0% to 27% (Figure 4-8). Implant body fracture has the least incidence of this type of complication, with an occurrence of 1% (Figure 4-9). This condition is reported with more frequency in long-term fixed prostheses and may even account for the majority of long-term failures. Resin veneer fractures of fixed implant prostheses averaged 22%, overdentures clip/attachment fractures averaged 17%, porcelain veneer fractures averaged 14%, overdenture fractures averaged 12%, and acrylic-base resin fractures averaged 7%. Prostheses-related fractures far outnumber implant component fractures.

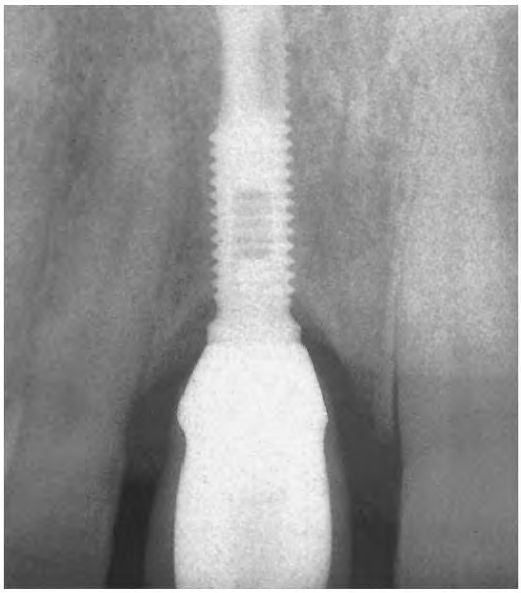

Figure 4-10 Marginal bone loss around the crestal portion of an implant often occurs during the first year of occlusal loading.

Uncemented restorations (or worse, partially uncemented prostheses) occur most likely when chronic loads are applied to the cement interface, or when shear forces are present (as found with cantilevers). Cement strengths are weakest in shear loads. Zinc phosphate cement may resist a compressive force of 12,000 psi but can only resist a shear force of 500 psi. It is interesting to note that bone is also strongest to compression and 65% weaker to shear forces. A similar scenario relative to shear load is found with porcelain or other occlusal materials. As a consequence, the evaluation, diagnosis, and modification of treatment plans related to stress conditions are of considerable importance. Therefore, once the implant dentist has identified the sources of additional force on the implant system, the treatment plan is altered in an attempt to minimize their negative impact on the longevity of the implant, bone, and final restoration.

MARGINAL BONE LOSS

Crestal bone loss has been observed around the permucosal portion of dental implants for decades. It has been described in the crestal region of successfully osteointegrated implants regardless of surgical approaches. It can range from loss of marginal bone to complete failure of the implant[17,23,37,38] and dramatically decreases after the first year (Box 4-2). For the one-piece blade implants, this phenomenon was described as a "saucerization" and occurred after implant loading.[37]

Occlusal Trauma: Bone Loss

Adell et al.[23] were the first to quantify and report marginal bone loss. The study also indicated greater magnitude and occurrence of bone loss during the first year of prosthesis loading, averaging 1.2 mm during this time frame, with a range of 0 to 3 mm. This report measured bone loss from the first thread as the 0-mm baseline, not from the original level of crestal bone at insertion, which was 1.8 mm above this baseline point. Thus the actual first-year crestal bone loss averaged 3.3 mm around the implants observed (Figure 4-10). Years subsequent to the first showed an average of 0.05 to 0.13 mm bone loss per year. Other studies report an average first-year bone loss of 0.93 mm, with a range from 0.4 to 1.6 mm and a mean loss of 0.1 mm after the first year.[31,32] The early crestal bone loss has been observed so frequently that proposed criteria for successful implants often do not even include the first-year bone loss amount.[39]

The initial transosteal bone loss around an implant forms a V- or a U-shaped pattern, which has been described as *ditching* or *saucerization* around the implant. The current hypotheses for the cause of crestal bone loss have ranged from reflection of the periosteum during surgery, preparation of the implant osteotomy, the position of the microgap between the abutment and implant body, micromovement of the abutment components, bacterial invasion, the establishment of a biological width, and factors of stress.[23,17,38-42]

An understanding of the causes of marginal crestal bone loss around dental implants and early implant failure is critical in preventing such occurrences, fostering long-term periimplant health, and improving long-term implant success rates and, foremost, implant prosthesis success. Marginal crestal bone loss may influence esthetics, as the height of the soft tissue (e.g., interdental papilla) is directly related to the marginal bone. If the tissue shrinks as a consequence of the bone loss, the emergence profile of the crown elongates and the papilla may disappear next to the adjacent tooth or

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

implant. If the soft tissue does not shrink, the increase in pocket depth may be related to the presence of anaerobic bacteria and peri-implantitis.

Over the years, the cause of marginal bone loss has kept the implant community busy with academic debates and clinical studies. However, clinical consequences are such that all phases of implant dentistry, from diagnosis and treatment planning to the final stages of occlusion and prosthesis delivery, must focus on its reduction or elimination.

Periosteal Reflection Hypothesis

Periosteal reflection causes a transitional change in the blood supply to the crestal cortical bone. Ninety percent of the arterial blood supply and 100% of the venous return are associated with the periosteum in the long bones of the body.[43] When the periosteum is reflected off the crestal bone, the cortical bone blood supply is affected dramatically, causing osteoblast death on the surface from trauma and lack of nutrition. These events have fostered the periosteal reflection theory as a cause for early bone loss around an endosteal implant.

Although crestal bone cells may die from the initial trauma of periosteal reflection, the blood supply is reestablished once the periosteum regenerates. Cutting cones develop from monocytes in the blood and precede new blood vessels into the crestal regions of bone. Osteoblasts then are able to remodel the crestal bone anatomy.[44] Composite bone forms rapidly on periosteal surfaces to restore its original condition. In addition, the underlying trabecular bone is also a vascular source because its blood supply often is maintained in spite of crestal periosteal reflection. The greater the amount of trabecular bone under the crestal cortical bone, the less crestal bone loss is observed.[45] To place the implant in sufficient available bone, an implant ridge is usually 5 mm or wider at the crest. As a result, trabecular bone is readily available to assist in cortical blood supply and remodeling around the implants. The cortical bone is remodeled to its original contour, without significant loss of height.

The periosteal reflection theory would lead to a generalized horizontal bone loss of the entire residual ridge reflected, not the localized ditching pattern around the implant that typically is observed. In addition, generalized bone loss already would be directly noticeable at the second-stage uncovery of the implant body, 4 to 8 months after Stage I implant placement surgery. Yet generalized bone loss rarely is observed at the second-stage uncovery surgery (Figure 4-11). Therefore, the periosteal reflection hypothesis does not appear as a primary causal agent of marginal crestal bone loss around an implant.

Implant Osteotomy Hypothesis

Preparation of the implant osteotomy has been reported as a causal agent of early implant bone loss. Bone is a labile organ and is sensitive to heat. The implant osteotomy causes trauma to the bone in immediate contact with the implant, and a devitalized bone zone of about 1 mm is created around the implant. A renewed blood supply and cutting cones are necessary to remodel the bone at the interface. The crestal region is more susceptible to bone loss during initial repair because of its limited blood supply and the greater heat generated in this denser bone, especially with the less efficient cutting of countersink drills used in this region.[45-47] This condition supports implant osteotomy preparation as a causal agent for marginal crestal bone loss around the implant.

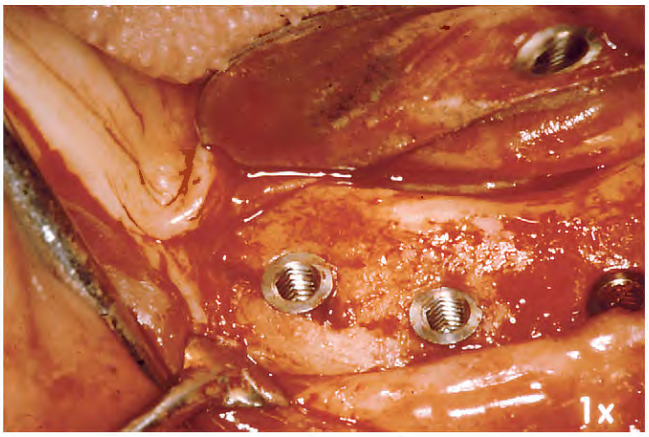

Figure 4-11 At Stage II uncovery, the marginal bone level most often is similar to the initial day of surgery and may even have grown over the top of the implant. Because the periosteum is reflected and bone is prepared to insert the implants, the cause of frequently occurring early crestal bone loss may not be related to the reflection of the periosteum or the osteotomy preparation.

However, if heat and trauma during implant osteotomy preparation were responsible for marginal crestal bone loss, the effect would be noticeable at the second-stage uncovery surgery 4 to 8 months later. The average bone loss of 1.5 mm from the first thread is not observed at Stage II uncovery. In fact, bone often has grown over the first-stage cover screw, especially when level or slightly countersunk below the bone (see Figure 4-11). Reports in the literature indicate different surgical trauma causes and numbers for bone loss. For example, Manz[48] observed that bone loss at second-stage surgery ranged from 0.89 to 0.96 mm regardless of the bone density. Hoar et al.[49] reported only 0.2-mm bone loss at Stage II uncovery. The surgical system or approach may influence these data, but usually this bone loss remains minimal.

One should remember that these are averages of bone loss reported. Therefore if 2 mm of bone loss is found on one implant, and the next nine implants exhibit no bone loss, the average bone loss would be 0.2 mm. Most implants at Stage II uncovery do not demonstrate any bone loss. Therefore the implant osteotomy hypothesis for marginal crestal bone loss cannot be primarily responsible for this routinely observed phenomenon.

Autoimmune Response of Host Hypothesis

The primary cause of bone loss around natural teeth is bacteria induced. Repeat studies demonstrate that bacteria are the causative element for vertical defects around teeth. Occlusal trauma may accelerate the process, but trauma alone is not deemed a determining factor.[50] The implant gingival sulcus in the partially edentulous implant patient exhibits a bacterial flora similar to that of natural teeth.[1] A logical assumption is that if implants are similar to teeth, the marginal implant bone loss is caused primarily by bacteria, with occlusal factors playing a contributing or accelerating role.

In a prospective study of 125 implants, Adell et al.[38] reported 80% of implant sulcular regions were without inflammation. Lekholm et al.[51] found that deep gingival pockets around implants were not associated with crestal bone loss. Yet the marginal crestal bone loss to the first thread of screw-type implants is a common radiologic finding. If bacteria were the causal agent for the initial bone loss, why does most bone loss occur the first year (1.5 mm) and less (0.1 mm) each successive year? The implant sulcus depth progressively increases from the early bone loss, impairing hygiene and making anaerobic bacteria more likely as the cause of bacteria-related bone loss. If bacteria are responsible for 1.5-mm early crestal bone loss, what local environmental changes occur to reduce their effect by 15 times after the first year?[23] The bacteria autoimmune theory cannot explain the marginal bone loss condition when it follows the pattern most often reported.

Although the bacteria theory does not explain adequately the marginal crestal bone loss phenomenon, this does not mean that bacteria are not a major contributor to bone loss around an implant. Threads and porous implant surfaces exposed to bacteria are reported to cause a more rapid loss of bone around an implant.[51] Poor hygiene also is reported to accelerate the bone loss observed around endosteal implants[52,53] (Figure 4-12). To state that bacteria are never involved in marginal bone loss around an implant would be incorrect. Bone loss often is associated with bacteria as a causal agent. However, when most bone loss occurs in the first year and less bone loss is observed afterward, the hypothesis of bacteria as the primary causal agent for the early crestal bone loss cannot be substantiated.

Figure 4-12 Exudate around an implant is more likely to be present when the probing depth is greater than 5 mm and an aerobic environment exists around the implant.

Biological Width Hypothesis

The sulcular regions around an implant and around a tooth are similar in many respects. The rete peg formation within the attached gingiva and the histologic lining of the gingiva within the sulcus are similar in implants and teeth. A free gingival margin forms around an implant with nonkeratinized sulcular epithelium, and the epithelial cells at its base are similar to the functional epithelial cells described with natural teeth.[54] However, a fundamental difference characterizes the base of the gingival sulcus.

For a natural tooth, an average biological width of 2.04 mm exists between the depth of the sulcus and the crest of the alveolar bone (Figure 4-13). It should be noted the biological "width" is actually a height dimension with a greater range in the posterior region compared with the anterior, and may be greater than 4 mm in height. In teeth, it is composed of a connective tissue (CT) attachment (1.07 mm average) above the bone and a junctional epithelial attachment (0.97 mm average) at the sulcus base, with the most consistent value between individuals being the CT attachment.[55-57] The biological width allows gingival fibers and hemidesmosomes to establish direct contact with the natural

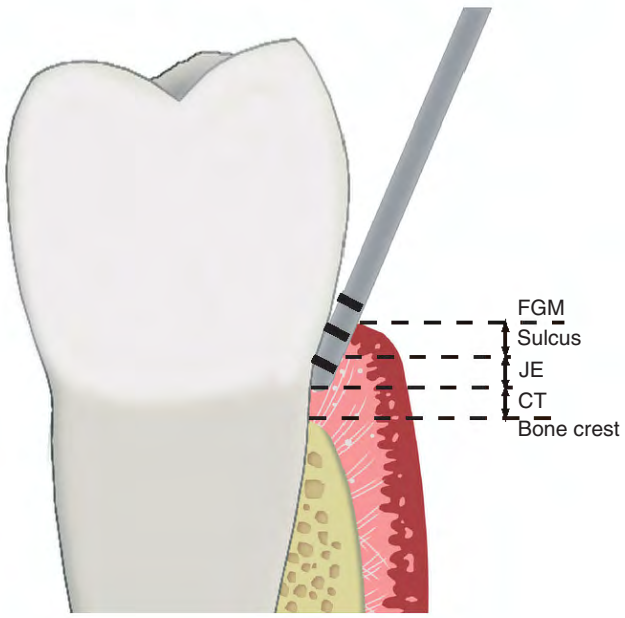

Figure 4-13 The biological width of a natural tooth has a connective tissue zone that inserts into the cementum of the tooth. A periodontal probe will penetrate the sulcus and the junctional epithelial attachment. *FGM,* Free gingival margin; *JE,* junctional epithelium; *CT,* connective tissue.

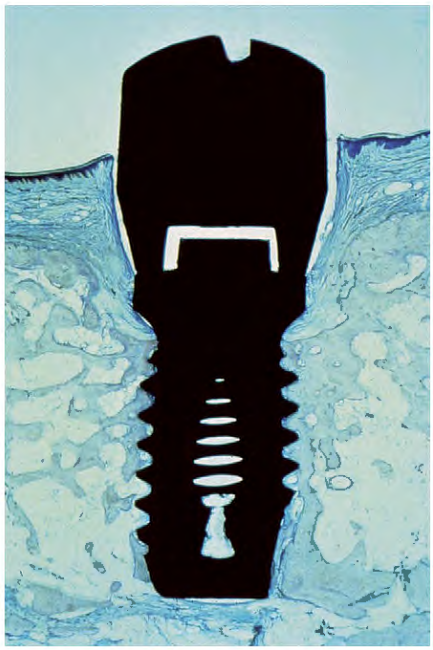

Figure 4-14 The bone levels recede to at least 0.5 mm around an abutment to implant connection after the implant extends through the soft tissue, regardless of whether the implant is loaded. *(Courtesy Steve Wallace.)*

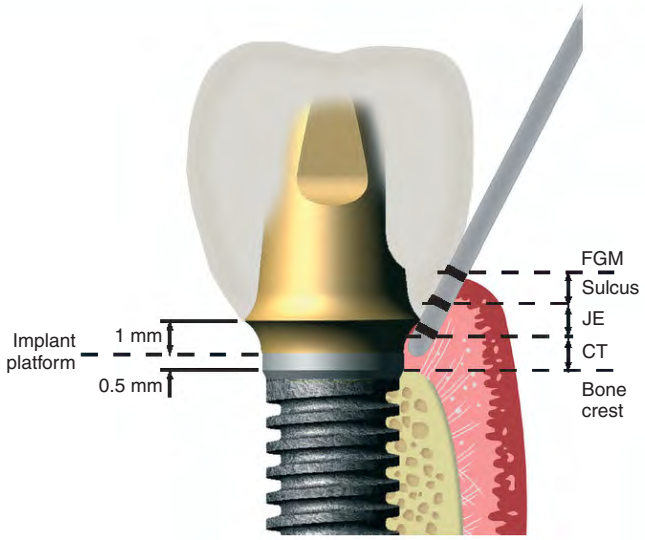

Figure 4-15 There are primarily two soft tissue fiber groups around an implant: circular fibers and crestal bone fibers. Neither of these fiber types insert into the implant or the abutment. The peri-implant probe penetrates the sulcus, junctional epithelial attachment, and most of the connective tissue zone. *FGM,* Free gingival margin; *JE,* junctional epithelium; *CT,* connective tissue.

tooth and acts as a barrier to the bacteria in the sulcus to the underlining periodontal tissues. When a crown margin invades the biological width, the crestal bone recedes to reestablish a favorable environment for the gingival fibers.[58,59]

Many surgical protocols recommend the placement of endosteal implants at or below the crest of the ridge during the first-stage surgery. The abutment-to-implant body connection may be compared with a crown margin. Berglundh et al.[60] observed 0.5 mm of bone loss below the implant-abutment connection within 2 weeks after stage II uncovery and abutment connection in dogs (Figure 4-14). Lindhe et al.[61] reported an inflammatory connective tissue extending 0.5 mm above and below this implant abutment connection. Wallace and Tarnow[62,63] stated that the biological width also occurs with implants and may contribute to some of the marginal bone loss observed. The biological width theory seems attractive to explain the lack of bone loss from the first stage of surgery and the early bone loss seen within the first year after the second-stage abutment placement. However, it should be noted that the biological "width" in implants, as reported, often includes the sulcus depth, whereas the natural tooth biological width does not include the sulcus depth.

Eleven different gingival fiber groups are observed around a natural tooth: dentogingival (coronal, horizontal, and apical), alveologingival, intercapillary, transgingival, circular, semicircular, dentoperiosteal, transseptal, periosteogingival, intercircular, and intergingival. At least six of these gingival fiber groups insert into the cementum of the natural tooth: the dentogingival (coronal, horizontal, and apical), dentoperiosteal, transseptal, circular, semicircular, and transgingival fibers. In addition, some crestal fibers from the periodontal fiber bundles also insert into the cementum above the alveolar bone.[57] However, in a typical implant gingival region, only two of these gingival fiber groups and no periodontal fibers are present (Figure 4-15). These fibers do not insert into the implant body below the abutment margin as they do into the cementum of natural teeth.[56,64] Instead, the collagen fibers in the CT attachment around an implant run parallel to the implant surface, not perpendicular, as with natural teeth.[65,66] The gingival and periosteal fiber groups are responsible for the connective tissue attachment component of the biological width around teeth, and these are not present around the transosteal region of an implant. Therefore the CT attachment around the abutment-implant connection cannot be compared with the CT attachment of a tooth.

James and Keller[64] were first to begin a systematic scientific study to investigate the biological seal phenomenon of the soft tissue around dental implants. Hemidesmosomes help form a basal lamina–like structure on the implant, which can act as a biological seal. However, collagenous components of the linear body cannot physiologically adhere to or become embedded into the implant body as they do in the cementum of the tooth.[67] The hemidesmosomal seal only has a circumferential band of gingival tissue to provide mechanical protection against tearing.[68] Therefore the biological seal around dental implants can prevent the migration of bacteria and endotoxins

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

into the underlying bone. It is unable, however, to constitute a junctional epithelial attachment component of the biological width similar to the one found with natural teeth. The amount of early crestal bone loss therefore seems unlikely to be solely the result of the remodeling of the hard and soft tissues to establish a biological width below an abutment connection. No connective tissue attachment zone or components of the linear body are embedded into an implant. The importance, amount, and mechanism for these anatomical structures require further investigation.

The crevice between the cover screw and the implant body during initial healing is similar to the crevice of the abutment-implant connection. Yet bone can grow over the cover screw, and therefore the crevice, in and of itself, may not be the cause of bone loss. The crevice between the implant and the abutment connection has been called a "microgap." The actual dimension of this connection is usually 0 µm and has a direct metal to metal connection. However, when the crevice is exposed to the oral environment, bone loss is usually observed for at least 0.5 mm below the connection.[68-70]

The biological width hypothesis cannot fully explain the several millimeters of marginal crestal bone loss, which also has been observed readily with one-stage implants that extend through the tissue at the initial implant placement surgery and have no abutment-implant connections. For example, plate form (blade) implants, transosteal implants, pins, one-piece screw implants, and even subperiosteal implants demonstrate the marginal crestal bone loss phenomenon.

It is true that, bone loss does occur around an exposed abutment-implant connection placed below the bone and is observed within 2 to 4 weeks, once the connection is exposed to the oral environment. The bone loss often occurs before the implant is loaded with the prosthesis. It is logical to call this marginal bone loss the *biological width*.

The primary question remains, when the surgeon places the implant abutment connection below the bone, how much bone loss is from the implant biological width, and therefore out of the influence of the dental practitioner? Several reports in the literature note implant macro- and microgeometry may affect the biological width dimensions or the amount of early crestal bone loss.[31,32,49,71-74]

The bone loss to the first thread observation implies the amount of bone loss is similar for different implant designs. However, the first thread is a different distance from the abutment margin for several implant designs. A smooth polished 4-mm collar below the bone has been associated with greater bone loss than a smooth 2-mm collar below the bone. The implant biological width concept does not explain completely the total amount of vertical bone loss observed. In addition, the amount of bone loss from the biological width occurs within 1 month, whether the implant is loaded or not, and is related to the crest module implant design and the position of the abutment-implant connection in relation to the bone but is unrelated to the density of the bone. The concept does not explain why greater crestal bone loss often is observed in soft bone compared with denser bone after loading, nor does it explain the higher implant failure rates in lesser-quality bone after loading.

Occlusal Trauma

Marginal bone loss on an implant may be from occlusal trauma.[40] *Occlusal trauma* may be defined as an injury to the attachment apparatus as a result of excessive occlusal force.[1] A controversy exists as to the role of occlusion in the bone loss observed after an implant prosthesis delivery.[8] Some articles state that peri-implant bone loss without implant failure is primarily associated with biological formations or complications.[16-18] Other authors suggest a correlation of crestal bone loss to occlusal overload.[8,40,41,75,76] The determination of the etiology of bone loss around dental implants is needed in order to minimize its occurrence and foster long-term peri-implant health that may ultimately determine implant prosthesis survival.

The association of occlusal trauma and bone loss around natural teeth has been debated since Karolyi claimed a relationship in 1901.[76] A number of authors conclude trauma from occlusion is a related factor in bone loss, although bacteria is a necessary agent.[77-82] On the other hand, Waerhaug and many others state there is no relationship between occlusal trauma and the degree of periodontal tissue breakdown.[83-85] According to Lindhe et al., "trauma" from occlusion cannot induce periodontal tissue breakdown.[86] However, occlusal trauma may lead to tooth mobility that can be transient or permanent. By extrapolation of this rationale, several authors have also concluded occlusal trauma is not related to marginal bone loss around a dental implant.[16-18]

To establish further a correlation between marginal bone loss and occlusal overload, related articles from cellular biomechanics, engineering principles, mechanical properties of bone, physiology of bone, implant design biomechanics, animal studies, and clinical reports were procured.[40]

Cellular Biomechanics

Bone remodeling at the cellular level is controlled by the mechanical environment of strain.[87] *Strain* is defined as the change in length divided by the original length, and the units of strain are given in percentages. The amount of strain in a material is directly related to the amount of stress applied.[88] Occlusal stress applied through the implant prosthesis and components can transmit stress to the bone-implant interface.[87] The amount of bone strain at the bone-implant interface is directly related to the amount of stress applied through

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان
لابراتوار دندانسازی های دنت

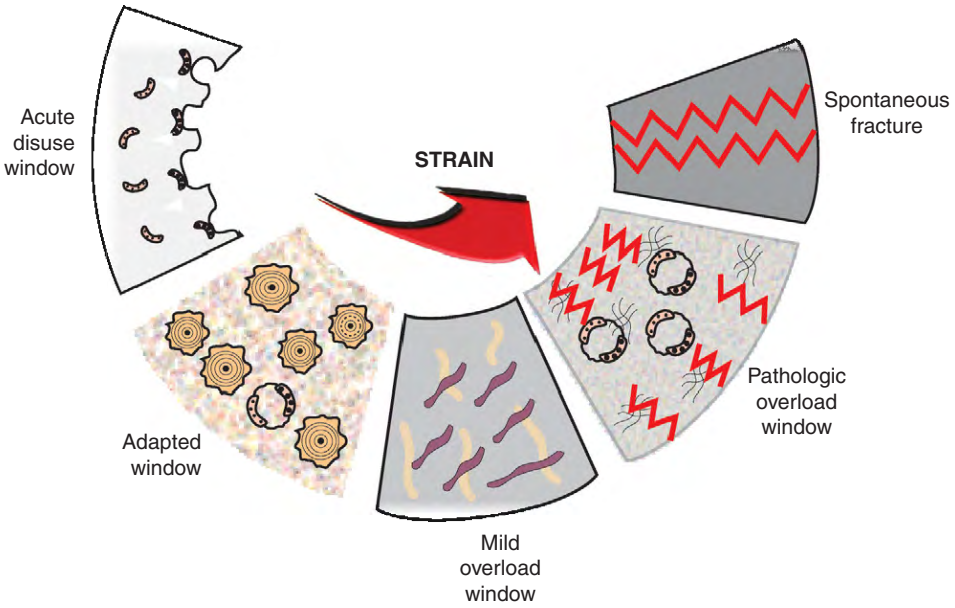

Figure 4-16 Mechanical stress applied to bone cells causes a change in shape or strain. The microstrains may trigger the release of cytokines and bone resorption.

the implant prosthesis. Mechanosensors in bone respond to minimal amounts of strain, and microstrain levels 100 times less than the ultimate strength of bone may trigger bone remodeling[89] (Figure 4-16).

One of the earliest remodeling theories for a direct relationship between stress and the magnitude of bone remodeling was proposed by Kummer in 1972.[90] More recently, Frost reported on the cellular reaction of bone to different microstrain levels.[91,92] He observed that bone fractures at 10,000 to 20,000 microstrain units (1% to 2% deformation). However, at levels 20% to 40% of this value (4000 units), bone cells may trigger cytokines to begin a resorption response. In other words, excessive bone strain may not only result in physical fracture, but may also cause bone cellular resorption. Therefore the hypothesis that occlusal stresses beyond the physiologic limits of bone may result in strain in the bone significant enough to cause bone resorption is plausible from a cellular biomechanics standpoint. To date, bone cellular studies have not replicated this bone condition next to a dental implant. However, cytokines in the bone-implant interface tissue obtained from failed hip replacement devices leading to bone loss have been reported in humans.[93]

Engineering Principles

The relationship between stress and strain determines the modulus of elasticity (stiffness) of a material.[88] The modulus conveys the amount of dimensional change in a material for a given stress level. The modulus of elasticity of a tooth is similar to cortical bone. Dental implants are typically fabricated from titanium or its alloy. The modulus of elasticity of titanium is five to ten times greater than that of cortical bone (Figure 4-17). An engineering principle called the *composite beam analysis* states that when two materials of different elastic moduli are placed together with no intervening material and one is loaded, a stress contour increase will be observed where the two materials first come into contact.[94] In an implant-bone interface, these stress contours are of greater magnitude at the crestal bone region. This phenomenon was observed in both photoelastic and three-dimensional finite element analysis (Figure 4-18) studies when implants were loaded within a bone simulant.[95-98] These authors note that the marginal bone loss observed clinically and radiographically around implants follows a similar pattern as the stress contours in these reports.

Bone Mechanical Properties

Bone density is directly related to the strength and elastic modulus of bone.[99] In denser bone, there is less strain under a given load compared with softer bone. As a result, there is less bone remodeling in denser bone compared with softer bone under similar load conditions.[91] A decrease in bone remodeling can result in a reduction of bone loss. In a prospective human study, Manz observed the amount of marginal bone loss next to an implant was related to the density of bone.[48] The initial peri-implant bone loss from implant insertion to uncovery was similar for all bone qualities. However, 6 months after prosthesis delivery, the additional radiographic-observed peri-implant bone loss ranged from 0.68 mm for quality 1 to 1.1 mm for quality 2, 1.24 mm for quality 3, and 1.44 mm for quality 4-type bone (Figure 4-19). In other words, the more dense the bone, the less peri-implant bone loss was observed after prosthesis delivery. A clinical report by Appleton

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

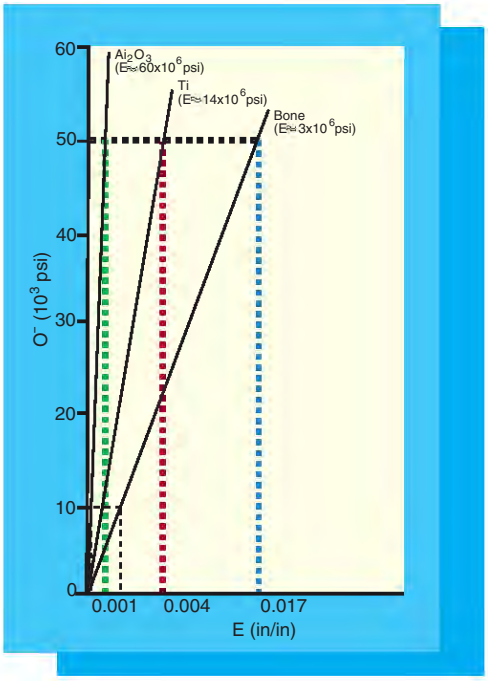

Figure 4-17 The modulus of elasticity is greater for titanium (Ti) compared with bone. When stress is plotted on the Y axis and strain on the X axis, the modulus of elasticity can be obtained. Titanium is five to ten times more rigid than cortical bone.

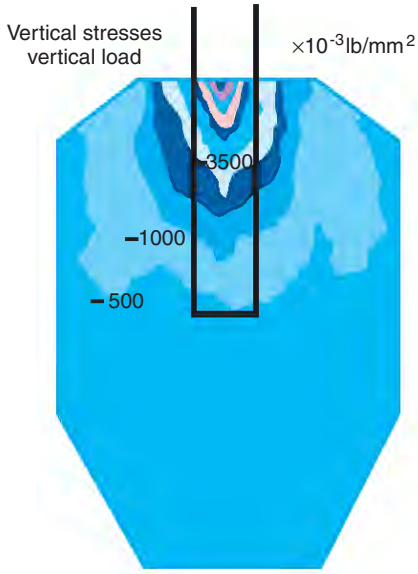

Figure 4-18 A three-dimensional finite element analysis of a titanium implant in a bone model after axial loading. The V-shape pattern of strain is greatest at the crestal region and decreases in intensity as the stress is dissipated throughout the implant length.

et al.[100,101] demonstrated that progressively loaded single-tooth implants in the first premolar region of human beings exhibited greater bone density increase in the crestal half of the implant interface and less marginal bone loss compared with nonprogressively loaded implants in the same jaw region and even the same patient on the contralateral side without progressive loading. Because an increase in bone density is related to bone strength, elastic modulus, bone remodeling, and a decrease in marginal bone loss, these entities may be related to each other.

Animal Studies

Several animal studies in the literature demonstrate the ability of bone tissue to respond to a dental implant. For example, Hoshaw et al. inserted dental implants into a dog femur perpendicular to the axis of the long bone and perpendicular to the direction of the osteons.[102,103] After applying a tensile load to the implants for only 5 days, the bone cells reorganized to follow the implant thread pattern and resist the load. This unique bone pattern was only observed for 3 to 4 mm around the implants. Crestal bone loss was also noted around these implants and explained as stress overload. To rearrange its osteal structure, bone must remodel.

Miyata placed crowns on integrated dental implants with no occlusal contacts (control group), and premature interceptive occlusal contacts of 100 µm, 180 µm, and 250 µm in a monkey animal model.[104-106] After 4 weeks of premature occlusal loads, the implants were removed in a block section and evaluated. The crestal bone levels for 100 µm and control implants with no loading were similar. However, statistically significant crestal bone loss was observed in the 180-µm group (Figure 4-20). The 250µm group experienced two to three times the bone loss of

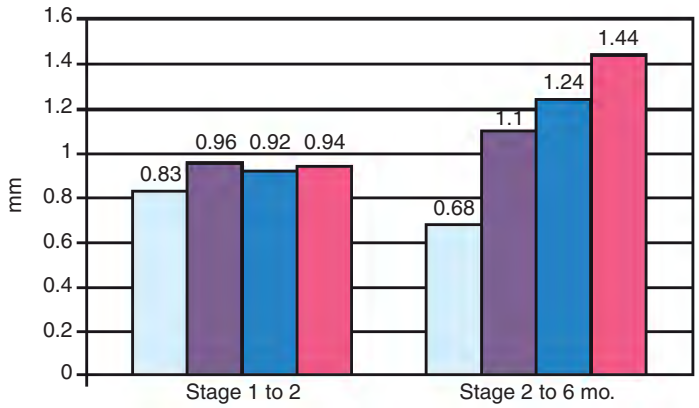

Figure 4-19 Mean peri-implant vertical bone change for study intervals by bone quality score. Many observed the amount of bone loss from Stage 1 to Stage 2 was similar, regardless of bone quality. However, after 6 months of loading, the amount of marginal bone loss was directly related to the quality of the bone, with type 4 (the softest bone) exhibiting the greatest bone loss. *(Reproduced from Manz MC: Radiographic assessment of peri-implant vertical bone loss: DIRG Implant Report No 9,* J Oral Maxillofac Surg *55 (Suppl):62-71,1997.)*

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

Figure 4-20 Miyata et al. loaded integrated implants for 4 weeks with premature contacts on crowns of 100 μm, 180 μm, and 250 μm. The implants with 180 μm premature contacts demonstrate a V-shaped crestal bone loss. *(From Miyata T, Kobayashi Y, Araki H et al: The influence of controlled occusal overload on periimplant tissue: 3, a histologic study in monkeys,* Int J Oral Maxillofac Implants *15:425-431, 2000.)*

Figure 4-21 The implants with 250-μm premature contacts demonstrated greater bone loss than the 180-μm group. The 250-μm premature contact for 4 weeks lost the most bone. The higher stresses resulted in more crestal bone loss. *(From Miyata T, Kobayashi Y, Araki H et al: The influence of controlled occusal overload on periimplant tissue: 3, a histologic study in monkeys,* Int J Oral Maxillofac Implants *15:425-431, 2000.)*

the crowns with moderate prematurities (Figure 4-21). Duyck used a dog model to evaluate the crestal bone loss around screw-type dental implants with no loads (controls), static loads, and dynamic loads.[107] The dynamic-loaded implants were the only group to demonstrate crestal bone loss. As the only variable in these two studies was the intensity or type of occlusal load applied to the implants, these animal reports imply dynamic occlusal loading may be a factor in crestal bone loss around rigid fixated dental implants.

Clinical Reports

Clinical reports have shown an increase in marginal bone loss around implants closest to a cantilever used to restore the lost dentition[108-110] (Figure 4-22). Cantilever length and an increase in occlusal stress to the nearest abutment are directly related[111] and point to the fact that the increase in marginal bone loss may be related to occlusal stress. Quirynen et al. evaluated 93 implant patients with various implant restorations and concluded that the amount of crestal bone loss was definitely associated with occlusal loading.[31] These authors also reported increased crestal bone loss around implants in patients with no anterior occlusal contacts and parafunctional habits in full-arch fixed prostheses in both jaws.[31,32] These clinical reports do not provide statistical analyses to demonstrate a clear link between occlusal stress and bone loss. However, they indicate a consensus by some authors that occlusal overload

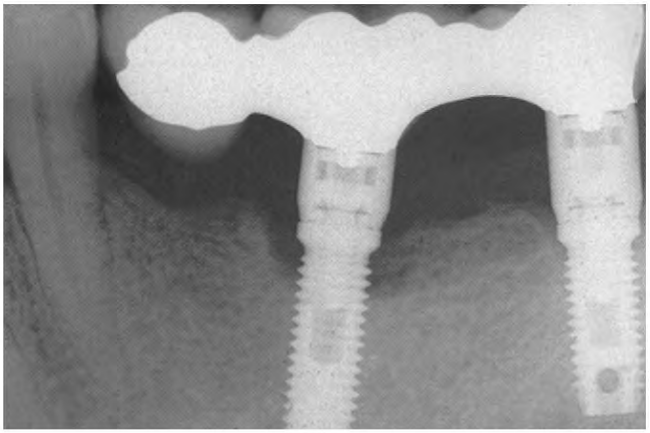

Figure 4-22 Rangert et al. observed that cantilevers on fixed partial dentures increase the marginal bone loss on the implant next to the cantilever. Note the more distal implant with less bone loss. *(From Rangert B, Krogh PHJ, Langer B et al: Bending overload and implant fracture: a retrospective clinical analysis,* Int J Oral Maxillofac Implants *10:326-334, 1995.)*

may be related to the incidence of peri-implant bone loss around the cervical aspect of an implant. In fact, in a study of 589 consecutive implants, Naert et al. suggested overload from parafunctional habits may be the most probable cause of implant loss and marginal bone loss after loading.[112]

Rangert et al. have noted that occlusal loads on an implant may act as a bending moment, which increases

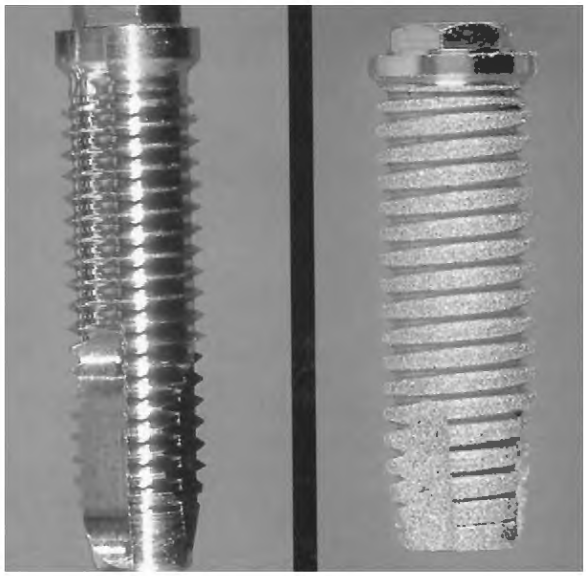

Figure 4-23 Researchers have compared crestal bone loss for the implant design on the *left* (a V-shaped machined thread) with the implant design on the *right* (a roughened square thread) in the anterior mandible for 3 to 7 years.

stress at the marginal bone level and can cause implant body fracture.[33] Before the fracture of the implant body, marginal bone loss was noted in this retrospective clinical evaluation. The same stress that caused implant fracture is the logical cause of the peri-implant bone loss before the event.

Rosenberg et al. found microbial differences in implant failures from both overload and biological complications.[75] Uribe et al. presented the case of a mandibular implant crown with a marginal peri-implantitis and osseous defect.[113] Histologic analysis revealed an infiltrate and a central zone of dense fibroconnective tissue with scanty inflammatory cells. According to the authors, this finding differs from chronic inflammatory tissue associated with infectious peri-implantitis and can be directly related to occlusal overload.

A clinical report by Leung et al. observed radiographic angular crestal bone loss to the 7th thread around one of two implants supporting a fixed prosthesis in hyper-occlusion 2 weeks after prosthesis delivery.[114] The prosthesis was removed and over the next few months, radiographic observation showed the crestal defect was repaired to almost the initial level, without any surgical or drug intervention. The prosthesis was then seated with proper occlusal adjustment. The bone levels stabilized at the second thread of the implant and remained stable over the next 36 months. This report indicates bone loss from occlusal overload is not only possible, but may even be reversible when found early in the process. Therefore, although no prospective clinical study to date has clearly demonstrated a direct relationship between stress and bone loss without implant failure, several practitioners agree a causal relationship may exist.

Implant Design Biomechanics

Different amounts of marginal bone loss have been reported for different implant body designs. The design and surface condition of the implant body may affect the amount of strain distributed to an implant-bone interface. A report by Zechner et al. evaluated the peri-implant bone loss around functionally loaded screw-type implants with machined surfaced V-threads or a sandblasted/acid-etched square-thread design[115] (Figure 4-23). Both these implant designs had a similar crest module and external hex connection. Four interforaminal implants were placed in the mandible in 36 patients and followed for 4 years. Over this period, the average bone loss was 2.4 mm (V-thread) versus 1.6 mm (square thread). However, the range of bone loss in the study was 0.1 to 8.5 mm for machined V-threaded implants and 0.2 to 4.8 mm for rough-surfaced square-threaded implants. Twenty-two V-threaded implants lost more than 4 mm of bone of less than 1 mm was reported for 16 rough-surface square-threaded implants compared with only two machined-surfaced V-threaded implants (Figure 4-24). There were no clinical findings of inflammation or exudate. The range of bone loss with the different implant surface conditions and designs in a clinical report suggests that more than the biological width, microgap position, and/or surgical causes are involved in the individual implant marginal bone loss process. The three most probable factors that influenced the amount of crestal bone loss in this report are the amount of force applied to the prosthesis, the quality of the bone to resist these forces, and the implant body design. All three of these conditions implicate occlusal overload as the cause of marginal bone loss around an implant.

A prospective study by Karousis et al. also indicated that different implant designs and surface conditions correspond to different incidences of crestal bone loss.[116] Three different implant designs from the

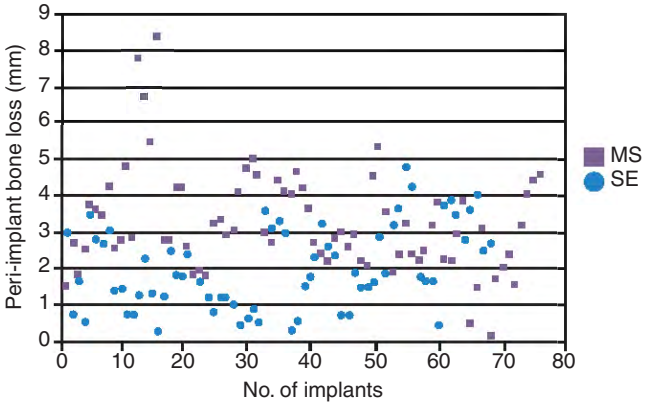

Figure 4-24 Most of the implants that lost more than 4 mm of bone were of the machined V-shaped-thread design. The implants that lost less than 1 mm of bone were primarily roughened square-thread designs.

t.me/highdent www.highdentlab.com instagram.com/high_dent

همیار دندانسازان و دندانپزشکان لابراتوار دندانسازی های دنت

same manufacturer were evaluated over 10 years in a prospective report. One implant body design lost more than 5 mm of bone 26% of the time, whereas the other two designs reported 37% and 39% incidence. More than 6 mm of marginal bone loss occurred in 22% of the implants with the first design, compared with 35% and 33% for the other two designs. These results indicate that one implant design may result in less marginal bone loss than another and point to the fact that clinical reports with similar healing and loading protocols, but of variable implant body designs and surface conditions, may yield different amounts of crestal bone loss. Because the implant design and surface condition affect the amount of stress transferred to the bone, one of the reasons for a different amount of bone loss for different implant designs may be related to the stress transmitted to the bone.

In the field of orthopedics, hip joint replacement has several complications, including wound infection, periprosthetic fracture, dislocation, mechanical failure, and osteolysis.[117] *Osteolysis* refers to the bone resorption that occurs around both cemented and uncemented orthopedic implants (Figure 4-25). Aseptic loosening from osteolysis of the bone-implant interface is the leading cause of late joint replacement failure (10% within 10 years). Mechanical loading factors primarily are associated with this condition.[118-120] Patient factors that increase loading failure include body weight and activity level.[120] An animal model and human report have linked the resorption of bone at the interface to mechanical overload.[121] Treatment of the disorder, if the patient is asymptomatic with a large osteolytic defect but no implant mobility, includes curettage of the osteolytic membrane and bone grafting.[122] These orthopedic reports accept that mechanical overload can cause bone resorption at the bone-implant interface. The metal most often used in hip replacement therapy is titanium alloy, and the bone-implant interface is very similar to a dental implant. In addition, potential causative elements encountered intraorally, such as oral bacteria contamination, microgap position, and microbial-related bone loss, are eliminated in this aseptic environment. It is logical to assume these studies further support a relationship between marginal bone loss around implants and biomechanical stress.

Discussion

Limited marginal bone loss during the first year of function after Stage II surgery has been observed around the permucosal portion of dental implants for decades.[23,38] Hypotheses for the causes of crestal bone loss have included the reflection of the periosteum during surgery, preparation of the implant osteotomy, level of the microgap between the abutment and implant body, bacterial invasion, the establishment of a biological width, the implant crest module design, and occlusal overload.[8,40,41,123]

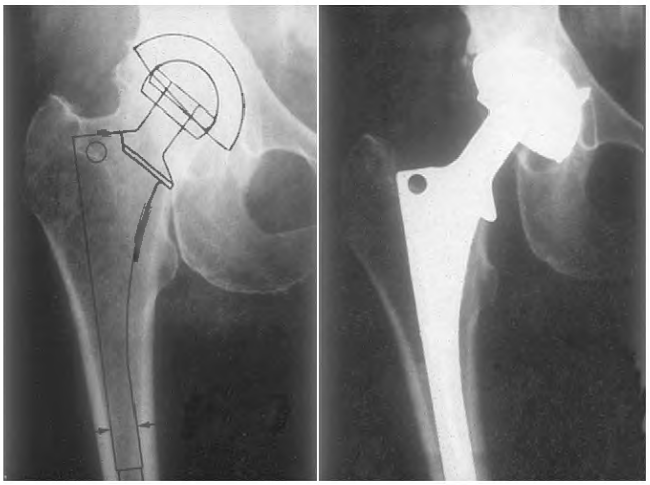

Figure 4-25 Bone loss around orthopedic implants (osteolysis) is primarily caused by mechanical stress to the bone-implant interface.

The fact that occlusal overload may be an etiology for crestal bone loss does not mean other factors are not present. For example, the microgap position of the implant platform and abutment and the biological width often affect the marginal bone during the first month after the implant becomes permucosal.[48] However, the clinician has certain variables under their control that may influence the amount of peri-implant bone loss. The position of the microgap in relation to the bony crest and the implant crest module design are primarily under the control of the implant surgeon. On the other hand, the autoimmune or bacterial response of the patient, the biological width, and the patient response to the surgical trauma of implant placement are variables often escaping the control of the dentist. Once the final prosthesis is delivered to the patient, many events responsible for marginal bone loss have already occurred, whereas others such as occlusal overload and its relationship to the quality of bone persist. Occlusal overload is one factor most in control of the restoring dentist. If a relationship between occlusal overload and crestal bone loss exists, approaches to decrease stress to an implant interface appear appropriate.

A puzzling element in the relationship between occlusal force and peri-implant bone loss is the lack of continued bone loss until the implant fails. Implant crown height may be measured from the occlusal plane to the crest of the bone. The crown height is a vertical cantilever, which may magnify the stresses applied to the prosthesis. As a result of the greater crown height from the vertical bone loss, occlusal overload will be increased after crestal bone loss occurs. Therefore, if occlusal loading forces can cause crestal bone loss, the resulting increased moment forces should further promote the loss of bone until the implant fails. Yet most clinical studies indicate the rate of bone loss decreases after the first year of loading and is minimal thereafter. There are

Figure 4-26 In evaluating the bone around an implant after healing in a monkey model, a fine trabecular pattern is noted. *(From Piatelli A, Ruggeri A, Franchi M et al: A histologic and histomorphometric study of bone reactions to unloaded and loaded non-submerged single implants in monkeys: a pilot study,* J Oral Implantol *19:314-319, 1993.)*

Figure 4-27 Once the implant was loaded, the fine trabecular bone became coarse trabecular bone, especially at the crestal region. When the stresses are too great, bone loss occurs. When the stresses are within the physiologic range, the bone density increases. *(From Piatelli A, Ruggeri A, Franchi M et al: A histologic and histomorphometric study of bone reactions to unloaded and loaded non-submerged single implants in monkeys: a pilot study,* J Oral Implantol *19:314-319, 1993.)*

two reasons why the bone levels may become stable after initial marginal bone loss, even when the cause is from occlusal overload: bone physiology and implant design mechanics.

Bone Physiology

The bone is less dense and weaker at Stage 2 implant surgery than it is 1 year later after prosthetic loading.[124] Bone is 60% mineralized at 4 months and takes 52 weeks to complete its mineralization.[125] Partially mineralized bone is weaker than fully mineralized bone. In addition, the microscopic organization of bone progresses during the first year. Woven bone is unorganized and weaker than lamellar bone, which is organized and more mineralized. Lamellar bone develops several months after the woven bone repair has replaced the devitalized bone caused by the surgical insertion trauma around the implant.[124] The occlusal stress levels may be high enough to cause woven bone microfracture or overload during the first year, but the increase in bone strength achieved after complete mineralization and organization may be able to resist the same stress levels during the subsequent years.

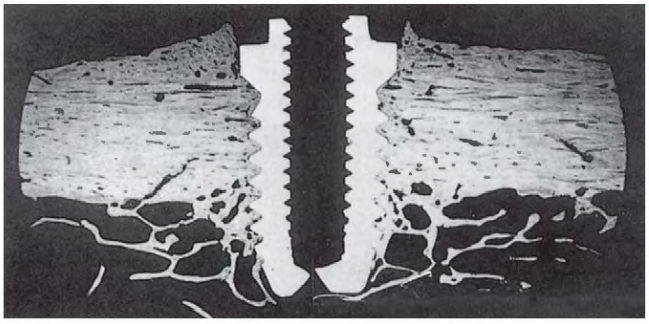
As functional forces are placed on an implant, the surrounding bone can adapt to the stresses and increase its density, especially in the crestal half of the implant body during the first 6 months to 1 year of loading.[125] In a histologic and histomorphometric study of bone, Piatelli et al. reported reactions to unloaded and loaded nonsubmerged implants in monkeys (Figures 4-26, 4-27). The bone changed from a fine trabecular pattern after initial healing to a more dense and coarse trabecular pattern after loading, especially in the crestal half of the implant interface.[126] Hoshaw loaded threaded implants in dogs with a tensile load and noted that the fine trabecular bone pattern became coarse trabecular bone around the implant.[102,103] In addition, the bone reorganized to a more favorable condition to assist the direction and type of occlusal load (Figure 4-28).

Fine trabecular bone is less dense than coarse trabecular bone.[124] Because the density of bone is directly related to its strength and elastic modulus, the crestal bone strength and biomechanical mismatch between titanium and bone may diminish gradually during the functional loading phase. In other words, the stresses applied to the peri-implant bone may be great enough to cause bone resorption during the first year, because bone strains are greatest at the crest. However, the stresses applied below the crest of bone are of less magnitude and may correspond to the physiologic strain that allows the bone to gain density and strength. As a result, the occlusal load that causes bone loss initially (overload) is not great enough to cause continued bone loss once the bone matures and becomes more dense.

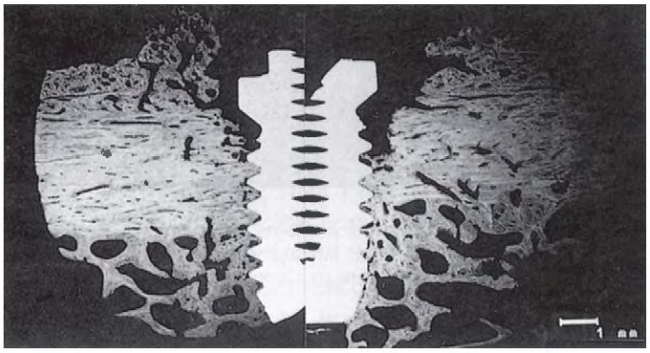
A clinical report by Appleton et al. demonstrated that progressively loaded single-tooth implants in the first premolar region of humans exhibited less bone loss and greater bone density increase in the crestal half of the implant interface, compared with nonprogressively loaded implants in the same jaw region, and even

t.me/highdent www.highdentlab.com instagram.com/high_dent

WWW.HIGHDENT.IR



A



B

Figure 4-28 Researchers loaded threaded implants in dog tibiae and noted the fine trabecular bone in the apical region **(A)** became coarse trabecular after loading. In addition, crestal bone loss was observed on the loaded implant. *(From Hoshaw SJ, Brunski JB, Cochran GVB: Mechanical loading of Brånemark fixtures affects interfacial bone modeling and remodeling,* Int J Oral Maxillofac Implants *9:345-360, 1994.)*

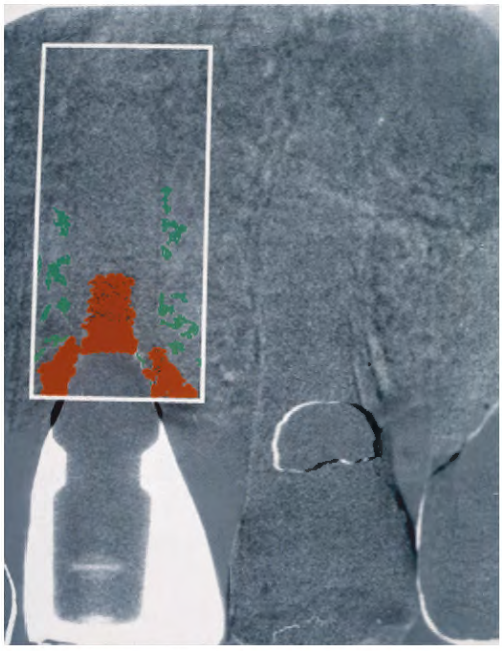


Figure 4-29 Researchers observed in humans that less crestal bone loss and an increase in bone density were present around implants progressively loaded in the maxillary first premolar region. *(From Appleton RS, Nummikoski PV, Pigno MA et al: A radiographic assessment of progressive loading on bone around single osseointegrated implants in the posterior maxilla,* Clin Oral Implants Res *16:161-167, 2005.)*

in the same patient on the contralateral side[100,101] (Figure 4-29). Marginal bone loss is less in the mandible compared with the maxilla in several clinical reports. The bone is denser in the mandible than the maxilla. The reduced crestal bone loss that has been reported in the mandible, in greater bone densities, and in progressively loaded implants point to the fact that stress/strain is a primary etiology of crestal bone loss after the implant is loaded. Therefore the stresses at the crest of the ridge may cause microfracture or overload during the first year, and the change in bone strength after loading and mineralization is complete alters the stress/strain relationship and reduces the risk of microfracture during the following years.[127]

Implant Design Biomechanics

Implant design may affect the magnitude or type of forces applied to the bone-implant interface. A smooth collar at the crest module may transmit shear forces to the bone. Bone is strongest under compressive forces, 30% weaker under tensile loads, and 65% weaker to shear forces.[128] Bone may heal to the smooth metal collar of the implant crest module from the time of implant insertion to implant uncovery; but placed under loading conditions, the weaker shear interface is more likely to overload the bone. The first thread

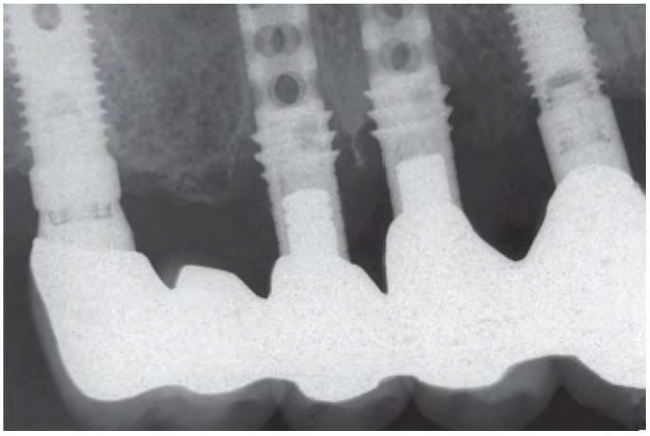

Figure 4-30 This prosthesis is supported by four implants. The center two implants with a long smooth crest module have 5 mm of bone loss. The anterior implants with a moderate smooth crest module have 3 mm of bone loss; the distal implant with the smallest smooth crest module has the least bone loss. The crestal bone loss is related in part to implant design.

or a roughened surface condition of the implant is where the type of force changes from primarily shear to compressive or tensile loads. Therefore, in many situations the 35% to 65% increase in bone strength, through changes from shear to compressive and/or tensile loads, is sufficient to halt the bone loss process. This may be one of the reasons why implant designs with a 2-mm smooth collar above the first thread and a 4-mm smooth collar above the first thread lose bone to this "first thread" landmark[129] (Figure 4-30). A previous

WWW.HIGHDENT.IR

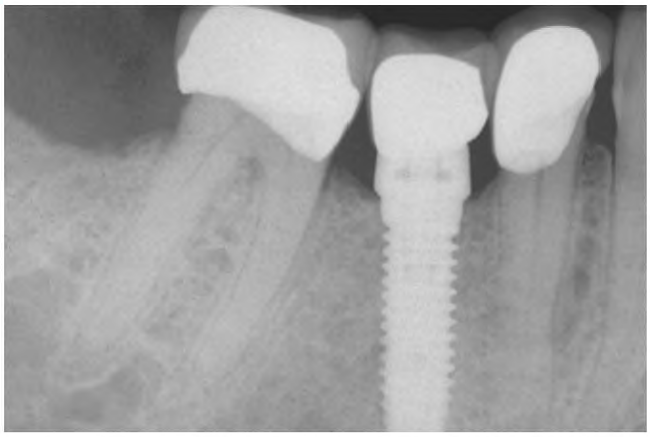

Figure 4-31 Crestal bone loss during the first year varies and is related to bone density and the amount of occlusal stresses. Some implant designs lose less bone than others. The BioHorizons Maestro dental implant is shown with no radiographic bone loss after 2 years.

review addressed the range of bone loss with different implant designs.[115,116,130] Because implant crest module designs may affect the amount of bone loss, and the implant design contributes to the force transfer of the bone-implant interface, the stress-related theory for one of the etiologies of crestal bone loss is further enhanced (Figure 4-31).

Literature from cellular biomechanics, engineering principles, differences in bone loss related to bone density, animal studies and clinical reports all substantiate that occlusal overload may be an etiology of peri-implant bone loss. Literature related to orthopedic joint replacement devices clearly indicate biomechanical stress and overload contribute to bone loss at the implant interface. The increase in bone mineralization and organization during the first year, the increase in bone density at the implant interface, and the type of force changes at the first thread of the implant body all are factors that may halt the bone loss phenomenon after the initial marginal loss. Although this occlusal overload concept does not negate other factors related to marginal bone loss, it is more clinician dependent than most other parameters. Treatment plans that emphasize occlusal stress reduction to the prosthesis are therefore mandated.

EFFECT ON TREATMENT PLANNING

Understanding the relationships of stress and related complications provides a basis for a consistent treatment system. A general concept in engineering is to determine the cause of a complication and develop a method to reduce the conditions that cause the problem. The clinical success and longevity of endosteal dental implants as load-bearing abutments are controlled largely by the biomechanical milieu in which they function.[129,131] The Stress Treatment Theorem, developed by the author, states that most all treatment related to the science of implant dentistry should be centered around the biomechanical aspects of stress.[131]

Stress-related conditions that affect the treatment planning in implant dentistry include the bone volume lost after tooth loss, bone quality decrease after tooth loss, complications of surgery, implant positioning, initial implant interface healing, initial loading of an implant, implant design, occlusal concepts, prosthesis fixation, marginal bone loss, implant failure, component fracture, prosthesis fracture, and implant fracture. Biomechanical parameters are excellent predictors of increased risks because they are objective and can be measured. One can not only predict which condition presents greater stress, and therefore greater risk, but also how much the risk is increased. A risk factor is not an absolute contraindication, but it significantly increases the complication rate. With so many variables, success or failure in implant dentistry is often a complex subject and not necessarily an exact science. But this does not mean a method cannot be established to decrease the risk. For example, smoking is a risk factor for longevity. A long-term smoker has a 75% less chance of living past 75 years of age. This does not mean a long-term smoker always dies before the average lifespan of a nonsmoker—smoking is not a poison that kills immediately. Several years ago, the oldest person on earth, who was 116 years old, was a smoker. However, this does not negate the fact that smoking is a considerable risk factor for longevity. Likewise, force factors are a considerable risk factor. Greater forces in one aspect of treatment do not always equal implant failure or complications, especially as so many factors are involved, including the density of bone around the implant. Yet the risks may be considerably reduced by decreasing the overall stress to the overall system. To assess the increase in risk factors, each factor is considered separately. The goal is to decrease the overall risk.

Understanding the relationships of stress and related complications provides a basis for a consistent treatment system. The Stress Treatment Theorem has evolved into a particular sequence of treatment planning (Box 4-3).

Prosthesis Design

Partially and completely edentulous patients want teeth, not implants. The final result (the prosthesis) should be visualized prior to the selection of the foundation (the implants). The design of the prosthesis is related to a number of factors. Nearly all treatments for partially edentulous patients are planned as a fixed restoration. The fixed restoration must consider the soft tissue and whether it requires a surgical or prosthetic replacement approach.

Completely edentulous patients may be treated with either a removable overdenture or a fixed prosthesis. In either approach, the loss of bone from tooth loss and methods to reduce future bone loss is part of the treatment plan. Most all patients should eventually have a completely implant-supported restoration (see Chapter 5).

Patient Force Factors

An implant team should evaluate more than 60 items before developing a treatment plan. Of all these conditions, the factors that influence the amount of patient stress may influence treatment more than several other factors combined.[132,133] Because stress equals force divided by the area to which the forces are applied, the amount of force is directly related to the amount of stress. There are several force factors to consider, including: (1) bruxism, (2) clenching, (3) tongue thrust, (4) crown height, (5) masticatory dynamics, and (6) the opposing arch. The forces applied to the restoration also differ by their (1) magnitude, (2) duration, (3) type, and (4) predisposing factors (e.g., cantilevers).

Some patient force factors are more important than others. For example, severe bruxism is the most significant factor and, on a risk scale from 1 to 10, is a 10.[132] Forces from bruxism are often the most difficult forces to contend with on a long-term basis.[132,133] As a result of this condition, marginal implant bone loss, unretained abutments, and fatigue fractures of implants or prostheses are more likely. The increase in force magnitude and duration is a significant problem. A bruxing patient is at higher risk in two ways. The magnitude of the force increases because the muscles become stronger and the number of cycles on the prosthetic components is greater as a result of the parafunction. Eventually "something" will break if the occlusal disease cannot be reduced in intensity or duration. No long-term prosthetic result without complications can be expected in patients with severe bruxism.

The second highest risk factor is severe clenching, which is a 9 on the risk scale. Cantilevers, including crown height, are next on the list, followed by masticatory muscle dynamics. The position of the implant in the arch is followed by the direction of load, with a risk of 5. These numbers are arbitrary, as they are influenced by the other force factors. For example, angled forces greater than 30 degrees to the implant body are more damaging than a crown height of 20 mm with a long axis load.[134-136] The clinician should evaluate the number of force conditions and their influencing severity factors. As the overall number increases, the risks increase, and the overall treatment plan should be modified to decrease the increased force or by increasing the area of support (see Chapter 6).

Bone Density

The density of bone is directly related to the strength of the bone.[99,137] Misch et al. have reported on the biomechanical properties of four different densities of bone in the jaws.[99] Dense cortical bone is 10 times stronger than the soft, fine trabecular bone. D2 bone is approximately 50% stronger than D3 bone. In addition, the stiffness of the bone is affected by the bone density. Young's modulus for compact bone is 10 times larger than cancellous bone. The denser the bone, the stiffer the bone, and the less biomechanical mismatch to titanium during loading.

Progressive bone loading changes the amount and density of the implant-bone contact. The bone is given time to respond to a gradual increase in occlusal load. This increases the quantity of bone at the implant interface, improves the bone density, and improves the overall support system mechanism.

Key Implant Positions and Implant/Abutment Number

Key Implant Positions

In any prostheses, there are implant positions that are more important from a stress management perspective. In one- or two-unit prostheses, an implant should be placed in each prospective tooth position, without a cantilever crown contour in any direction (e.g., facial, lingual, mesial, or distal). In a three- to four-unit restoration, the most important abutments are the terminal abutments. If a terminal abutment is not present, a cantilever is created, which magnifies the stress to the rest of the support system. Cantilevers are a force magnifier and represent a considerable risk factor in implant support, screw loosening, crestal bone loss, fracture, and any other item negatively affected by force.[134,136,138] Therefore position should aim at the elimination of cantilevers whenever possible, especially when other force factors are increased.

In a 5- to 14-unit prosthesis, intermediary abutments are also important in order to limit the edentulous spans to less than three pontics. A three-pontic prosthesis flexes 18 times more than a two-pontic prosthesis, whereas a two-pontic restoration flexes eight times more than a one-pontic prosthesis. It is suggested that multiple missing adjacent teeth be replaced in a staggered position (tripod effect),[139,140] or a larger intermediary implant be inserted.

WWW.HIGHDENT.IR

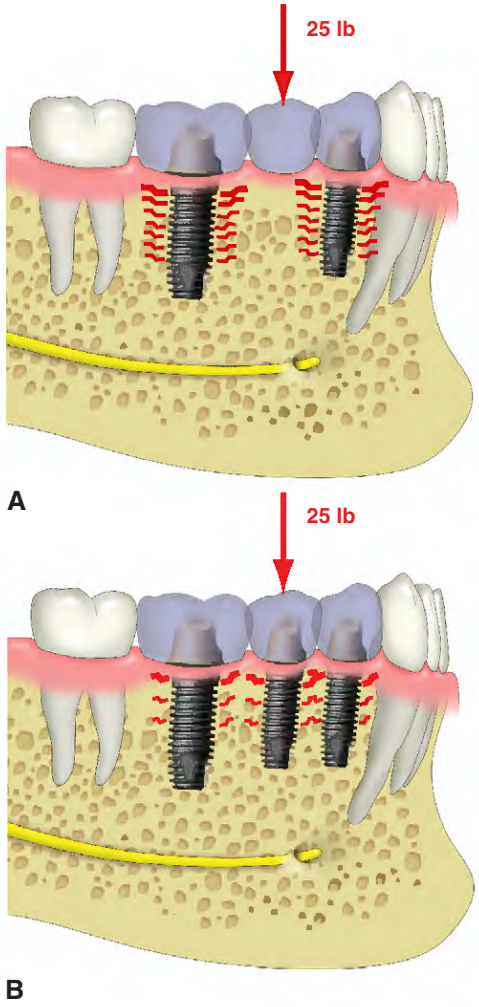

Figure 4-32 Increasing the implant number is an effective method to decrease the stress to each component in the system. Two implants supporting a three-unit prosthesis **(A)** have more stress to the implant interface than three implants supporting a similar restoration **(B)**. The additional implant also decreases the pontic number and increases the retention of the prosthesis.

The canine is an important implant position whenever the canine and two adjacent teeth are missing. Therefore, when the two premolars, a first premolar and lateral, or a lateral and a central, are missing next to a canine, a canine implant is warranted.

An edentulous mandible may be divided into three sections from a biomechanical perspective: the anterior (canine to canine) and the bilateral posterior regions (premolar and molars). A key implant position is one implant in each region, or at least three key implants.

An edentulous maxilla is divided in five regions: the anterior region (laterals and centrals), bilateral canines, and the bilateral posterior (premolar and molars). A key implant position is one implant in each region, or at least five key implants.

Treatment plans should incorporate methods to reduce stress and minimize its initial and long-term complications. Several parameters are in the doctor's control to improve the environment of the transosteal region to manage stress around and within endosteal implants. The definition of *stress* is force divided by the functional area over which it is applied. One biomechanical approach to decrease stress is to increase the surface area of the implant support system[134] (see Chapter 8).

The overall stress to the implant system may be reduced by increasing the area over which the force is applied. The most effective method to increase the surface area of implant support is by increasing the number of implants used to support a prosthesis (Figure 4-32). For example, previous studies by Bidez and Misch demonstrated that force distributed over three abutments results in less localized stress to crestal bone than two abutments.[140] This study applies only to implants that are splinted together. Therefore the number of pontics should be reduced and the number of implant abutments should be increased whenever forces are increased, compared with a treatment plan for an ideal patient with minimal force factors.[136,138,139,141,142]

The retention of the prosthesis is also improved with a greater number of splinted abutments. This approach also decreases the incidence of unretained restorations. Splinted implants also decrease porcelain fracture. The overall amount of stress to the system is reduced, and the marginal ridges on the implant crowns are supported by the connectors of the splinted crowns, with resulting compressive forces rather than shear loads on the porcelain.

Common clinical sense indicates that it is better to err with one extra implant than to err with too few. One implant too few, and the whole treatment may fail. One implant too many, and rarely is a problem noticed. Placing one implant for each buccal root is rarely indicated, regardless of the total number of risk factors. However, one implant for each tooth missing may be indicated in the posterior regions of the mouth for a large, young, male patient with severe parafunction. Rarely are more than 10 implants required in the completely edentulous arch, and more rarely are fewer than five implants suggested.

Implant Size

An excessive implant length is not critical at the crestal bone interface, but rather for initial stability and the overall amount of bone-implant interface. The increased length also provides resistance to torque or shear forces when abutments are screwed into place. However, the extra length does little to decrease the stress that occurs at the transosteal region around the implant at the crest of the ridge during occlusal loading.[143-145] Excessive implant length is not as effective a method to decrease stress from force factors.

On the other hand, with improper biomechanical management, shorter implants may have higher failure rates after loading.[146,147] Therefore, the initial treatment plan should use implants at least 12 mm in length. Ideally, softer bone types require longer implants than denser bone. The surface area of each implant is directly

WWW.HIGHDENT.IR

related to the width of the implant. Wider root form implants have a greater area of bone contact than narrow implants (of similar design), resulting from their increased circumferential bone contact areas. Each 0.25-mm increase in implant diameter may increase the overall surface area approximately 5% to 10% in a cylinder implant body. Bone augmentation in width may be indicated to increase implant diameter by 1 mm when force factors are greater than ideal. In addition, it has been suggested that an increase in implant diameter may be more effective than implant staggering to reduce stress.[148,149]

It is interesting to note that the natural teeth are narrower in the anterior regions of the mouth, where the amount of force generated is less. The natural teeth increase in diameter in the premolar region and again in the molar region as the amount of force increases, with a total 300% surface area increase from the lower anterior teeth to the maxillary molars. The length of natural teeth roots do not increase from anterior to posterior regions of the arch, but their cross section does. The supplemental implant support gained from the greater diameter not only decreases stress, but also decreases the likelihood of implant fracture and reduces the force to the abutment screw, which results in less screw loosening (see Chapter 9).

Available Bone

Once the previous steps to the treatment plan sequence have been determined, the available bone in the potential implant sites is evaluated. If adequate bone is present to position the preselected implant number, size, and design, the treatment sequence proceeds to the next factor. If available bone is not present, bone augmentation or modification is required. If these options are not possible, the sequence of treatment is begun again, starting from the prosthesis design.

In the past, the available bone was the first condition evaluated and the treatment would proceed, based upon the number and position of implants, with little regard to size or design. This approach often led to the high complication rates related to increased stress conditions (see Chapter 10).

Implant Design

Implant macrodesign may affect surface area even more than an increase in width. A cylinder (bullet-shaped) implant provides 30% less surface area than a conventional threaded implant of the same size. Strong et al. have identified 11 different variables that affect the overall functional surface area of an implant.[150] A threaded implant with 10 threads for 10 mm has more surface area than one with five threads. A thread depth of 0.2 mm has less surface area than an implant with 0.4 mm. Therefore, implant design may be the easiest method to increase surface area significantly and decrease overall risk to the implant interface (see Chapter 11).

In addition to the stress theorem and relative sequence of treatment plan, corollaries have been developed to facilitate the selection of the most appropriate therapy (Box 4-4).

SUMMARY

An understanding of the etiology of the most common implant complications has led to the development of a stress-based treatment plan theorem. Once the implant dentist has identified the sources of forces on the implant system, the treatment plan can be designed to minimize their negative impact on the implant, bone, and final restoration. Under these conditions, a

Box 4-4 Stress Treatment Theorem Corollaries

A. Patients want teeth, not implants.
B. If you had (1) ideal bone conditions, (2) optimal patient economic conditions, (3) optimal training, and (4) no time limitation, what would the treatment plan be?
C. Do not compromise a 30-year prosthesis for a 3- to 6-month delay in treatment.
D. Understand the difference between *can* versus *should* (possible versus predictable).
E. When in doubt, overengineer the foundation (e.g., add in implant, increase the design area).
F. When two or more approaches may obtain a similar result, use the least invasive and least complicated to achieve a predictable result.
G. When two or more methods may obtain a similar result, use the least expensive yet predictable method when developing the treatment plan.
H. When two or more approaches may obtain a similar result, use the most predictable rather than the fastest method.
I. Time is a factor in treatment only when all other factors are equal.
J. The patient with economic limitations cannot afford complications.
K. Apply primarily compressive loads when possible at the following levels:
   1. Porcelain
   2. Cement
   3. Abutment
   4. Screw
   5. Implant body
   6. Implant-bone interface
L. If you do not understand biomechanical stress, it will lead to psychological stress.
M. It is often necessary to modify the mouth or modify the mind of the patient.
N. It is better to see the back of the patient's head once than it is to see their face over and over again.

WWW.HIGHDENT.IR

consistent solution is an increase in implant-bone surface area. Additional implants are the solution of choice to decrease stress, along with an increase in implant width or height and the use of more implants to decrease the number of pontics and dissipate stresses more effectively to the bone structure, especially at the crest. The retention of the final prosthesis or superstructure is further improved with additional implant abutments. The amount of bone in contact with the implant is increased as a multiple of the number of implants.

Chapter 5

Prosthetic Options in Implant Dentistry

Carl E. Misch

Implant dentistry is similar to all aspects of medicine in that treatment begins with a diagnosis of the patient's condition. Many treatment options stem from the diagnostic information. Traditional dentistry provides limited treatment options for the edentulous patient. Because the dentist cannot add abutments, the restoration design is directly related to the existing oral condition. On the other hand, implant dentistry can provide a range of additional abutment locations. Bone augmentation may further modify the existing edentulous condition in both the partial and total edentulous arch and therefore also affects the final prosthetic design. As a result, a number of treatment options are available to most partially and completely edentulous patients. Therefore, once the diagnosis is complete, the implant treatment plan of choice at a particular moment is patient and problem based. Not all patients should be treated with the same restoration type or design.

Almost all man-made creations, whether art, building, or prostheses, require the end result to be visualized and precisely planned for optimal results. Blueprints indicate the finest details for buildings. The end result should be clearly identified before the project begins, yet implant dentists often forget this simple but fundamental axiom. Historically in implant dentistry, bone available for implant insertion dictated the number and locations of dental implants. The prosthesis then was often determined after the position and number of implants were selected.

The goals of implant dentistry are to replace a patient's missing teeth to normal contour, comfort, function, esthetics, speech, and health, regardless of the previous atrophy, disease, or injury of the stomatognathic system. It is the final restoration, not the implants, that accomplish these goals. In other words, patients are missing teeth, not implants. To satisfy predictably a patient's needs and desires, the prosthesis should first be designed. In the stress treatment theorem,[1] the final restoration is first planned, similar to the architect designing a building before making the foundation. Only after this is accomplished can the abutments necessary to support the specific predetermined restoration be designed (Figure 5-1).

COMPLETELY EDENTULOUS PROSTHESIS DESIGN

The completely edentulous patient is too often treated as though cost were the primary factor in establishing a treatment plan. However, the doctor and staff should specifically ask about the patient's desires. Some patients have a strong psychologic need to have a fixed prosthesis as similar to natural teeth as possible. On the other hand, some patients do not express serious concerns whether the restoration is fixed or removable as long as specific problems are addressed. To assess the ideal final prosthetic design, the existing anatomy is evaluated *after* it has been determined whether a fixed or removable restoration is desired.

An axiom of implant treatment is to provide the most predictable, most cost-effective treatment that will satisfy the patient's anatomical needs and personal desires. In the completely edentulous patient, a removable implant-supported prosthesis offers several advantages over a fixed-implant restoration (Box 5-1).

Box 5-1 Advantages of Removable Implant-Supported Prostheses in the Completely Edentulous Patient

- Facial esthetics can be enhanced with labial flanges and denture teeth compared with customized metal or porcelain teeth. The labial contours of the removable restoration can replace lost bone width and height and support the labial soft tissues without hygienic compromise.
- The prosthesis can be removed at night to manage nocturnal parafunction.
- Fewer implants may be required.
- Less bone augmentation may be necessary before implant insertion.
- Shorter treatment if no bone augmentation is required.
- The treatment may be less expensive for the patient.
- Long-term treatment of complications is facilitated.
- Daily home care is easier.

WWW.HIGHDENT.IR
انجمن پروتزسازان و دندانپزشکان

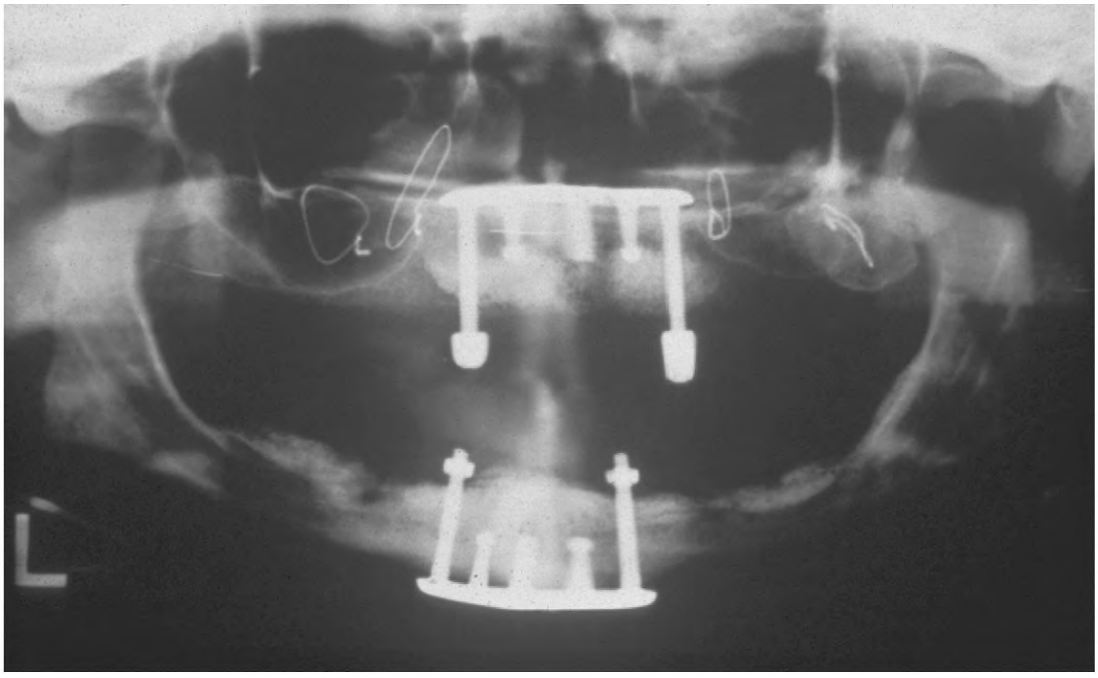

Figure 5-1 The dentist should select the implant type and position after determining a clear indication for a prosthesis. The final restoration, not the implant type and position, should be determined first. The patient wanted a fixed restoration in the maxilla and mandible. The surgeon only used one implant type (a mandibular staple implant). As a consequence, the patient was forced to accept the overdenture in the mandible with soft tissue support in the posterior region (a hydroxyapatite graft was used that increased the soft tissue trauma and risk of paresthesia in the mandible). The mandibular staple also was used in the maxilla, which required a LeFort I (downfracture) procedure. The maxillary abutments are in the middle of the palate. The consequence of the maxillary procedure was sloughing and loss of the maxilla.

However, some completely edentulous patients require a fixed restoration because of desire or because their oral condition makes the fabrication of teeth difficult if a superstructure and removable prosthesis are planned. For example, when the patient has abundant bone and implants have already been placed, the lack of crown height space may not permit a removable prosthesis.[2]

Too often, treatment plans for completely edentulous patients consist of a maxillary denture and a mandibular overdenture with two implants. However, in the long term, this treatment option may prove a disservice to the patient. The maxillary arch will continue to lose bone, and the bone loss may even be accelerated in the premaxilla.[3,4] Once this dimension is lost, the patient will have much more difficulty with retention and stability of the restoration. In addition, the lack of posterior implant support in the mandible will allow posterior bone loss to continue.[5] Paresthesia, facial changes, and reduced posterior occlusion on the maxillary prosthesis are to be expected. The doctor should diagnose the amount of bone loss and its consequences on facial esthetics, function, and the psychological and overall health. Patients should be made aware of future compromises in bone loss and its associated problems with minimal treatment options, which do not address the continued loss of bone in regions where implants are not inserted.

It is even more important to visualize the final restoration at the onset with a fixed-implant restoration. After this first important step, the individual areas of ideal or key abutment support are determined to assess whether it is possible to place the implants to support the intended prosthesis. The patient's force factors and bone density in the region of implant support are evaluated. The additional implants to support the expected forces on the prosthesis designed may then be determined with implant size and design selected to match force and area conditions. Only then is the available bone evaluated to assess whether it is possible to place the implants to support the intended prosthesis. In inadequate natural or implant abutment situations, the existing oral conditions or the needs and desires of the patient must be altered. In other words, either the mouth must be modified by augmentation to place implants in the correct anatomical positions, or the mind of the patient must be modified to accept a different prosthesis type and its limitations. A fixed-implant restoration may be indicated for either the partially or the completely edentulous patient. The psychological advantage of fixed teeth is a major benefit, and edentulous patients often feel the implant teeth are better than their own. The improvement over their removable restoration is significant.

The completely implant-supported overdenture requires the same number of implants as a fixed-implant restoration. Thus the cost of implant surgery may be similar for fixed or removable restorations. Fixed prostheses often last longer than overdentures, because

WWW.HIGHDENT.IR

Box 5-2 Advantages of Fixed Restorations in the Partially Edentulous Patient

1. Psychological (feels more like natural teeth)
2. Less food entrapment
3. Less maintenance (no attachments to change or adjust)
4. Longevity (lasts the life of the implants)
5. Similar overhead cost as completely implant-supported overdentures

Table 5-1 Prosthodontic Classification

TYPE	DEFINITION
FP-1	Fixed prosthesis; replaces only the crown; looks like a natural tooth
FP-2	Fixed prosthesis; replaces the crown and a portion of the root; crown contour appears normal in the occlusal half but is elongated or hypercontoured in the gingival half
FP-3	Fixed prosthesis; replaces missing crowns and gingival color and portion of the edentulous site; prosthesis most often uses denture teeth and acrylic gingiva, but may be porcelain to metal
RP-4	Removable prosthesis; overdenture supported completely by implant
RP-5	Removable prosthesis; overdenture supported by both soft tissue and implant

From Misch CE: Bone classification training keys, *Dent Today* 8:39-44, 1989.

attachments do not require replacement and acrylic denture teeth wear faster than porcelain to metal.[6] The chance of food entrapment under a removable overdenture is often greater than for a fixed restoration, as soft tissue extensions and support are often required in the latter. The laboratory fees for a fixed prosthesis may be similar to a bar, coping attachments, and overdenture. Because the denture or partial denture fees are much less than fixed prostheses, many clinicians charge the patient a much lower fee for removable overdentures on implants. Yet chair time and laboratory fees are often similar for fixed or removable restorations that are completely implant supported. One should consider increasing the patient fees for overdentures to a level more in line with fixed restorations.

PARTIALLY EDENTULOUS PROSTHESIS DESIGN

A common axiom in traditional prosthodontics for partial edentulism is to provide a fixed partial denture whenever applicable.[7,8] The fewer natural teeth missing, the better the indication for a fixed partial denture. This axiom also applies to implant prostheses in the partially edentulous patient. Ideally, the fixed partial denture is completely implant supported rather than joining implants to teeth. This concept leads to the use of more implants in the treatment plan. Although this may be a cost disadvantage, it is outweighed by significant intraoral health benefits. The added implants in the edentulous site result in fewer pontics, more retentive units in the restoration, and less stress to the supporting bone. As a result, complications are minimized and implant and prosthesis longevity are increased (Box 5-2).

PROSTHETIC OPTIONS

In 1989, Misch proposed five prosthetic options for implant dentistry[9,10] (Table 5-1). The first three options are fixed prostheses (FPs). These three options may replace partial (one tooth or several) or total dentitions and may be cemented or screw retained. They are used to communicate the appearance of the final prosthesis to all the implant team members. These options depend on the amount of hard and soft tissue structures replaced and the aspects of the prosthesis in the esthetic zone. Common to all fixed options is the inability of the patient to remove the prosthesis. Two types of final implant restorations are removable prostheses (RPs); they depend on the amount of implant support, not the appearance of the prosthesis.

Fixed Prostheses

FP-1

An FP-1 is a fixed restoration and appears to the patient to replace only the anatomical crowns of the missing natural teeth. To fabricate this restoration type, there must be minimal loss of hard and soft tissues. The volume and position of the residual bone must permit ideal placement of the implant in a location similar to the root of a natural tooth. The final restoration appears very similar in size and contour to most traditional fixed prostheses used to restore or replace natural crowns of teeth (Figure 5-2).

The FP-1 prosthesis is most often desired in the maxillary anterior region, especially in the esthetic zone during smiling or speaking. The final FP-1 restoration appears to the patient to be similar to a crown on a natural tooth. However, the implant abutment can rarely be treated exactly as a natural tooth prepared for a full crown. The cervical diameter of a maxillary central incisor is approximately 6.5 mm with an oval to triangular cross section. However, the implant abutment is usually 4 mm in diameter and round in cross section. In addition, the placement of the implant rarely corresponds exactly to the crown-root position of the original

WWW.HIGHDENT.IR

A B

Figure 5-2 **A,** An implant is positioned in the maxillary right canine position. The hard and soft tissue conditions are ideal for a crown of normal contour and size. **B,** The maxillary right canine implant crown in position. The soft tissue drape is similar to a natural tooth, and the crown contour is similar to the clinical crown contour of a natural tooth. This is the goal of an FP-1 prosthesis.

tooth. The thin labial bone lying over the facial aspect of a maxillary anterior root remodels after tooth loss and the crest width shifts to the palate, decreasing 40% within the first 2 years.[11] The occlusal table is also usually modified in unesthetic regions to conform to the implant size and position and to direct vertical forces to the implant body. For example, posterior mandibular implant-supported prostheses have narrower occlusal tables at the expense of the buccal contour, because the implant is smaller in diameter and placed in the central fossa region of the tooth[12] (Figure 5-3).

Because the width or height of the crestal bone is frequently lacking after the loss of multiple adjacent natural teeth, bone augmentation is often required before implant placement to achieve natural-looking crowns in the cervical region (Figure 5-4). There are no interdental papillae in edentulous ridges; therefore soft tissue augmentation also is often required to improve the interproximal gingival contour. Ignoring this step causes open "black" triangular spaces (where papillae should usually be present) when the patient smiles. FP-1 prostheses are especially difficult to achieve when more than two adjacent teeth are missing. The bone loss and lack of interdental soft tissue complicate the final esthetic result, especially in the cervical region of the crowns.

The restorative material of choice for an FP-1 prosthesis is porcelain to noble-metal alloy. A noble-metal substructure can easily be separated and soldered in case of a nonpassive fit at the metal try-in, and noble metals in contact with implants corrode less than nonprecious alloys. Any history of exudate around a subgingival base-metal margin will dramatically increase the corrosion effect between the implant and the base metal. A single-tooth FP-1 crown may use aluminum oxide cores and porcelain crowns, or ceramic abutments and porcelain crowns. However, the risk of fracture may increase with the latter scenario, as impact forces are greater on implants than natural teeth.

Figure 5-3 This full-arch FP-1 prosthesis has posterior crown contours that are narrower than natural teeth, because the implant is smaller in diameter than the tooth. As a general rule, the maxillary arch has reduced lingual contours and the mandibular posterior has reduced buccal contours.

FP-2

An FP-2 fixed prosthesis appears to restore the anatomical crown and a portion of the root of the natural tooth. The volume and topography of the available bone is more apical compared with the ideal bone position of a natural root (1 to 2 mm below the cement-enamel junction) and dictate a more apical implant placement compared with the FP-1 prosthesis. As a result, the incisal edge is in the correct position, but the gingival third of the crown is overextended, usually apical and lingual to the position of the original tooth. These restorations are similar to teeth exhibiting periodontal bone loss and gingival recession (Figure 5-5).

WWW.HIGHDENT.IR

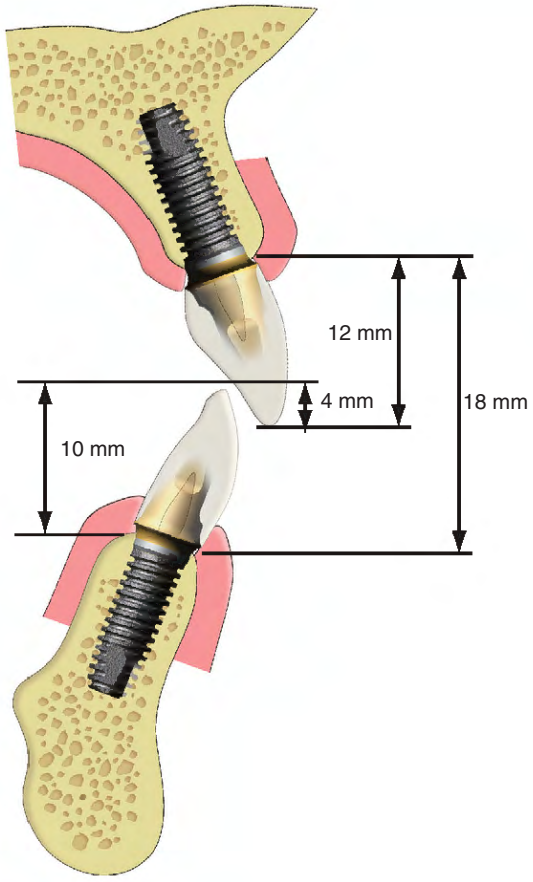

Figure 5-4 The bone and soft tissue must be ideal in volume and position to obtain an FP-1 appearance for the final restoration. When multiple teeth are replaced, bone and tissue augmentation is usually required to obtain an FP-1 prosthesis.

The patient and the clinician should be aware from the onset of treatment that the final prosthetic teeth will appear longer than healthy natural teeth (without bone loss). The esthetic zone of a patient is established during smiling in the maxillary arch and during speech of sibilant sounds for the mandibular arch (Figures 5-6, 5-7). If the high lip line during smiling or the low lip line during speech do not display the cervical regions, the longer teeth are usually of no esthetic consequence, provided that the patient has been informed before treatment (see Figure 5-5, *B*).

As the patient becomes older, the maxillary esthetic zone is altered. Only 10% of younger patients do not show any soft tissue during smiling, whereas 30% of 60 year olds and 50% of 80 year olds do not display gingival regions during smiling (Figure 5-8). The low lip position during speech is not affected as much as the high smile line. Only 10% of older patients show the mandibular soft tissue during speech.[13,14]

A multiple-unit FP-2 restoration does not require as specific an implant position in the mesial or distal position because the cervical contour is not displayed during function. The implant position may be chosen in relation to bone width, angulation, or hygienic considerations rather than purely esthetic demands (as compared with the FP-1 prosthesis). On occasion, the implant may even be placed in an embrasure between two teeth (Figure 5-9). This often occurs for mandibular anterior teeth for full-arch fixed restorations. If this occurs, the most esthetic area usually requires the incisal two thirds of the two crowns to be ideal in width, as though the implant were not present (Figure 5-10). Only the cervical region is compromised. Although the implant is not positioned in an ideal mesiodistal position, it should be placed in the correct facial-lingual position to ensure that contour, hygiene, and direction of forces are not compromised.

The material of choice for an FP-2 prosthesis is precious metal to porcelain. The amount and contour of the metal work is different than for a FP-1 restoration and is more relevant in an FP-2 prosthesis, because the

A B

Figure 5-5 **A,** An FP-2 prosthesis has longer clinical crowns than healthy natural teeth. The soft tissue drape is also reduced around the prosthesis. **B,** The high maxillary lip line during smiling is noted before fabrication of the prosthesis. When the upper lip during smile does not expose any of the interdental papillary regions, an FP-2 prosthesis may be fabricated.

WWW.HIGHDENT.IR

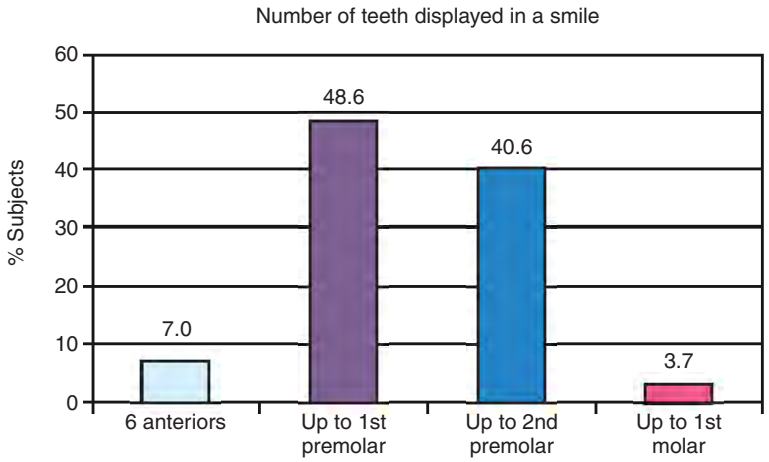

Figure 5-6 The number of teeth observed during a high smile line is variable. Almost 50% of patients display the teeth up to a first premolar. Only 3.7% of patients display the maxillary teeth to the first molar. *(Adapted from Tjan AH, Miller GD, The JG: Some esthetic factors in a smile,* J Prosthet Dent *51:24-28, 1984.)*

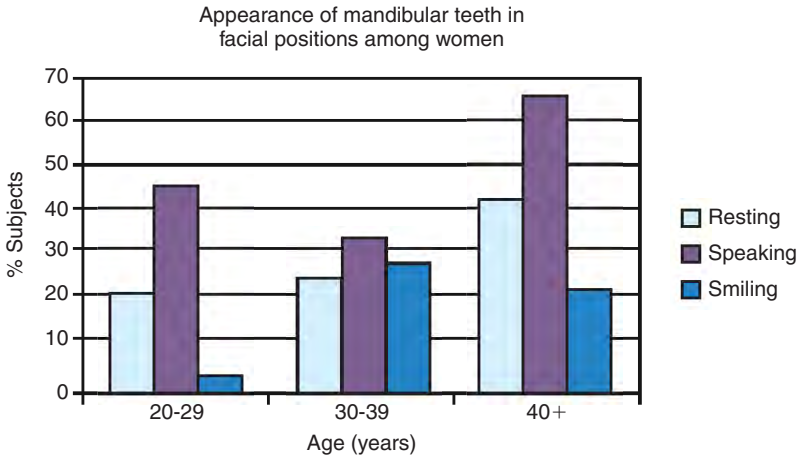

Figure 5-7 The mandibular teeth in the esthetic zone are observed during sibilant sounds, as more teeth show during speech than at rest or smiling. *(Adapted from Cade RE: The role of the mandibular anterior teeth in complete denture esthetics,* J Prosthet Dent *42:368-370, 1979.)*

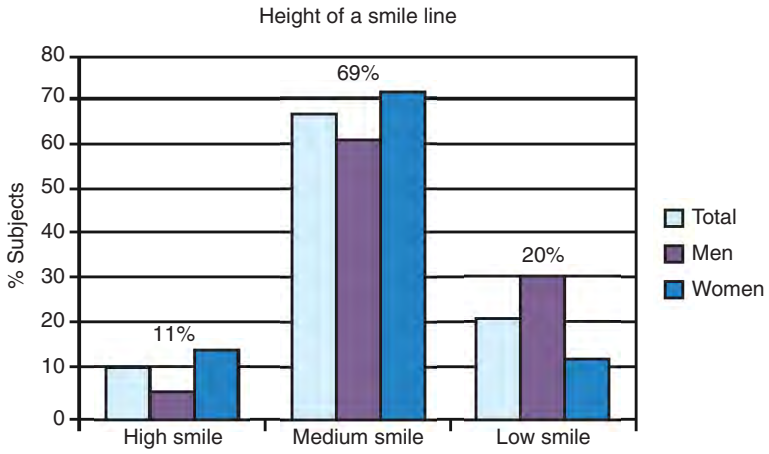

Figure 5-8 A smile that shows interdental papillae but no cervical tissue is ideal and found in 70% of patients. A low smile line shows no soft tissue during smiling and is seen in 20% of patients (more men than women). A high smile line displays interdental papillae and the cervical regions above the teeth and are observed in 11% of patients (more women than men). *(Adapted from Tjan AH, Miller GD, The JG: Some esthetic factors in a smile,* J Prosthet Dent *51:24-28, 1984.)*

amount of additional volume of tooth replacement increases the risk of unsupported porcelain in the final prosthesis, when the metal work is undercontoured.

FP-3

The FP-3 fixed restoration appears to replace the natural teeth crowns and has pink-colored restorative materials to replace a portion of the soft tissue. As with the FP-2 prosthesis, the original available bone height has decreased by natural resorption or osteoplasty at the time of implant placement. To place the incisal edge of the teeth in proper position for esthetics, function, lip support, and speech, the excessive vertical dimension to be restored requires teeth that are unnatural in length. However, unlike the FP-2 prosthesis, the patient may have a normal to high maxillary lip line during smiling

WWW.HIGHDENT.IR

A B

Figure 5-9 **A,** A full-arch maxillary implant prosthesis. Note the maxillary right anterior implant is in an embrasure. **B,** The high smile line of the same patient. The low lip position during smiling permitted the fabrication of an FP-2 prosthesis.

A B

Figure 5-10 **A,** An FP-2 complete mandibular fixed prosthesis from an occlusal view. The anterior teeth appear ideal in width and contour. **B,** The same restoration. or a low mandibular lip line during speech. The ideal high smile line displays the interdental papilla of the maxillary anterior teeth but not the soft tissue above the midcervical regions. Approximately 7% of males and 14% of females have a high smile or "gummy" smile and display more than 2 mm of gingival above the free gingival margin of the teeth.[13]

The patient may also have greater esthetic demands even when the teeth are out of the esthetic smile and speech zones. Patients complain that the display of longer teeth appears unnatural even though they must lift or move their lips in unnatural positions to see the covered regions of the teeth. As a result of the restored gingival color of the FP-3, the teeth have a more natural appearance in size and shape and the pink restorative material mimics the interdental papillae and cervical emergence region. The addition of gingival-tone acrylic or porcelain for a more natural fixed prosthesis appearance is often indicated with multiple implant abutments because bone loss is common with these conditions (Figure 5-11).

There are basically two approaches for an FP-3 prosthesis: (1) a hybrid restoration of denture teeth and acrylic and metal substructure[15] or (2) a porcelain-metal restoration (Figures 5-12 to 5-14; Table 5-2). The primary factor that determines the restoration material is the amount of crown height space.[2,16] An excessive crown height space means a traditional porcelain-metal restoration will have a large amount of metal in the substructure, so the porcelain thickness will not be greater than 2-mm thick. Otherwise there is an increase in porcelain fracture. Precious metals are indicated for implant restorations to decrease the risk of corrosion

WWW.HIGHDENT.IR

A B

Figure 5-11 **A,** An intraoral view of this FP-3 restoration shows how it replaces the interdental papillae with pink porcelain. **B,** The high lip line during smiling shows the interdental papillary regions in the anterior maxilla. The fixed prosthesis should replace the gingival regions in the esthetic zone by soft tissue surgery or with the final restoration (FP-3).

Figure 5-12 An FP-3 prosthesis with pink porcelain on a porcelain-to-metal restoration.

Figure 5-13 An FP-3 prosthesis with pink porcelain on a porcelain-to-metal fixed restoration.

and improve the accuracy of the casting, as nonprecious metals shrink more during the casing process. However, the large amount of metal in the substructure acts as a heat sink and complicates the application of porcelain during the fabrication of the prosthesis. In addition, as the metal cools after casting, the thinner regions of metal cool first and create porosities in the structure. This may lead to fracture of the framework after loading. Furthermore when the casting is reinserted into the oven to bake the porcelain, the heat is maintained within the casting at different rates, thus the porcelain cool-down rate is variable, which increases the risk of porcelain fracture. In addition, the amount of precious metal in the casting adds to the weight and cost of the restoration. An FP-3 porcelain-to-metal restoration is more difficult to fabricate for the laboratory technician than an FP-2 prosthesis. The pink porcelain is harder to make appear as soft tissue and usually requires more baking cycles. This increases the risk of porosity or porcelain fracture.

An alternative to the traditional porcelain-metal fixed prosthesis is a hybrid restoration (see Table 5-2). This restoration design uses a smaller metal framework, with denture teeth and acrylic to join these elements together (Figure 5-15). This restoration is less expensive to fabricate and is highly esthetic because of the premade denture teeth and acrylic pink soft tissue replacements. In addition, the intermediary acrylic between the denture teeth and framework may reduce the impact force of dynamic occlusal loads. The hybrid prosthesis is easier to repair in porcelain fracture, as the denture tooth may be replaced with less risk than adding porcelain to a traditional porcelain-metal restoration. However, the fatigue of acrylic is greater than the traditional prosthesis; therefore repair of the restoration is more commonly needed.

The crown height space determination for a hybrid versus the traditional porcelain-metal restoration is 15 mm from the bone to the occlusal plane. When

WWW.HIGHDENT.IR

Table 5-2 Comparison of Porcelain-to-Metal versus Hybrid Prostheses (FP-3)

CONSIDERATION	PORCELAIN -METAL	HYBRID
Occlusal vertical dimension	≤15 mm	≥15 mm
Technique	Same	Same

Hygiene	Same	Same
Complications	Same	Same
Aging of materials	Less	More

less than this dimension is available, a porcelain-to-metal restoration is suggested. When a greater crown height space is present, a hybrid restoration is often fabricated.

Implants placed too facial, lingual, or in embrasures are easier to restore when vertical bone has been lost and an FP-2 or FP-3 prosthesis is fabricated, because even extremely high smile lip lines do not expose the

Figure 5-16 **A,** An RP-4 restoration is a removable prosthesis (usually an overdenture) that is completely implant supported. In this patient, the mandibular restoration has five implants between the mental foramina and a cantilevered bar to the posterior regions. The prosthesis is rigid and therefore requires attention to implant position and an implant number similar to an FP-3 restoration. **B,** A maxillary denture opposing an RP-4 overdenture in the mandible.

implant abutments. The greater crown heights allow the correction of incisal edge positions. However, the FP-2 or FP-3 restoration has greater crown height compared with the FP-1 fixed types of prostheses; therefore a greater moment of force is placed on the implant cervical regions, especially during lateral forces (e.g., mandibular excursions or with cantilevered restorations). As a result, additional implant abutments or shorter cantilever lengths should be considered with these restorations.

An FP-2 or FP-3 prosthesis rarely has the patient's interdental papillae or ideal soft tissue contours around the emergence of the crowns, because these restorations are used when there is more crown height space and the lip does not expose the soft tissue regions of the patient. In the maxillary arch, wide open embrasures between the implants may cause food impaction or speech problems. These complications may be solved by using a removable soft tissue replacement device or making overcontoured cervical restorations. The maxillary FP-2 or the FP-3 prosthesis is often extended or juxtaposed to the maxillary soft tissue so that speech is not impaired. Hygiene is more difficult to control, although access next to each implant abutment is provided.

The mandibular restoration may be left above the tissue, similar to a sanitary pontic. This facilitates oral hygiene in the mandible, especially when the implant permucosal site is level with the floor of the mouth and the depth of the vestibule. However, if the space below the restoration is too great, the lower lip may lack support in the labiomental region.

Removable Prostheses

There are two kinds of removable prostheses, based upon support of the restoration (see Table 5-1). Patients are able to remove the restoration, but not the implant-supported superstructure attached to the abutments. The difference in the two categories of removable restorations is not in appearance (as it is in the fixed categories). Instead, the two removable categories are determined by the amount of implant support.[17] The most common removable implant prostheses are overdentures for completely edentulous patients. Traditional removable partial dentures with clasps on implant abutment crowns have not been reported in the literature with any frequency. No long-term or short-term studies are currently available. On the other hand, complete removable overdentures have often been reported with predictability.[6,18-22] As a result, the removable prosthetic options are primarily overdentures for the completely edentulous patient.

RP-4

RP-4 is a removable prosthesis completely supported by the implants, teeth, or both. The restoration is rigid when inserted: overdenture attachments usually connect the removable prosthesis to a low-profile tissue bar or superstructure that splints the implant abutments. Usually five or six implants in the mandible and six to eight implants in the maxilla are required to fabricate completely implant-supported RP-4 prostheses in patients with favorable dental criteria (Figure 5-16).

The implant placement criteria for an RP-4 prosthesis is different than that for a fixed prosthesis. Denture teeth more acrylic are required for the removable restoration. In addition, a superstructure and overdenture attachments must be added to the implant abutments. This requires a more lingual and apical implant placement in comparison with the implant position for a fixed prosthesis. The implants in an RP-4 prosthesis

WWW.HIGHDENT.IR

Figure 5-17 Intraoral view of three mandibular implants inserted between the foramina. A bar connects the implants and can support an RP-5 mandibular overdenture. Soft tissue support of the restoration is required in the posterior regions because the implant position and number are not conducive to a completely implant-supported prosthesis.

(and an FP-2 or FP-3 restoration) should be placed in the mesiodistal position for the best biomechanical and hygienic situation. On occasion, the position of an attachment on the superstructure or prosthesis may also affect the amount of spacing between the implants. For example, a Hader clip requires the implant spacing to be greater than 6 mm from edge to edge, and as a consequence reduces the number of implants that may be placed between the mental foramina. The RP-4 prosthesis may have the same appearance as an FP-1, FP-2, or FP-3 restoration. A porcelain-to-metal prosthesis with attachments in selected abutment crowns can be fabricated for patients with the cosmetic desire of a fixed prosthesis. The overdenture attachments permit improved oral hygiene or allow the patient to sleep without the excess forces of nocturnal bruxism on the prosthesis.

RP-5

RP-5 is a removable prosthesis combining implant and soft tissue support. The amount of implant support is variable. The completely edentulous mandibular overdenture may have: (1) two anterior implants independent of each other; (2) splinted implants in the canine region to enhance retention; (3) three splinted implants in the premolar and central incisor areas to provide lateral stability; or (4) implants splinted with a cantilevered bar to reduce soft tissue abrasions and to limit the amount of soft tissue coverage needed for prosthesis support. The primary advantage of an RP-5 restoration is the reduced cost. The prosthesis is very similar to traditional overdentures supported by natural teeth (Figure 5-17).

A preimplant treatment denture may be fabricated to ensure the patient's satisfaction. This technique is especially indicated for patients with demanding needs and desires regarding the final esthetic result. The implant dentist can also use the treatment denture as a guide for implant placement. The patient can wear the prosthesis during the healing stage. After the implants are uncovered, the superstructure is fabricated within the guidelines of the existing treatment restoration. Once this is achieved, the preimplant treatment prosthesis may be converted to the RP-4 or RP-5 restoration.

The clinician and the patient should realize that the bone will continue to resorb in the soft tissue–borne regions of the prosthesis. Relines and occlusal adjustments every few years are common maintenance requirements of an RP-5 restoration. Bone resorption with RP-5 restorations may occur two to three times faster than the resorption found with full dentures.[5] This can be a factor when considering this type of treatment in young patients, despite the lesser cost and low failure rate.

SUMMARY

In traditional dentistry, the restoration reflects the existing condition of the patient. Existing natural abutments are first evaluated, and a removable or fixed restoration is fabricated accordingly. Implant dentistry is unique because additional foundation units may be created for a desired prosthodontic result. Therefore both the psychological and anatomical needs and desires of the patient should be determined. The prosthesis that satisfies these goals and eliminates the existing problems may then be designed. The prosthesis may be fixed or removable for the completely edentulous patient, whereas fixed restorations are planned for most partially edentulous patients.

If only one implant approach is used for all patients, the same surgical and prosthetic scenarios and flaws are invariably repeated. For example, if a traditional fixed mandibular staple bone plate is used on all edentulous mandibles, not only are the implant and surgery similar regardless of intraoral or extraoral conditions, but an RP-5 prosthesis will usually result despite the patient's needs and desires.

The benefits of implant dentistry can be realized only when the prosthesis is first discussed and determined. An organized treatment approach based on the prosthesis permits predictable therapy results. Five prosthetic options are available in implant dentistry. Three restorations are fixed and vary in the amount of hard and soft tissue replaced; two are removable and are based on the amount of support for the restoration (Figures 5-18, 5-19). The amount of support required for an implant prosthesis should initially be designed similar to traditional tooth-supported restorations. Once the intended prosthesis is designed, the implants and treatment surrounding this specific result can be established.

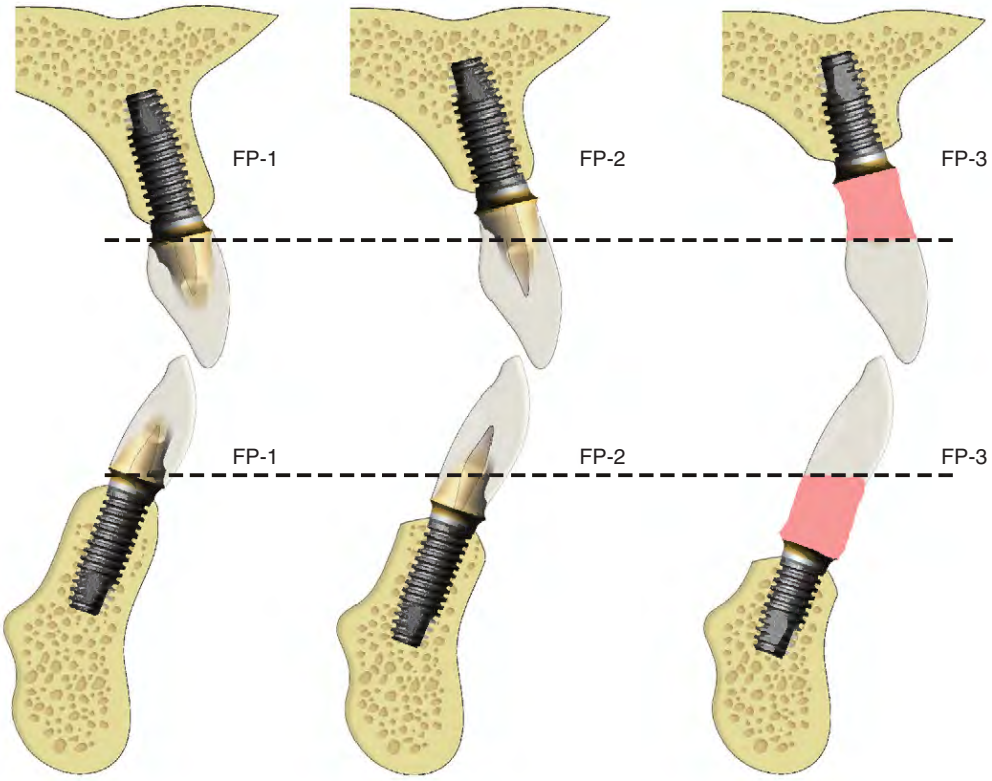

Figure 5-18 Fixed restorations have three categories: FP-1, FP-2, and FP-3. The restoration type is related to the contour of the restoration. (FP-1 is ideal, FP-2 is hypercontoured, and FP-3 replaces the gingiva drape with pink porcelain or acrylic.) The difference between FP-2 and FP-3 most often is related to the high maxillary lip position during smiling or the mandibular lip position during sibilant sounds of speech. FP-2 and FP-3 restorations often require more implant surface area support by increasing implant number or size or by adjusting design considerations.

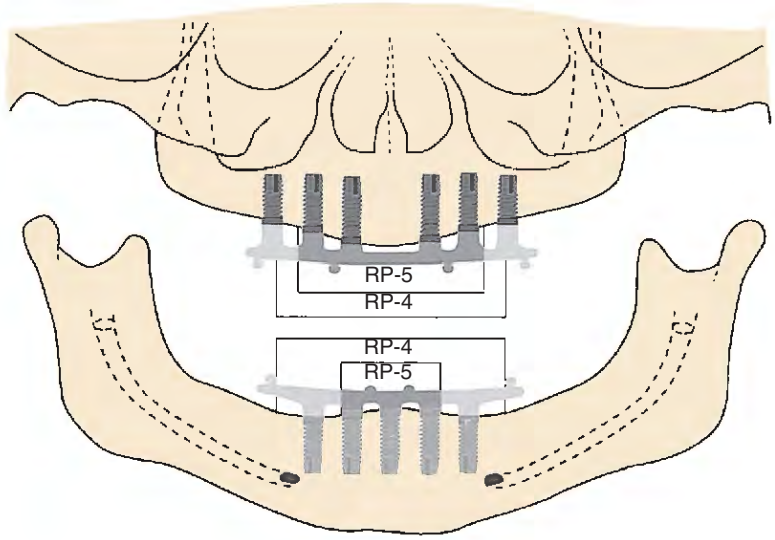

Figure 5-19 Removable restorations have two categories based on implant support. RP-4 prostheses have complete implant support anterior and posterior. In the mandible the superstructure bar often is cantilevered from implants positioned between the foramina. The maxillary RP-4 prosthesis usually has more implants and little to no cantilever. An RP-5 restoration has primarily anterior implant support and posterior soft tissue support in the maxilla or mandible. Often fewer implants are required and bone grafting is less indicated.

Chapter 6

Treatment Planning: Force Factors Related to Patient Conditions

Carl E. Misch

Biomechanical stress is a significant risk factor in implant dentistry. Its magnitude is directly related to force. As a result, an increase in any dental force factor magnifies the risk of stress-related complications. Different patient conditions place different amounts of force in magnitude, duration, type, and direction. In addition, several factors may multiply or increase the effect of these other conditions. Once the prosthesis option and key implant positions are determined, the potential force levels that will be exerted on the prosthesis should be evaluated and accounted for in order to modify the overall treatment plan. Several elements observed during the dental evaluation predict additional forces on future implant abutments. The initial implant survival, loading survival, marginal crestal bone loss, incidence of abutment or prosthetic screw loosening, and unretained restorations, porcelain fracture, and component fracture are all influenced by the force factors.

Box 6-1 includes primary patient factors affecting the stress environment of the implant and prosthesis.

NORMAL BITE FORCE

The greatest *natural* forces exerted against teeth, and thus against implants, occur during mastication.[1,2] These forces are primarily perpendicular to the occlusal plane in the posterior regions, are of short duration, occur only during brief periods of the day, and range from 5 to 44 lb for natural teeth. The actual force on each tooth during function has been recorded on strain gauges in inlays.[3] A force of 28 psi was needed to chew a raw carrot, and 21 psi was needed to chew meat. The actual time during which chewing forces are applied on the teeth is about 9 minutes each day.[4] The perioral musculature and tongue exert a more constant, yet lighter horizontal force on the teeth or on implants. These forces reach 3 to 5 psi during swallowing.[5] A person swallows 25 times per hour while awake and 10 times per hour while sleeping, for a total of 480 times each day.[4] Therefore natural forces against teeth are primarily in their long axis, less than 30 psi, and for less than 30 minutes for all normal forces of deglutition and mastication (Box 6-2). Forces of mastication placed on implant-supported bridges have been measured in a similar range as natural teeth.

The maximum bite force differs from mastication force, varies widely among individuals, and depends on the state of the dentition and masticatory musculature. There have been many attempts to quantify the normal maximum bite force. In 1681, Borelli suspended weights on a thread over the molars while the mandible was open. The maximum load recorded for which the person was still able to close ranged from 132 to 440 lb. A force

of 165 lb was recorded on a gnathodynamometer, the first instrument to record occlusal force, which was developed by Patrick and Dennis in 1892. Black improved this early design and recorded average forces of approximately 170 lb.[6] More recent studies indicate normal maximum vertical biting forces on teeth or implants can range from 45 to 550 psi.[7-22] The forces on the chewing side and the opposite side appear very similar in amplitude[8] (Table 6-1).

It should be emphasized that the maximum bite forces are not expressed by our patients in any routine fashion. However, there are conditions that increase our risks of occlusal overload on the implant prosthesis. Most noteworthy are the parafunctional forces of bruxism and clenching.

PARAFUNCTION

Parafunctional forces on teeth or implants are characterized by repeated or sustained occlusion and have long been recognized as harmful to the stomatognathic system.[23-25] These forces are also most damaging when applied to implant prostheses.[18] The lack of rigid fixation during healing is often a result of parafunction on soft tissue–borne prostheses overlying the submerged implant. The most common cause of both early and late implant failure after successful surgical fixation is the result of parafunction. Such complications occur with greater frequency in the maxilla, because of a decrease in bone density and an increase in the moment of force.[26] The presence of these conditions must be carefully noted during the early phases of treatment planning.

Nadler has classified the causes of parafunction or nonfunctional tooth contact into the following six categories[24]:

1. Local
2. Systemic
3. Psychological
4. Occupational
5. Involuntary
6. Voluntary

Local factors include tooth form or occlusion, as well as soft tissue changes such as ulcerations or pericoronitis. Systemic factors include cerebral palsy, epilepsy, and drug-related dyskinesia. Psychological causes occur with the greatest frequency and include the release of emotional tension or anxiety.[27] Occupational factors concern professionals such as dentists, athletes, and precision workers, as well as the seamstress or musician

WWW.HIGHDENT.IR

who develops altered oral habits. The fifth cause of parafunctional force is involuntary movement that provokes bracing of the jaws, such as during lifting of heavy objects or sudden stops while driving. Voluntary causes include chewing gum or pencils, bracing the telephone between the head and shoulder, and pipe smoking.

The parafunctional groups presented in this chapter are divided into bruxism, clenching, and tongue thrust or size. The dental literature usually does not identify bruxism and clenching as separate entities. Although several aspects of treatment are similar, their diagnosis and treatment are in some ways different. As such, they will be presented as different entities in this discussion. The magnitude of parafunction may be categorized as absent, mild, moderate, or severe. Bruxism and clenching are the most critical factors to evaluate in any implant reconstruction. No long-term success will be obtained with severe parafunction of bruxism or clenching. Therefore the dentist should always try to diagnose the presence of these conditions.

This does not mean that patients with moderate and severe parafunction cannot be treated with implants. A physician treats a patient with uncontrolled diabetes. However, the patient may lose their vision or need their feet amputated, despite treatment, Unsuccessful treatment of the diabetic may not be the fault of the physician. Not recognizing diabetes in the presence of obvious signs and symptoms, of course, is another issue. Because the patient with moderate to severe parafunction represents so many additional risks in implant dentistry, one must be aware of these conditions and the methods to reduce their noxious effects on the entire implant-related system.

Bruxism

Bruxism primarily concerns the horizontal, nonfunctional grinding of teeth. The forces involved are in significant excess of normal physiologic masticatory loads. Bruxism may affect the teeth, muscles, joints, bone, implants, and prostheses. These forces may occur while the patient is awake or asleep and may generate increased force on the system several hours per day. Bruxism is the most common oral habit.[25] Sleep clinic studies have evaluated nocturnal bruxism and found approximately 10% of those observed had obvious movement of the mandible with occlusal contacts.[28,29] More than half of these patients had tooth wear affecting esthetics. Only 8% of these patients were aware of their nocturnal bruxism, and only one quarter of the patients' spouses were aware of the nocturnal habit. Muscle tenderness in the morning was observed less than 10% of the time.[30] A study on bruxing patients with implants showed 80% of sleep bruxism occurred during light sleep stages but did not cause arousal.[31] Therefore patients with bruxism may or may not have obvious tooth wear affecting esthetics; may brux nocturnally, but their bed partners do not know most of the time; rarely have muscle tenderness when they are awake; and are usually unaware of their oral habit. In other words, nocturnal bruxism is sometimes difficult to diagnose.[32]

The maximum biting force of bruxing patients is greater than average. Just as an experienced weight-lifter can lift more weight, the patient constantly exercising the muscles of mastication develops a greater bite force. A man who chews paraffin wax for an hour each day for a month can increase the bite force from 118 to 140 psi within 1 week. Chewing gum, bruxism, and clenching may accomplish the same feat. Eskimos, with a very tenacious diet and who chew their leather to soften it before fabrication of clothing, have maximum bite forces above 300 psi. A 37-year-old patient with a long history of bruxism recorded a maximum bite force of more than 990 psi (four to seven times normal).[33] Fortunately, the bite force does not continue to increase in most bruxing patients. When muscles do not vary their exercise regimen, their size and function adjust to the dynamics of the situation. As a result, the higher bite forces and muscle size usually do not continue in an unending spiral.

Diagnosis

Bruxism does not necessarily represent a contraindication for implants, but it does dramatically influence treatment planning. The first step is to recognize the condition before the treatment is rendered. The symptoms of this disorder, which may be ascertained by a dental history, may include repeated headaches, a history of fractured teeth or restorations, repeated uncemented restorations, and jaw discomfort upon awakening.[23,34] Therefore when the patient is aware of muscle tenderness or the spouse is conscious of the nocturnal condition, the diagnosis is readily obtained. However, many patients do not attribute these problems to excessive forces on the teeth and report a negative history. A lack of these symptoms does not negate bruxism as a possibility.

Fortunately many clinical signs warn of excessive grinding. The signs of bruxism include an increase in size of the temporal and masseter muscles (these muscles and the external pterygoid may be tender), deviation of the lower jaw on opening, limited occlusal opening, increased mobility of teeth, cervical abfraction of teeth, fracture of teeth or restorations, and uncemented crowns or fixed prostheses. However, the best and easiest way to diagnose bruxism is to evaluate the wearing of teeth. Not only is this the easiest method to determine bruxism in an individual patient, it also allows the disorder to be classified as absent, mild, moderate, or severe (Figures 6-1 to 6-3). No anterior wear patterns in the teeth signify an absence of bruxism. Mild bruxism has slight wearing of anterior teeth but is not a cosmetic compromise. Moderate bruxism has obvious anterior

WWW.HIGHDENT.IR

Figure 6-1 This patient has mild bruxism. Note the wear facet on the mandibular canine and the slight notch in the maxillary lateral incisor.

Figure 6-2 Patients often grind their teeth in a specific, repeated movement of the mandible. When the opposing wear facets of the teeth are in contact, one should note the occlusal position of the teeth. The patient shown in Figure 6-1 has a working contact on the mandibular premolar with the maxillary canine in this engram position. The slight cervical abfraction of the mandibular first premolar is a consequence of the parafunction. The patient's posterior teeth should not occlude in this position to decrease the amount of force on the anterior teeth.

incisal wear facets but no posterior occlusal wear pattern. Severe bruxism has absent incisal guidance from excessive wear, and posterior wearing of the teeth is obvious.

Nonfunctional wear facets on the incisal edges may occur on both natural or replacement teeth, especially in the mandible and maxillary canines, and there may be notching of the cingulum in the maxillary anterior teeth. Isolated anterior wear is not much of a concern if all posterior teeth contacts can be eliminated in excursions.

Figure 6-3 This patient has severe bruxism because occlusal wear is anterior and posterior. The incisal guidance should be reestablished before a maxillary arch fixed reconstruction.

Figure 6-4 This patient exhibits an engram pattern of bruxism primarily toward the left canine to central incisors. The right canine and lateral incisor have far fewer wear facets. This "pathway of destruction" is specific.

Tooth wear is most significant when found in the posterior regions and changes the intensity of bruxism from the moderate to the severe category. Posterior wear patterns are more difficult to manage, because this usually is related to a loss of anterior guidance in excursions; once the posterior teeth contact in excursive jaw positions, greater forces are generated.[35] The masseter and temporalis muscles contract when posterior teeth contact. With incisal guidance and an absence of posterior contact, two thirds of these muscles do not contract and, as a consequence, the bite force is dramatically reduced. However, when the posterior teeth maintain contact, the bite forces are similar in excursions, as during posterior biting. Therefore in the patient with severe bruxism, the occlusal plane, the anterior incisal guidance, or both may need modification to eliminate all posterior contacts during mandibular excursions before the implant restoration.

Bruxing patients often repeat mandibular movements, which are different from border movements of the mandible and are in one particular direction. As a result, the occlusal wear is very specific and primarily on one side of the arch, or even on only a few teeth (Figure 6-4).

WWW.HIGHDENT.IR

This engram pattern usually remains after treatment. If the restoring dentist reestablishes incisive guidance on teeth severely affected by an engram bruxing pattern, the incidence of complications on these teeth will be increased. The most common complications on teeth restored in this "pathway of destruction" are porcelain fracture, uncemented prostheses, and root fracture.[34] When implants support the crowns in the pathway of destruction, the implant may fail, fracture, or have crestal bone loss, abutment screw loosening, porcelain fracture, or unretained restorations.[36-39] If the patient continues the severe bruxism pattern, the question is not whether, but when and which complications will occur. The dentist should tell the patient that these habits will cause these problems. Treatment may be rendered to repair these problems, but there will be complications if the bruxism is not reduced.

Bruxism changes normal masticatory forces by the magnitude (higher bite forces), duration (hours rather than minutes), direction (lateral rather than vertical), type (shear rather than compression), and magnification (four to seven times normal).[33,40-42] The method to restore severe bruxism may be problematic, even when the desire is primarily cosmetic. As the anterior teeth wear, they often erupt and the overall occlusal vertical dimension remains unchanged. In addition, the alveolar process may follow the eruption of the tooth. As such, when the anterior teeth are restored for esthetics (or to obtain an incisal guidance), the reduced crown height cannot be increased merely by increasing the height of the crown to an average dimension. Instead, the following guidelines are suggested:

1. Determine the position of the maxillary incisor edge of the anterior teeth. They may be acceptable (if eruption occurred as they wore) or need greater coronal length to correct related incisal wear.
2. Determine the desired occlusal vertical dimension. This is not an exact dimension and may exist at several different positions without consequence. However, like most factors, there is a range that is patient specific and does follow guidelines. The most common methods to determine this dimension relate to facial measurements, closest speaking space, physiologic rest position, speech, and esthetics. This is one of the most important steps. If the vertical dimension is collapsed because of anterior and posterior occlusal wear, much more rehabilitation is required. This condition is observed more often when bruxism is severe, the anterior incisal guidance was lost, and, as a consequence, the severe bruxism wear is increased due to an increase in force factors. The accelerated occlusal wear may cause a loss of occlusal vertical dimension (OVD). The OVD is rarely decreased when incisal guidance is still present, as the posterior teeth maintain the dimension and the anterior teeth have time to erupt because the forces are less and the wear rate is slower.
3. Evaluate and restore the position of the lower anterior teeth where necessary. In the past, several authors have stated that a reconstruction begins with the lower anterior teeth. The mandibular arch cannot be restored until the maxillary anterior teeth and occlusal vertical dimension are established. Many esthetic and speech guidelines are available to help the restoring dentist with the position of the maxillary anterior teeth. For example, when a dentist begins the restoration of a completely edentulous patient, the maxillary anterior wax rim position is often first determined, for similar reasons.

The position of the lower anterior teeth should contact the lingual surfaces of the maxillary anterior teeth at the established occlusal vertical dimension, and the amount of vertical overlap of the maxillary incisal edge and the angle of the incisal contacts in protrusive movements of the mandible determines the angle and height of the anterior guidance. This dimension must be greater than the condylar disc assembly (the angle of the eminentia) so the posterior teeth will separate during mandibular excursions.

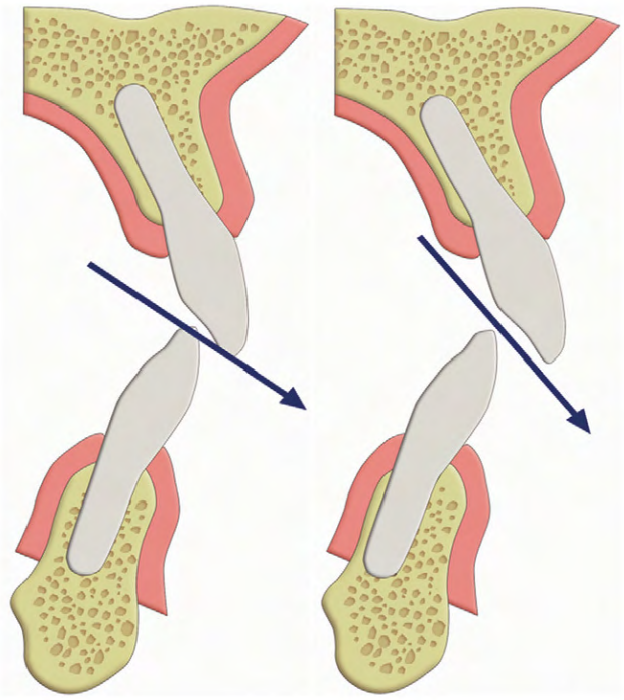
In patients with moderate to severe bruxism, the height of the vertical overjet and the angle of incisal guidance should not be extreme, as the amount of the force on the anterior abutments, cement seals, and porcelain is directly related to these conditions (Figure 6-5). In other words, the greater the incisal overjet, the greater the distance between the posterior teeth in excursions, and the greater the force generated on the anterior teeth during this movement. In patients with severe bruxism, the intensity of the force should be reduced, because the duration of the force is increased.

When anterior tooth wear is accompanied by tooth eruption and maintenance of the occlusal vertical dimension, and alveolar bone in the region has extruded toward the incisal plane, the incisal edges of the teeth should not be elevated. Instead, the alveolar bone and cervical regions should be reduced and crown lengthening should be performed on the teeth before their restoration. This is most often necessary in the mandibular anterior region but may be observed in any region of the mouth after long-term severe bruxism. In addition, endodontic therapy may be required to allow proper anterior tooth preparation.

Crown lengthening and associated procedures are not necessary when the vertical dimension has been reduced in relation to the incisal wear. Instead, the teeth may be prepared in their present state. The restoration restores the occlusal vertical dimension and reestablishes anterior incisal guidance.

4. The posterior plane of occlusion s then determined. This may be accomplished by using first the maxillary arch or the posterior mandibular arch.

WWW.HIGHDENT.IR



A B

Figure 6-5 The incisal guidance for a patient with moderate to severe bruxism **(A)** should be shallow to reduce the force on the anterior teeth during excursive movement **(B)** of the mandible.

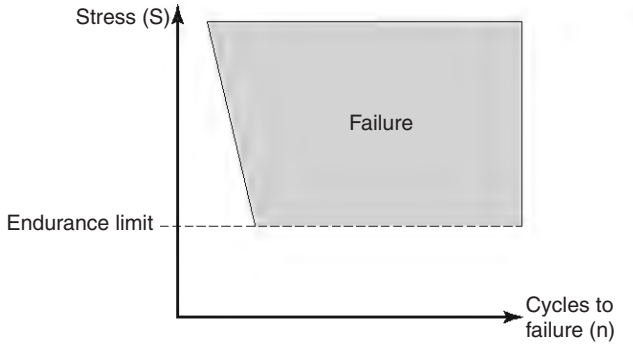


Figure 6-6 On a fatigue curve for a material, stress corresponds to the vertical axis and cycles to failure to the horizontal axis. A point exists at which the stress is so great that the material breaks with only one cycle. When the stress is low enough, the material will not break, regardless of the number of cycles. The stress amount at the highest point of this safe zone is called the en*durance limit*. Patients with parafunction increase the amount of stress to the implant-prosthetic system and increase the number of the cycles for the higher levels. Fatigue failures are therefore common.

However, it is best if the same bilateral posterior quadrants are addressed at the same time, so that the posterior plane may be parallel to the horizontal plane. The maxillary posterior region is most often determined first in the completely edentulous patient.

Fatigue Fractures

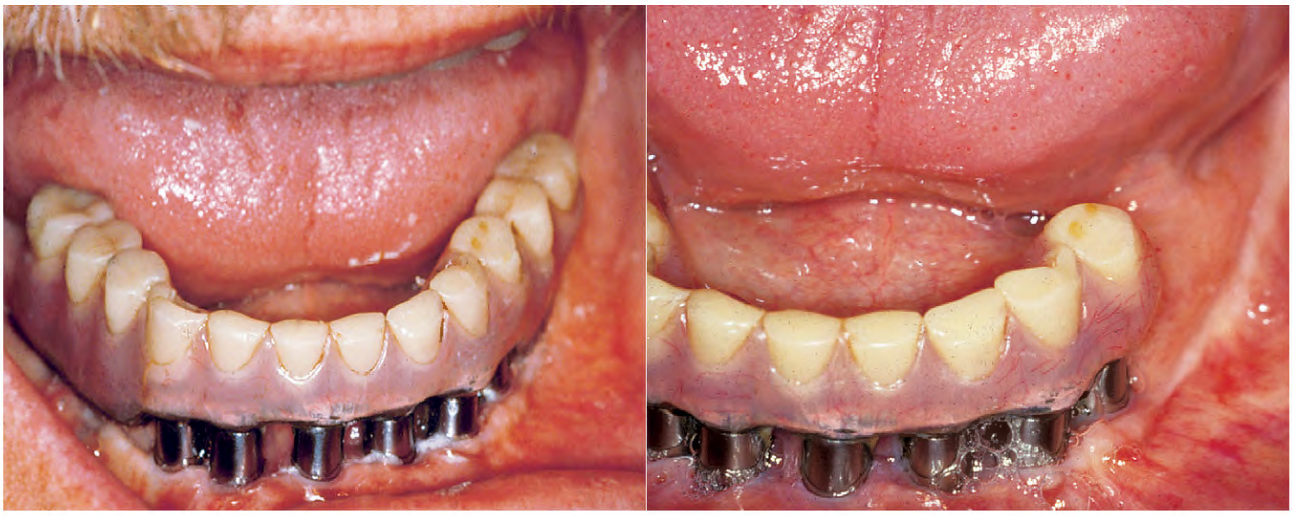
The increase in duration of the force is a considerable problem. Materials follow a fatigue curve, which is affected by the number of cycles and the intensity of the force[43-45] (Figure 6-6). A force can be so great that one cycle causes a fracture (e.g., a karate blow to a piece of wood). However, if a lower force magnitude repeatedly hits an object, the object will still fracture. The wire coathanger that is bent does not break the first time, but repeated bends will fracture the material, not because the last bend was more forceful but because of fatigue. A bruxing patient is at greater risk of fatigue fractures for two reasons. The magnitude of the forces increases over time as the muscles become stronger, and the number of cycles increase on the prosthetic components. Eventually, one of the components (implant, screw, abutment, prosthesis) will break if the parafunction cannot be reduced in intensity or duration (Figure 6-7). No long-term prosthetic result is expected in patients with severe bruxism. Therefore, once the implant dentist has identified the sources of additional force on the implant system, the treatment plan is altered in an attempt to minimize the negative effect on the longevity of the implant, bone, and final restoration. All elements able to reduce stress should be considered.

Occlusal Guards

The cause of bruxism is multifactorial and may include occlusal disharmony.[46] When an implant reconstruction is considered in a bruxing patient, occlusal analysis is warranted. Premature and posterior contacts during mandibular excursions increase stress conditions. An elimination of eccentric contacts may allow recovery of periodontal ligament health and muscle activity within 1 to 4 weeks. Occlusal harmony does not necessarily eliminate bruxism, but this is no reason not to perform an occlusal analysis and eliminate the premature contacts. No study demonstrates an increase in parafunction after occlusal adjustment. Therefore the ability to decrease the risk of occlusal overload on particular teeth and the added benefit of perhaps reducing parafunction is warranted in almost every patient diagnosed with a parafunctional habit of bruxism or clenching.

A night guard can be a useful diagnostic tool to evaluate the influence of occlusal disharmony on nocturnal bruxism. The Michigan night guard exhibits even occlusal contacts around the arch in centric relation occlusion and provides posterior disocclusion with

WWW.HIGHDENT.IR



A B

Figure 6-7 **A,** The patient has a cantilevered hybrid fixed prosthesis in the mandible. Severe bruxism is evident, with anterior and posterior wearing of the teeth. At this point the patient should be informed that the incisal guidance of the restoration should be restored. **B,** The patient from **A** elected not to restore the incisal guidance of the restoration. As a consequence of higher forces with posterior contact during excursions, fatigue failure of the prosthesis occurred.

anterior guidance in all excursions of the mandible.[47] This device may be fabricated with 0.5 to 1 mm colored acrylic resin on the occlusal surface. After 4 weeks of nocturnal wear, if the patient wears this device for an additional month or more, the influence of occlusion on the bruxism may be directly observed. There are no premature contacts while the device is worn; however, if the colored acrylic is still intact, the nocturnal parafunction has been reduced or eliminated.[48] Therefore occlusal reconstruction or modification may proceed. If the colored acrylic on the night guard is ground through, an occlusal adjustment will have little influence on decreasing this parafunctional habit. The night guard is still indicated to relieve stresses during nocturnal parafunction, but the treatment plan should account for the greater forces.

Forces from bruxism are the most difficult to address on a long-term basis. Education and informed consent of the patient are helpful to gain cooperation in eliminating or reducing the noxious effects. If the opposing arch is a soft tissue–supported removable prosthesis, the effects of the nocturnal habit may be minimized if the patient removes the prosthesis at night. The use of a night guard is helpful for a patient with a fixed prosthesis, in order to transfer the weakest link of the system to the removable acrylic device.[49] Centric contacts in centric relation occlusion and anterior-guided disocclusion of the posterior teeth in excursions are strongly suggested on the night guard, which may be designed to fit the maxilla or mandible.

Unlike teeth, implants do not extrude in the absence of occlusal contacts. As a result, in partially edentulous patients, the maxillary night guard can be relieved around the implant crowns so the remaining natural teeth bear the entire load. For example, for a maxillary implant restoration, the night guard is hollow so no occlusal force is transmitted to the implant crown. When the restoration is in the mandible, the occluding surfaces of the maxillary night guard are relieved over the implant crowns so no occlusal force is transmitted to the implants (Figure 6-8).

A mandibular posterior cantilever on a full-arch implant prosthesis may also be taken out of occlusion with a maxillary night guard. When a posterior quadrant of implants supports a fixed prosthesis in the maxilla opposing mandibular teeth, a soft reline material is placed around the implant crowns to act as a stress relief element and decrease the impact force on the restoration (Figure 6-9). When full-arch implant restorations are opposing each other, the night guard provides solely anterior contacts during centric occlusion and mandibular excursions. Thus the parafunctional force is reduced on the anterior teeth/implants and eliminated in the posterior regions.

Treatment Planning

The implant treatment plan is modified primarily in two ways when implants are inserted in the posterior region: (1) additional implants that are wider in diameter are one method used to reduce the overload risk or (2) the

WWW.HIGHDENT.IR

anterior teeth may be modified to recreate the proper incisal guidance and avoid posterior interferences during excursions. The elimination of posterior lateral occlusal contacts during excursive movements is recommended when opposing natural teeth or an implant or tooth-supported fixed prosthesis. This is beneficial in two aspects: (1) because lateral forces dramatically increase stress at the implant-bone interface, the elimination of posterior contacts diminishes the negative effect of angled forces during bruxism; (2) the presence of posterior contacts during excursions, almost all fibers of the masseter, temporalis, and the external pterygoid muscles contract and place higher forces on the anterior teeth/implants. On the contrary, during excursions in the absence of posterior contacts, fewer fibers of the temporalis and masseter muscles are stimulated, and the forces applied on the anterior implant-teeth system are reduced by as much as two thirds.[25]

Figure 6-8 A night guard for a partially edentulous patient restored with implants may be designed to transfer the force to the implant prosthesis. When the implant prosthesis is in the opposing arch to the guard, there are no occludal contacts in centric or during excursion with the guard in place.

Figure 6-9 Full-arch implant prostheses opposing each other may have only anterior occlusal contact in centric and during mandibular excursions with the guard in place.

Clenching

Clenching is a habit that generates a constant force exerted from one occlusal surface to the other without any lateral movement. The habitual clenching position does not necessarily correspond to centric occlusion. The jaw may be positioned in any direction before the static load; therefore a bruxing and clenching combination may exist. The clench position most often is in the same repeated position and rarely changes from one period to another. The direction of load may be vertical or horizontal. The forces involved are in significant excess of normal physiologic loads and are similar to bruxism in amount and duration; however, several clinical conditions differ in clenching.

Diagnosis

Many clinical symptoms and signs warn of excessive grinding. However, the signs for clenching are often less obvious. The forces generated during clenching are directed more vertically to the plane of occlusion, at least in the posterior regions of the mouth. Wearing of the teeth is usually not evident; therefore clenching often escapes notice during the intraoral examination. As a result, the dentist must be more observant to the diagnosis of this disorder.[25,46,49]

Many of the clinical signs of clenching often resemble bruxism. When a patient has a dental history of muscle tenderness upon awakening or tooth sensitivity to cold, parafunction is strongly suspected. In the absence of tooth wear, clenching is the prime suspect. Tooth mobility, muscle tenderness or hypertrophy, deviation during occlusal opening, limited opening, stress lines in enamel, cervical abfraction, and material fatigue (enamel, enamel pits, porcelain and implant components) are all associated clinical signs of clenching. All these conditions may also be found in the bruxing patient. However, enamel wear has such a strong correlation to bruxism that it is the primary and often the only factor needed to evaluate for bruxism. The clenching patient has the "sneaky disease of force." Therefore particular attention is paid to diagnose this disorder from less obvious clinical conditions.

A physical examination for the implant candidate should include palpation of the muscles of mastication. The masseter and temporalis muscles are easily examined at the initial appointment. Hyperactive muscles are not always tender, but tender muscles in the absence of trauma or disease is a sign of excess use or incoordination among muscle groups. The lateral pterygoid muscle is more often overused by the bruxing or clenching patient but is difficult to palpate. The ipsilateral medial pterygoid muscle provides more reliable information in this region. It acts as the antagonist to the lateral pterygoid in hyperfunction and, when tender, provides a good indicator of overuse of the lateral pterygoid.[46]

WWW.HIGHDENT.IR

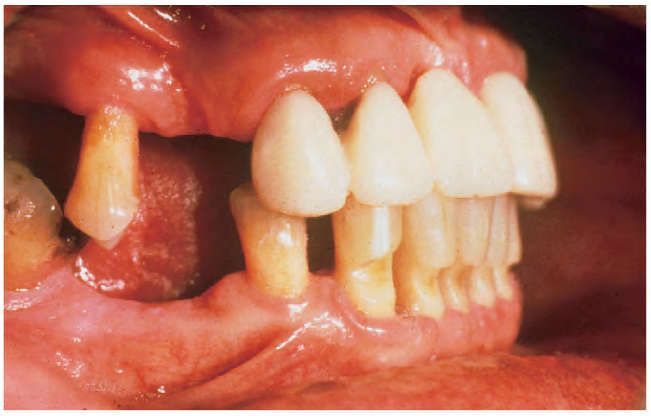


Figure 6-10 Clenching habits are more difficult to diagnose because occlusal wear is often absent. This clenching patient has cervical abfraction of the mandibular anterior teeth. In this patient, the abfraction obviously is not from toothbrush abrasion.

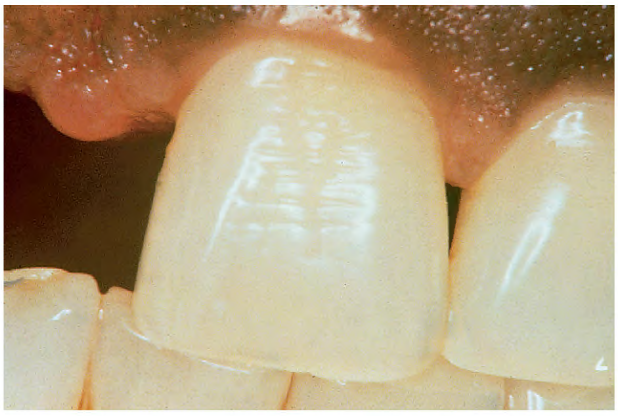

Figure 6-11 This patient has horizontal abfraction lines in the enamel from clenching.

Muscle evaluation for clenching also includes deviation during opening the jaw, limited opening, and tenderness of the temporomandibular joint. Deviation to one side during opening indicates a muscle imbalance on the same side.[46] Limited opening is easily evaluated and may indicate muscular imbalance or degenerative joint disease. The normal opening should be at least 40 mm from the maxillary incisal edge to the mandibular incisal edge in an Angle's Class I patient, taking into consideration an overjet or overlap. If any horizontal overjet or overlap exists, its value in millimeters is subtracted from the 40-mm minimum opening measurement.[50] The range of opening without regard for overlap or overjet has been measured in the range of 38 to 65 mm for men and 36 to 60 mm for women, from incisal edge to edge.[51]

Increased mobility of teeth may be an indication of a force beyond physiologic limits, bone loss, or their combination. This requires further investigation in regard to parafunction and is very important if an implant may be placed in the region of the mobile teeth. The rigid implant may receive more than its share of occlusal force when surrounded by mobile teeth. Fremitus, a vibration type of mobility of a tooth, is often present in the clenching patient. To evaluate this condition, the dentist's finger barely contacts the facial surface of one tooth at a time and feels for vibrations while the patient taps the teeth together. Fremitus is symptomatic of local excess occlusal loads.

Cervical erosion is primarily a sign of parafunctional clenching or bruxism (Figure 6-10). In the past, Black analyzed the eight most popular theories for gingival ditching of the teeth, finding all inconclusive. This observation has frequently been called "toothbrush abrasion." McCoy has reported this condition on every other tooth, only one tooth, and even on the teeth of some animals. Parafunction was the common link among patients presenting with this condition.[52] The notched appearance of the cervical portion of the tooth directly correlates with the concentration of forces shown in three-dimensional finite analysis[53] and photoelasticity studies.[54] Abfraction of teeth was also observed in cats, rats, and marmosets and was described in the literature as early as 1930.[55] A study of a noninstitutionalized older human population revealed that cervical abrasion was present in 56% of the participants.[56]

Other signs of enamel or occlusal material fatigue encountered in bruxing or clenching patients include occlusal invaginations or pits, stress lines in enamel, stress lines in alloy restorations or acrylic (lines of Luder), and material fracture (Figures 6-11 and 6-12). Fremitus can be noticed clinically on many cervically eroded, nonmobile teeth. Not all gingival erosions are caused by parafunction. However, when present, the occlusion should be carefully evaluated along with other signs of excess force. If excessive forces appear to be the cause, the condition is referred to as *cervical abfraction*.[57]

A common clinical finding of clenching is a scalloped border of the tongue (Figure 6-13). The tongue is often braced against the lingual surfaces of the maxillary teeth during clenching, exerting lateral pressures and resulting in the scalloped border. This braced tongue position may also be accompanied by an intraoral vacuum, which permits a clench to extend for a considerable time, often during sleep.

Fatigue Fractures

The increase in force magnitude and duration is a significant problem, whether by bruxism or clenching. The fatigue curve previously presented for bruxism also applies to clenching. In addition, the clenching patient may suffer from a phenomenon called *creep*, which also results in fracture of components. Creep occurs in a material when an increasing deformation is expressed as a function of time, when subjected to a constant load (Figure 6-14). Although the cycles of load may

WWW.HIGHDENT.IR

Figure 6-12 **A,** This patient has cervical abfraction on the mandibular hybrid fixed implant-supported prosthesis from clenching. **B,** The patient in **A** refused to wear an occlusal guard at night. The abfraction continued and affected the denture teeth and cervical areas of the hybrid fixed-implant restoration in the maxilla. The mandibular implants then fractured from fatigue and creep.

Figure 6-13 A scalloped border of the tongue most often is found in a clenching patient. To maintain the force between the teeth, a vacuum is created in the mouth, and the impression of the lingual contours of the upper teeth is seen on the tongue.

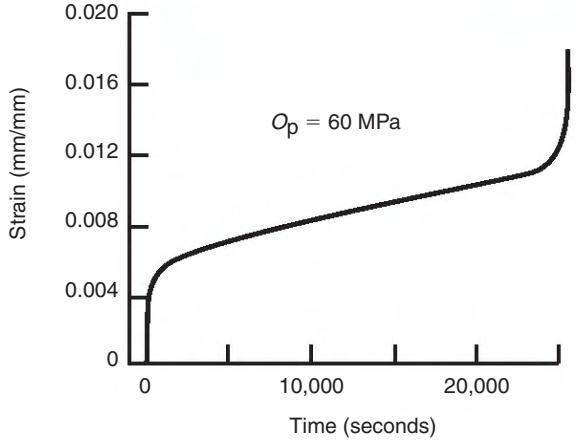

Figure 6-14 A creep curve for materials is created, placing strain on the vertical axis and time on the horizontal axis when a constant load is applied. This is a creep curve for bone at a load of 60 MPa. The bone changes shape (i.e., strain) at the initial stress condition and then at an increasing amount over time until the material breaks.

not be present to affect the deformation of a material, the constant force is still able to cause fracture. In other words, something will break if the continued force is not abated or at least reduced in intensity or duration (Figure 6-15). This condition may also occur in bone, which may result with implant mobility and failure. All elements to reduce the excessive force of clenching and its consequence should be considered.

Clenching affects the treatment plan in a fashion similar to bruxism. However, the vertical forces are less detrimental than horizontal forces, and alteration of the anterior occlusal scheme is not as critical as with the bruxing patient. Night guards are also less effective. However, a hard acrylic shell and softer, resilient liner night guard, which is slightly relieved over the implants, is often beneficial to a clenching patient. Unlike teeth,

WWW.HIGHDENT.IR

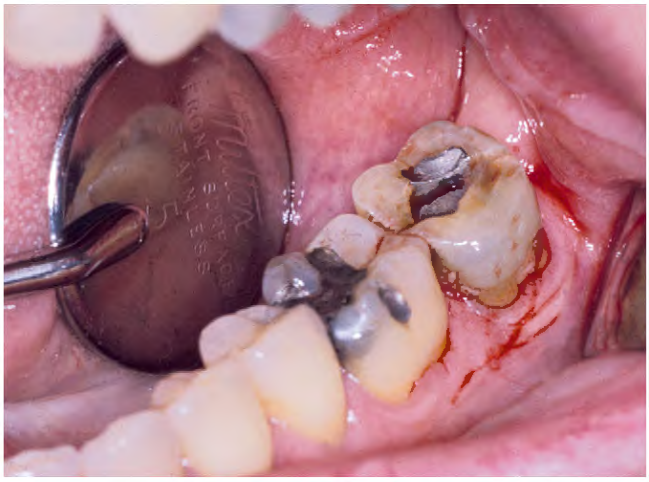

Figure 6-15 The patient exhibits clenching, diagnosed from the enlarged size of the masseter and temporalis muscles. The mandibular second molar has fractured from mesial to distal. Note the slight abfraction on the distal buccal root of the first mandibular molar.

Figure 6-16 A night guard with a rigid acrylic shell and a soft resilient liner can decrease stress during clenching episodes.

implants do not extrude. As a result, the night guard can be relieved around an intermediate implant, and the teeth bear the entire load. In a full-arch or quadrant implant restoration, the night guard provides a biomechanical advantage to reduce the impact of the force during clenching[58] (Figure 6-16).

A common cause of implant failure during healing is parafunction in a patient wearing a soft tissue–supported prosthesis over a submerged implant. The tissue overlying the implant is compressed during the parafunction. The premature loading may cause micromovement of the implant body in the bone and may compromise osteointegration. When an overlying soft tissue–borne restoration exerts pressure as a result

Figure 6-17 When a removable partial denture is worn over healing implants, a 6-mm hole over each implant site reduces the risk of parafunctional loads transferred through the overlying tissue.

of parafunction, pressure necrosis causes soft tissue dehiscence over the implant. This condition is not corrected by surgically covering the implant with soft tissue, but the soft tissue support region of the prosthesis over the implant should be generously relieved during the healing period whenever parafunction is noted. A removable partial denture over a healing implant is especially of concern. The acrylic between the soft tissue–borne region and metal substructure is usually less than 1 mm thick. Removing the thin acrylic region over the implant is often insufficient. Instead, a 6-mm–diameter hole through the metal substructure should be prepared (Figure 6-17).

Prosthetic Considerations

The time intervals between prosthodontic restoration appointments may be increased to provide additional time to produce load-bearing bone around the implants through progressive bone-loading techniques. Anterior implants submitted to lateral parafunction forces require further treatment considerations. Additional implants are indicated, preferably of greater diameter. The excursions are canine guided if natural, healthy canines are present. Mutually protected occlusion, with additional anterior implants or teeth distributing forces, is developed if the implants are in the canine position or if this tooth is restored as a pontic. The prosthesis may be designed to improve the distribution of stress throughout the implant system with centric vertical contacts aligned with the long axis of the implant whenever possible. Narrow posterior occlusal tables to prevent inadvertent lateral forces and to decrease the occlusal forces are beneficial.[59] Enamoplasty of the cusp tips of the opposing natural teeth is indicated to help improve the direction of vertical forces, within the guidelines of the intended occlusion.

Clenching increases the risk of mechanical failure, such as porcelain fracture, uncemented restoration,

WWW.HIGHDENT.IR

Figure 6-18 This patient fractured the porcelain on her fixed mandibular implant–supported restoration. The cervical regions were the primary sites of fracture because the patient had a clenching habit.

Figure 6-19 Six different types of tongue-thrust habits have been classified. This patient has an anterior tongue thrust and, as a result, does not have anterior guidance.

Figure 6-20 This patient has a unilateral posterior tongue thrust. When the patient swallows, the tongue is forced between the maxillary canine and first premolar, the mandibular lateral incisor and canine, and the posterior edentulous regions in both arches. Posterior one-stage implants would receive an immediate horizontal load. The patient will feel that the implant prosthesis is constricting the tongue.

abutment screw fracture, implant body fracture, and crestal bone loss (Figure 6-18).

TONGUE THRUST AND SIZE

Parafunctional tongue thrust is the unnatural force of the tongue against the teeth during swallowing.[60] A force of approximately 41 to 709 g/cm^2 on the anterior and lateral areas of the palate has been recorded during swallowing.[61] In orthodontic movement, a few grams of constant force are sufficient to displace teeth. Six different types of tongue thrust have been identified; anterior, intermediate, posterior, and either unilateral or bilateral may be found, and in most any combination (Figures 6-19 and 6-20). A common question is which came first, the aberrant tongue position or the misalignment of teeth? Regardless, this condition can contribute to implant healing and prosthetic complications. Although the force of tongue thrust is of lesser intensity than in other parafunctional forces, it is horizontal in nature and can increase stress at the permucosal site of the implant. This is most critical for one-stage surgical approaches in which the implants are in an elevated position at initial placement and the implant interface is in an early healing phase. The tongue thrust may also contribute to incision line opening, which may compromise both the hard and soft tissues.

A tongue-thrust habit may lead to tooth movement or mobility, which is of consequence when implants are present in the same quadrant. If the natural teeth in the region of the tongue thrust were lost as a result of an aberrant tongue position or movement, the implants are at increased risk during initial healing and early prosthetic loading. If the remaining teeth exhibit increased mobility, the implant prosthesis may be subject to increased occlusal loads. To evaluate anterior tongue thrust, the doctor holds the lower lip down, squirts water into the mouth with the water syringe, and asks the patient to swallow. A normal patient forms a vacuum in the mouth, positions the tongue on the anterior aspect of the palate, and is able to swallow without difficulty. A patient with an anterior tongue thrust is not able to create the vacuum needed to swallow when the lower lip is retracted, because the seal and vacuum for the patient are achieved between the tongue and the lower lip. As a consequence, the patient is unable to swallow while the lower lip is withdrawn.

A posterior tongue thrust is evaluated by retracting one cheek at a time away from the posterior teeth/edentulous region with a mirror, injecting water into the mouth with a water syringe, and asking the patient to swallow. Visual evidence of the tongue during

WWW.HIGHDENT.IR

Figure 6-21 This patient has a maxillary complete denture and no posterior mandibular teeth. The patient has developed a posterior tongue position to support the denture and prevent it from dropping posteriorly when the patient occludes. This tongue will adapt easily to a mandibular posterior implant prosthesis.

Figure 6-22 In a patient with missing teeth and no prosthetic replacement, such as a complete or partial denture, the tongue often increases in size. Although the tongue does not transfer an active lateral force during swallowing, prosthetic complications of tongue biting are at a greater risk.

deglutition may also be accompanied by pressure against the instrument and confirms a lateral force. The posterior tongue thrust may occur in patients wearing a maxillary denture opposing a Kennedy Class 1 mandibular arch, without a mandibular prosthesis replacing the posterior teeth. Under these conditions, the maxillary denture often loses valve seal and drops posteriorly, as only anterior teeth contact. To limit this problem, the patient extends the lateral aspect of the tongue into the edentulous region to prevent the maxillary denture from dislodgement (Figure 6-21).

A potential prosthetic complication for a patient with a lateral tongue thrust is the complaint of inadequate room for the tongue once the mandibular implants are restored. A prosthetic mistake is to reduce the width of the lingual contour of the mandibular teeth. The lingual cusp of the restored mandibular posterior teeth should follow the curve of Wilson and include proper horizontal overjet to protect the tongue during function. A reduction in the width of the posterior teeth often increases the occurrence of tongue biting and may not dissipate with time. Rather than being a short-term inconvenience, the prosthesis may need to be refabricated. The restoring dentist should identify the tongue position before treatment and inform the patient about the early learning curve for the tongue once the teeth are delivered on the implants.

Even in the absence of tongue thrust, the tongue often accommodates to the available space, and its size may increase with the loss of teeth. As a result, a patient not wearing a mandibular denture often has a larger than normal tongue. The placement of implants and prosthetic teeth in such a patient results in an increase in lateral force, which may be continuous. This patient complains of inadequate room for the tongue and may bite it during function. However, this condition is usually short-lived, and the patient eventually adapts to the new intraoral condition (Figure 6-22).

CROWN HEIGHT SPACE

The interarch distance is defined as the vertical distance between the maxillary and mandibular dentate or dentate arches under specific conditions (e.g., the mandible is at rest or in occlusion).[62] A dimension of only one arch does not have a defined term in prosthetics; therefore Misch proposed the term *crown height space* (CHS).[63] The CHS for implant dentistry is measured from the crest of the bone to the plane of occlusion in the posterior region and the incisal edge of the arch in question in the anterior region (Figure 6-23; Box 6-3). In the anterior regions of the mouth, the presence of a vertical overbite means the CHS is larger in the maxilla than the space from the crest of the ridge to the opposing teeths incisal edge. In general, when the anterior teeth are in contact in centric occlusion, there is a vertical overbite. The anterior mandibular CHS is therefore usually measured from the crest of the ridge to the mandibular incisal edge. However, the anterior maxillary CHS is measured from the maxillary crestal bone to the maxillary incisal edge, not the occlusal contact position.

The ideal CHS needed for a fixed implant prosthesis should range between 8 and 12 mm. This measurement accounts for the biological width, abutment height for cement retention or prosthesis screw fixation, occlusal material strength, esthetics, and hygiene considerations around the abutment crowns. Removable prostheses often require a CHS greater than 12 mm for denture teeth and acrylic resin base strength, attachments, bars, and oral hygiene considerations.[64,65]

WWW.HIGHDENT.IR

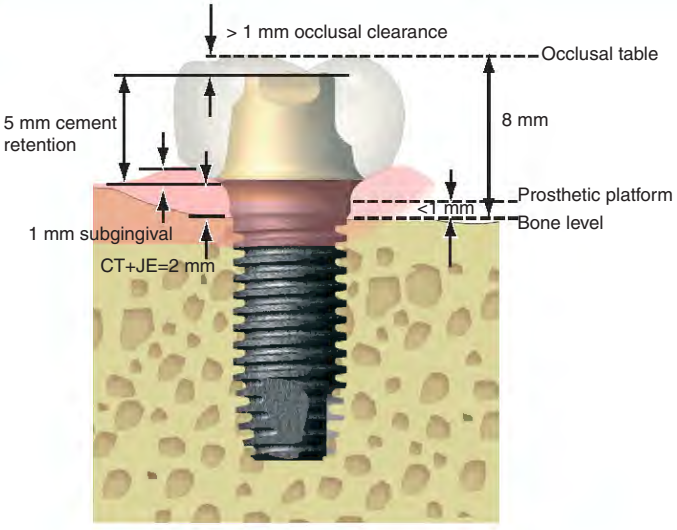

Figure 6-23 The crown height space (CHS) is measured from the occlusal plane to the crest of the bone.

Biomechanic Consequences of Excessive Crown Height Space

Mechanical complication rates for implant prostheses are often the highest of all complications reported in the literature.[39,66] Mechanical complications are often caused by excessive stress applied to the implant-prosthetic system (see Box 6-3). Implant failure may occur from overload and result in prosthesis failure and bone loss around the failed implants. Implant body fracture may result from fatigue loading of the implant at a higher force, but occurs at less incidence than most complications. The higher the force, the fewer the number of cycles before fracture, so the incidence increases. Crestal bone loss may also be related to excessive forces and often occurs before implant body fracture. Porcelain and occlusal material fracture rates may increase as the force to the restoration is increased. The risk of fracture to the opposing prosthesis increases with an average of 12% in implant overdentures opposing a denture.[66] With resin veneer implant fixed partial dentures, 22% of the veneers fractured. Clips or attachment fractures in overdentures may average 17%. Fracture of the framework or substructure may also occur as a result of an increase in biomechanical forces.

Force magnifiers are situations or devices that increase the amount of force applied and include a screw, pulley, incline plane, and a lever.[43] The biomechanics of CHS are related to lever mechanics. The properties of a lever have been appreciated since the time of Archimedes, 2000 years ago. The issues of cantilevers and implants were demonstrated in the edentulous mandible, where the length of the posterior cantilever directly related to complications or failure of the prosthesis.[39] Rather than a posterior cantilever, the CHS is a vertical cantilever when any lateral or cantilevered load is applied and, therefore, is also a force magnifier.[44,45] As a result, because CHS excess increases the amount of force, any of the mechanical-related complications related to implant prostheses may also increase (Figure 6-24).

When the direction of a force is in the long axis of the implant, the stresses to the bone are not magnified in relation to the CHS. However, when the forces to the implant are on a cantilever, or a lateral force is

Box 6-3 Biomechanical Principles Related to Crown Height Space

1. The CHS is measured from the occlusal plane to the crest of the bone.
2. Mechanical complications are the primary cause of complications after prosthesis delivery.
3. Mechanical complications are often caused by excessive stresses.
4. Excessive stress can cause implant failure, crestal bone loss, implant fracture, screw loosening, occlusal material fracture, prosthesis fracture, or attachment wear and fracture.
5. The crown height is a vertical cantilever.
6. The biomechanics are more unfavorable as the CHS increases.
7. An increase in CHS increases the forces on cantilevered or angled loads.
8. Crestal bone loss around the implant increases the CHS and therefore increases the moment forces to the implant and prosthesis components.
9. CHS does not have a specific ideal dimension. With fixed restorations, the acceptable range for CHS is between 8 and 12 mm.
10. Removable implant restorations often require a CHS of 12 mm or more, especially when a bar connects the individual implants.
11. Stresses applied to implants are concentrated in the crestal region, so increasing implant length is less effective to reduce the effects of crown height than a natural tooth root.
12. Methods to decrease stress should be considered when the CHS is increased (i.e., increase implant number, size, and surface area of design; splint implants together; shorten cantilevers; consider removable restorations; add soft tissue support in overdentures).
13. An increase in prosthetic complications occurs with either limited or excessive CHS.

CHS, Crown height space.

FP-1 FP-3

Figure 6-24 The crown height space (CHS) is a vertical cantilever. The FP-3 prosthesis on the right will deliver greater stresses to the implant compared with the implant on the left. Therefore a wider-diameter implant is of benefit to support the implant restoration on the right.

applied to the crown, the forces are magnified in direct relationship to the crown height. Bidez and Misch evaluated the effect of a cantilever on an implant and its relation to crown height.[44,45] When a cantilever is placed on an implant, there are six different potential rotation points (i.e., moments) on the implant body (Figure 6-25; Table 6-2). When the crown height is increased from 10 to 20 mm, two of six of these moments are increased 200%. A cantilevered force may be in any direction: facial, lingual, mesial, or distal. Forces cantilevered to the facial and lingual direction are often called *offset loads*. The bone width decrease is primarily from the facial aspect of the edentulous ridge. As a result, implants are often placed more lingual than the center of the natural tooth root. This condition often results in a restoration cantilevered to the facial. When the available bone height is also decreased, the CHS is increased. Therefore the potential length of the implant reduced in excessive CHS conditions, and the implant position results in offset loads.

An angled load to a crown will also magnify the force applied to the implant. A 12-degree force to the implant

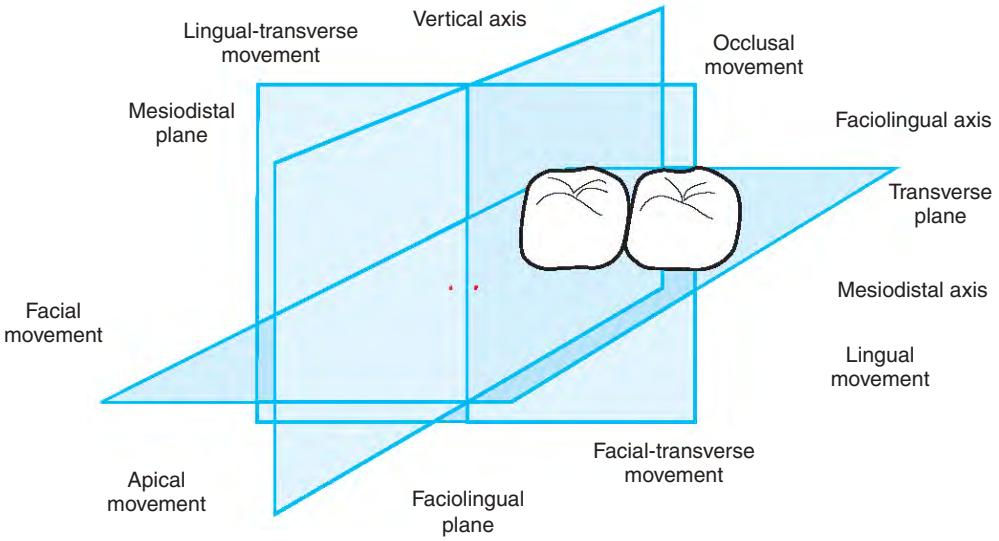

Figure 6-25 Moment loads tend to induce rotations in three planes. Clockwise and counterclockwise rotations in these three planes result in six moments: lingual-transverse, facial-transverse, occlusal, apical, facial, and lingual.

WWW.HIGHDENT.IR

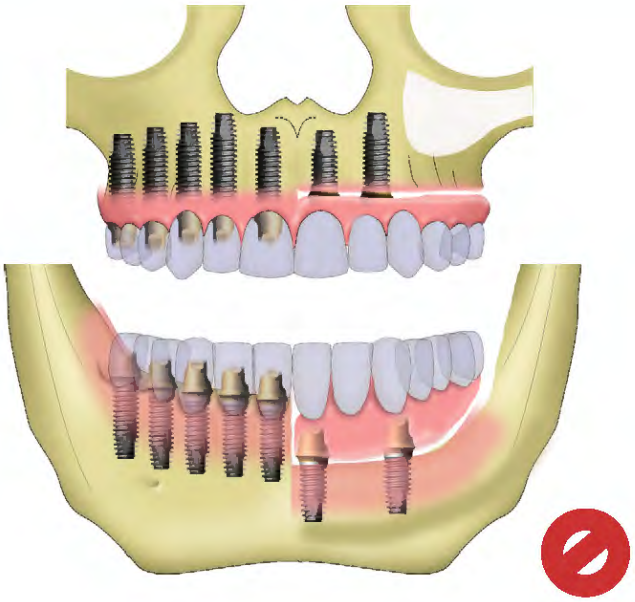

Figure 6-26 In the past, treatment plans included more implants in abundant bone and fewer implants in less available bone. However, crown height increases as bone height decreases, and this approach is creating unfavorable mechanics.

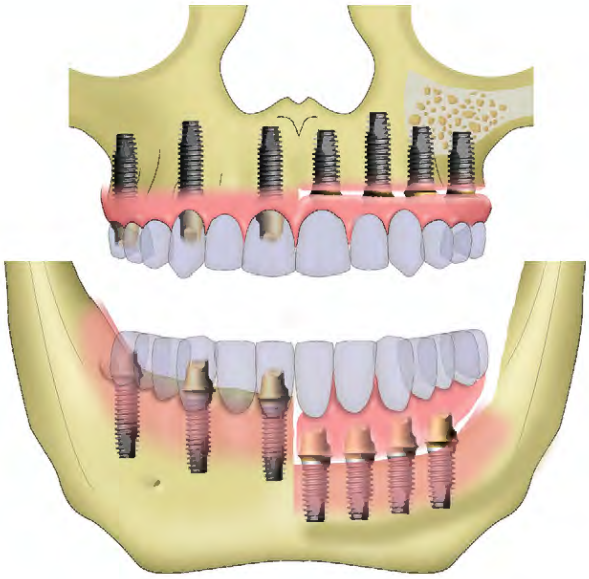

Figure 6-27 Crown height is a force magnifier to any lateral load or horizontal cantilever. Therefore when available bone height decreases, more implants should be inserted and cantilever length reduced.

will be increased by 20%. This increase in force is further magnified by the crown height. For example, a 12-degree angle with a force of 100 N will result in a force of 315 N-mm on a crown height of 15 mm.[44] Maxillary anterior teeth are usually at an angle of 12 degrees or more to the occlusal planes. Even implants placed in an ideal position are usually loaded at an angle. Maxillary anterior crowns are often longer than any other teeth in the arch, so the effects of crown height cause greater risk.

The angled force to the implant also may occur during protrusive or lateral excursions, as the incisal guide angle may be 20 degrees or more. Anterior implant crowns will therefore be loaded at a considerable angle during excursions, compared with the long axis position of the implant. As a result, an increase in the force to maxillary anterior implants should be compensated for in the treatment plan.

Most forces applied to the osteointegrated implant body are concentrated in the crestal 7 to 9 mm of bone, regardless of implant design and bone density.[67] Therefore implant body height is not an effective method to counter the effects of crown height. In other words, crown-root ratio is a prosthetic concept that may guide the restoring dentist when evaluating a natural tooth abutment. The longer the natural tooth root, the shorter the crown height, which acts as a lever to rotate the tooth around an axis located two thirds down the root. However, the crown height–implant ratio is not a direct comparison. Crown height is a vertical cantilever that magnifies any lateral or cantilever force in either a tooth- or an implant-supported restoration. However, this condition is not improved by increasing implant length to dissipate stresses. The implant does not rotate away from the force in relation to implant length. Instead, it captures the force at the crest of the ridge. The greater the CHS, the greater number of implants usually required for the prosthesis, especially in the presence of other force factors. This is a complete paradigm shift to the concepts advocated originally, with many implants in greater available bone and small crown heights and fewer implants with greater crown heights in atrophied bone (Figures 6-26 and 6-27).

The CHS increases when crestal bone loss occurs around the implants. An increased CHS may increase the forces to the crestal bone around the implants and increase the risk of crestal bone loss. This in turn may further increase both the CHS and the moment forces to the entire support system, resulting in screw loosening, crestal bone loss, implant fracture, and implant failure.

The vertical distance from the occlusal plane to the opposing landmark for implant insertion is typically a constant in an individual. Therefore as the bone resorbs, the crown height becomes larger, but the available bone height decreases (Figure 6-28). An indirect relationship is found between the crown and implant height. Moderate bone loss before implant placement may result in a crown height–bone height ratio greater than 1, with greater lateral forces applied to the crestal bone than in abundant bone (in which the crown height is less). A linear relationship exists between the applied load and internal stresses.[68,69] Therefore the greater the load applied, the greater the tensile and compressive stresses transmitted at the

WWW.HIGHDENT.IR

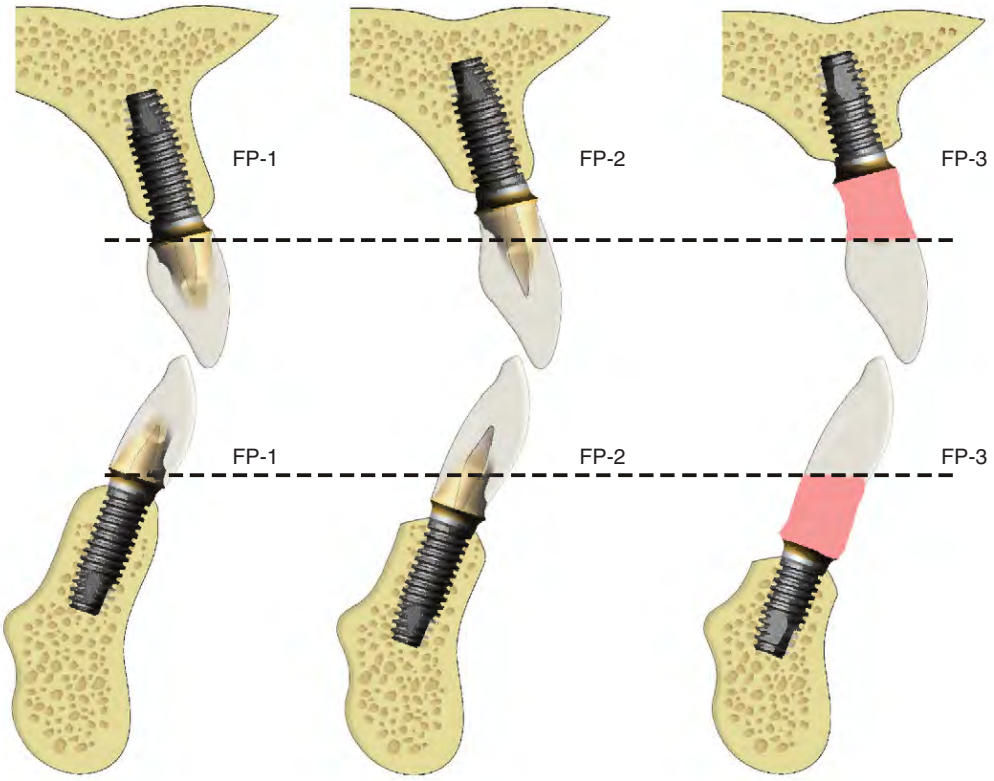

Figure 6-28 As the crown height increases, the available bone height decreases. This is especially noteworthy in the maxillary arch, as the initial available bone height is less than in the mandible. As a consequence, shorter implants in the maxilla are a common occurrence.

Box 6-4 Excessive Crown Height Space

1. Excessive CHS increases mechanical complications in fixed prostheses.
2. The need for gingival replacement procedures should be evaluated before implant placement for fixed restorations.
3. Metal and porcelain shrinkage is more of a problem in traditional fixed prosthetic cases.
4. Hybrid FP-3 fixed prostheses with denture teeth, metal substructure, and acrylic resin are indicated.
5. Overdentures in completely edentulous patients with RP-4 and RP-5.
6. The implant support for RP-4 should be as great as that for a fixed prosthesis.
7. With mobile overdentures, there should be adequate soft tissue support when designing RP-5.
8. In overdentures, there may be two different components of the CHS: the distance from the crest of the bone to the height of the attachment and the distance from the attachment to the occlusal plane.

CHS, Crown height space.

bone interface and to the prosthetic components. And yet, many implant treatment plans are designed with more implants in abundant bone situations and fewer implants in atrophied bone volume. The opposite scenario should exist. The lesser the bone volume, the greater the crown height, and the greater the number of implants indicated.

Excessive CHS

Crown height space greater than 15 mm is excessive; it is primarily the result of the vertical loss of alveolar bone from long-term edentulism. Other causes may include genetics, trauma, and implant failure (Box 6-4). Treatment of excessive CHS before implant placement includes orthodontic and surgical methods. Orthodontics in partially edentulous patients is the method of choice, as other surgical or prosthetic methods are usually more costly and have greater risks of complications. Several surgical techniques may also be considered, including block onlay bone grafts, particulate bone grafts with titanium mesh or barrier membranes, interpositional bone grafts, and distraction osteogenesis. A staged approach to reconstruction of the jaws is often preferred to simultaneous implant placement, especially when large-volume gains are required. Significant vertical bone augmentation may even require multiple surgical procedures.

Distraction osteogenesis has several advantages over onlay bone grafting techniques for vertical bone growth. Vertical bone gains are not limited by factors such as graft size or expansion of the existing soft tissue volume. There is no donor site morbidity, and the surgery may

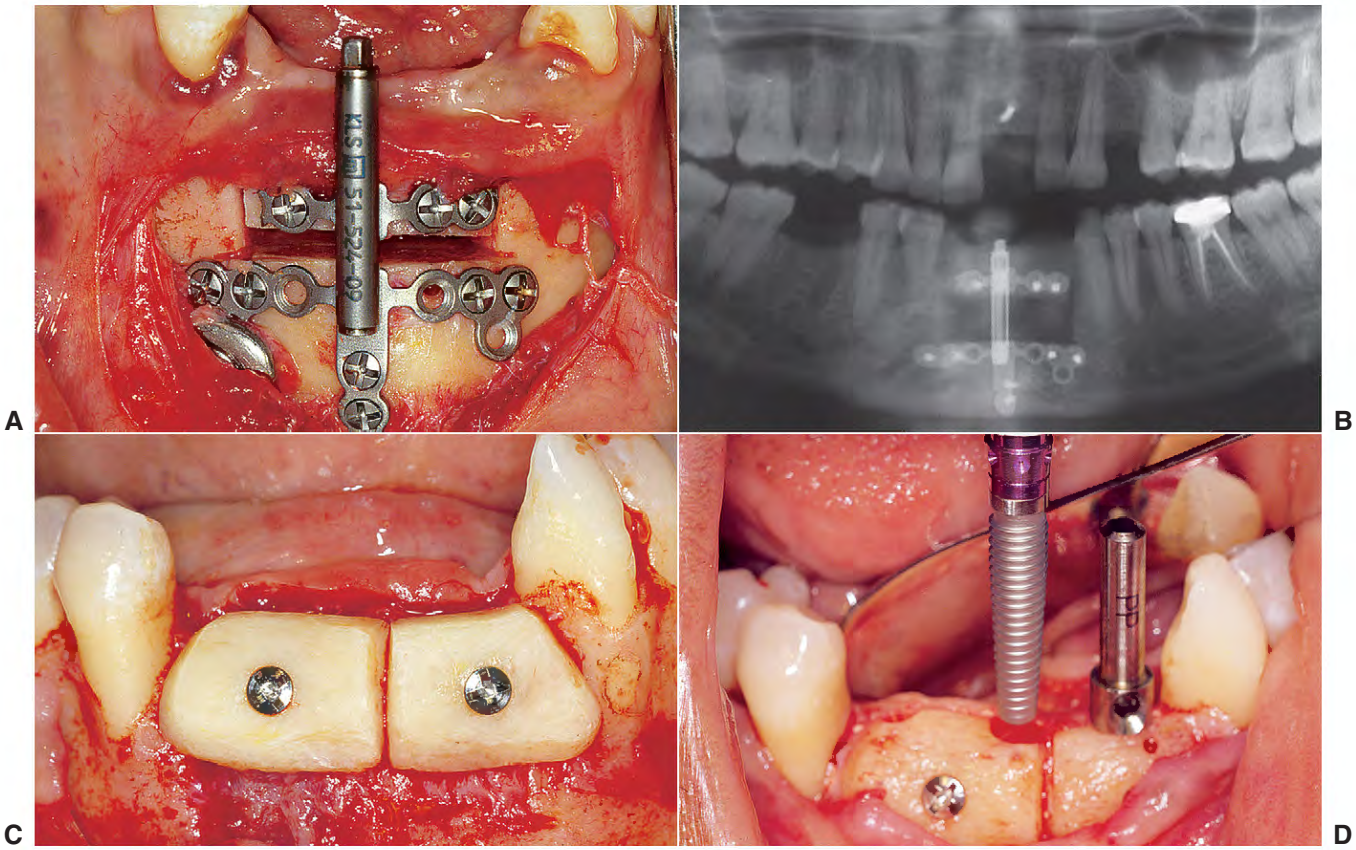

Figure 6-29 **A,** An anterior atrophic mandible with a distraction osteogenesis device to gain vertical bone height between the canines. **B,** A panoramic radiograph of the distracted anterior mandible. **C,** An onlay bone graft from the ramus is used to gain horizontal bone volume. **D,** Anterior endosteal implants are placed after distraction and onlay bone grafts have matured. (*Courtesy Craig Misch, Sarasota, Fla.*)

be performed in an office setting. However, distraction osteogenesis requires patient compliance, and bone volume gains are unidirectional. In addition, clinical studies found that secondary bone augmentation procedures are often required for dental implant placement.[70] Misch presented a unique approach combining vertical distraction and horizontal onlay bone grafting to reconstruct the deficiency three-dimensionally. Osseous distraction is performed first to vertically increase the ridge and expand the soft tissue volume. Secondarily an onlay bone graft is used to complete the repair of the defect (Figure 6-29).[65]

In case of excessive CHS, bone augmentation may be preferred to prosthetic replacement. Surgical augmentation of the residual ridge height will reduce the CHS and improve implant biomechanics. Augmentation will often permit the placement of wider body implants with the associated benefit of increased surface area. Although prosthetics is the most commonly used option to address excess CHS, it should be the last choice. Using gingival colored prosthetic materials (pink porcelain or acrylic resin) on fixed restorations or changing the prosthetic design to a removable restoration should often be considered when restoring excessive CHS.

In the maxilla, a vertical loss of bone results in a more palatal ridge position. As a consequence, implants are often inserted more palatal than the natural tooth position. Removable restorations have several advantages under these clinical circumstances. The removable prosthesis does not require embrasures for hygiene. The removable restoration may be removed during sleep to decrease the effects of an increase in CHS on nocturnal parafunction. The removable restoration may improve the lip and facial support, which is deficient because of the advanced bone loss. The overdenture may have sufficient bulk of acrylic resin to decrease the risk of prosthesis fracture. The increase in CHS permits denture tooth placement without infringement of the substructure.

Soft tissue support in addition to implant-supported removable implant restorations with an excessive CHS are recommended when it is not possible to overengineer the implant support system. A rigid overdenture has identical requirements to a fixed prosthesis, because it is rigid during function. Misch describes the "hidden cantilever" beyond the cantilevered bar with a rigid implant overdenture.[71] When the overdenture has no movement during function, the cantilever does not stop at the end of the cantilevered substructure but ends at the last occlusal contact position on the prosthesis, often the distal of a second molar.

The position and type of overdenture attachments may render an overdenture rigid during function, even

WWW.HIGHDENT.IR

Figure 6-30 When the crown height space is greater than 12 mm, pink porcelain (or acrylic) is often used to replace the soft tissue drape in the prosthesis.

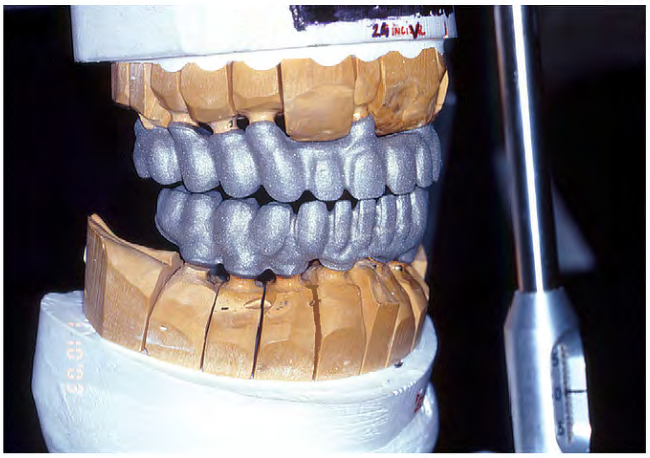

Figure 6-31 Porcelain thickness for fixed prostheses should not be greater than 2 mm. When the crown height space is greater than 15 mm, the amount of metal in the substructure may be extensive.

in the absence of distal cantilevers on the bar. For example, when three anterior implants are splinted together and a Hader clip is used to retain the prosthesis, if the Hader clips are placed at angles to the midline, the attachments have limited movement and result in a rigid overdenture during function. Misch suggests the prosthesis movement, not the individual attachment movement, should be evaluated.[71] Excessive CHS with overdentures are situations that benefit from a prosthesis designed to have more than one direction of movement.

The ideal CHS for a fixed prosthesis is between 8 and 12 mm, accounting for an ideal 3 mm of soft tissue, 2 mm of occlusal material thickness, and a 5-mm or greater abutment height. A CHS greater than 12 mm may be of concern in fixed restorations. The replacement teeth are elongated and often require the addition of gingival tone materials in esthetic regions (Figure 6-30). The greater impact force on implants compared with teeth, combined with the increased crown height, creates increased moment forces on implants and risks of component and material fracture. These problems are especially noted when associated with less favorable biomechanics on cantilevered sections of fixed restorations.[39,66]

A CHS greater than 15 mm means a large amount of metal must be used in the substructure of a traditional fixed restoration to keep porcelain to its ideal 2-mm thickness (Figure 6-31). Fine-tuning techniques for traditional fixed restorations allowed Dabrowsky to manufacture and monitor multiple full-mouth, cement-retained prostheses with a large CHS, delivered in various centers across the United States.[72] Controlling surface porosities of metal substructures after casting as their different parts cool at different rates becomes increasingly difficult. Furthermore, when the casting is reinserted into the oven to bake the porcelain, the heat is maintained within the casting at different rates, so the porcelain cools in different regions at different rates.[73] If not controlled properly, both these factors increase the risk of porcelain fracture after loading.[74] For excessive CHS, considerable weight of the prosthesis (approaching 3 oz of alloy) may affect maxillary trial placement appointments, because the restoration does not remain in place without the use of adhesive. Noble metals must be used to control alloy's heat expansion or corrosion; therefore the costs of such implant restorations have dramatically increased. Proposed methods to produce hollow frames to alleviate these problems, including the use of special custom trays to achieve a passive fit will double or triple the labor costs.[75]

An alternative method of fabricating fixed prostheses in situations of CHS of 15 mm or greater is the fixed complete denture or hybrid prosthesis, with a smaller metal framework, denture teeth, and acrylic resin to join these elements together (Figure 6-32). The reduced metal framework compared with a porcelain-to-metal fixed prosthesis exhibits fewer dimensional changes and may more accurately fit the abutments, which is important for a screw-retained restoration. It is less expensive to fabricate than a porcelain-to-metal fixed prosthesis, is highly esthetic (premade denture teeth), easily replaces teeth and soft tissue in appearance, and is easier to repair if fracture occurs. Because resin acts as an intermediary between the teeth and metal substructure, the impact force during dynamic occlusal loading may also be reduced. Therefore this type of fixed prosthesis is often indicated for implant restorations with a large CHS. On occasion, undercontoured interproximal areas are designed by the laboratory in such restorations to assist oral hygiene and have been referred to as "high water" restorations. This is an excellent method in the mandible; however, it results in food entrapment, affects air flow patterns, and may contribute to speech problems in the anterior maxilla.

A B

Figure 6-32 **A,** A metal framework for a hybrid prosthesis composed of metal, acrylic, and denture teeth presents several advantages for fixed prostheses with a CHS greater than 15 mm. **B,** Denture teeth are then added to the metal substructure.

Because an increase in the biomechanical forces are in direct relationship to the increase in CHS, the treatment plan of the implant restoration should consider stress reducing options whenever the CHS is increased. Methods to decrease stress include[63-65]:

1. Shorten cantilever length
2. Minimize offset loads to the buccal or lingual
3. Increase the number of implants
4. Increase the diameters of implants
5. Design implants to maximize the surface area of implants
6. Fabricate removable restorations that are less retentive and incorporate soft tissue support
7. Remove the removable restoration during sleeping hours to reduce the noxious effects of nocturnal parafunction
8. Splint implants together, whether they support a fixed or removable prosthesis

Because CHS is a considerable force magnifier, the greater the crown height, the shorter the prosthetic cantilever that should extend from the implant support system. In CHS greater than 15 mm, no cantilever should be considered, unless all other force factors are minimal. The occlusal contact intensity should be reduced on any offset load from the implant support system. Occlusal contacts in centric relation occlusion may even be eliminated on the most posterior aspect of a cantilever. In this way, a parafunction load may be reduced, as the most cantilevered portion of the prosthesis is only loaded during functional activity (such as chewing).

MASTICATORY DYNAMICS

Masticatory muscle dynamics are responsible for the amount of force exerted on the implant system. Several criteria are included under this heading: patient size, gender, age, and skeletal position.[9,16,11,21,76-79] The size of the patient can influence the amount of bite force. Large, athletic men can generate greater forces; patients of weak physical condition often develop less force than athletic patients (Figure 6-33). In general, the forces recorded in women are 20 lb less than those in men. In a clinical report by van Steenberghe et al., partially edentulous men have a 13% implant failure rate compared with women with a 77% failure rate.[80] In a report by Wyatt and Zarb, first-year radiograph bone loss was positively correlated with males, younger patients, and implants supporting a distal extension prosthesis.[81] Older patients record lower bite forces than young adults. In addition, the younger patient lives longer and requires the additional implant support for the prosthesis for a longer time. (An 80-year-old patient will need implant support for far fewer years than a 20-year-old, all other factors being equal.)

Figure 6-33 Masticatory dynamics are affected by the size of the patient (larger persons generally have greater bite forces).

The skeletal arch position may influence the amount of maximum bite force. The brachiocephalic, with a

WWW.HIGHDENT.IR

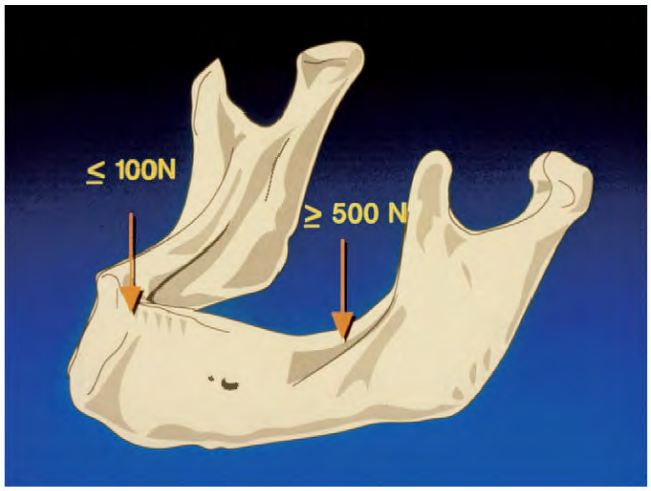

Figure 6-34 The maximum bite forces are greater in the posterior regions of the jaws compared with the anterior regions.

stout head shape, may generate three times the bite force compared with a regular head shape. This is especially noteworthy when accompanied by moderate to severe bruxism or clenching. The maximum bite force decreases as muscle atrophy progresses throughout years of edentulism. A maximum occlusal force of 5 psi may be the result of 15 years without teeth.[77] This force may increase 300% in the 3 years after implant placement.[21,22,77-79] Therefore sex, muscle mass, exercise, diet, state of the dentition, physical status, and age all influence muscle strength, masticatory dynamics, and maximum bite force.

The skeletal Class III patient is primarily a vertical chewer and generates vertical forces with little excursive movement. However, some patients appear "pseudo-Class III" as a result of anterior bone resorption or loss of posterior support and collapse of the vertical dimension with an anterior rotation of the mandible. These patients do exhibit lateral excursive movements when the incisal edge position is restored to its initial position.

As a general rule, the implant treatment plan should reduce other force magnifiers when masticatory musculature dynamics increase. For example, a cantilever length should be reduced in cases of elevated masticatory dynamics. A crown height may be reduced by bone augmentation. The prosthesis may be made removable so nocturnal bruxism is reduced (if they do not wear their prosthesis). The implant number, size, and design may also be increased to increase the surface area of load.

ARCH POSITION

The maximum biting force is greater in the molar region and decreases as measurements progress anteriorly. Maximum bite forces in the anterior incisor region correspond to approximately 35 to 50 psi; those in the canine region range from 47 to 100 psi; whereas those in the molar area vary from 127 to 250 psi[8] (Figure 6-34). Mansour et al. evaluated occlusal forces and moments mathematically using a Class III lever arm, the condyles being the fulcrum and the masseter and temporalis muscles supplying the force.[82] Similar figures were obtained by mathematical calculation and by direct measurement. In addition, the forces at the second molar were 10% higher than at the first molar, indicative of a range from 140 to 275 psi.

In a study by Chung et al. with 339 implants in 69 patients in function for an average of 8.1 years (range of 3 to 24 years), the posterior implants (even with keratinized mucosa) showed a 3.5-fold greater average bone loss per year than anterior implants.[83]

The anterior biting force is decreased in the absence of posterior tooth contact and greater in the presence of posterior occlusion or eccentric contacts.[35,84] Besides the mechanical properties of a Class III lever function, there also is a biological component to increased bite force in the posterior regions. When the posterior teeth are in contact, the large masticatory muscles contract. When the posterior teeth are not in contact, two thirds of the temporalis and masseter muscles do not contract their fibers. As a consequence, the bite force is reduced.

In the anterior regions with less force, the anterior natural tooth roots are smaller in diameter and root surface area compared with posterior teeth. Yet in implant dentistry, we often alter the implant length primarily and place longer implants in the anterior region and shorter implants in the posterior regions (or cantilever off the anterior implants, which results in posterior bite forces magnified by the cantilever length). This approach should be corrected to conform to biomechanics similar to that observed with natural teeth. In other words, implants in the posterior regions should often be of greater diameter, especially in the presence of additional force factors. The greater increase in natural tooth surface area occurs in the molar region, with a 200% increase compared with the premolars. Hence, the larger implant diameter is especially considered in the molar region.

The edentulous bone density varies in function of arch position. The natural teeth are surrounded by a thin cortical plate of bone and periodontal complex, which is similar for all teeth and arch positions. However, after the teeth are lost, the bone density in the edentulous site is different for each region of the mouth. The posterior regions, in general, form less bone density after tooth loss than the anterior regions. The mandibular anterior implant sites benefit from denser bone than the maxillary anterior implant sites. The denser the bone, the greater its resistance to stress applied at the implant-bone interface. In other words, the edentulous bone density is inversely related to the amount of force generally applied in that arch position. As a result, the posterior

WWW.HIGHDENT.IR

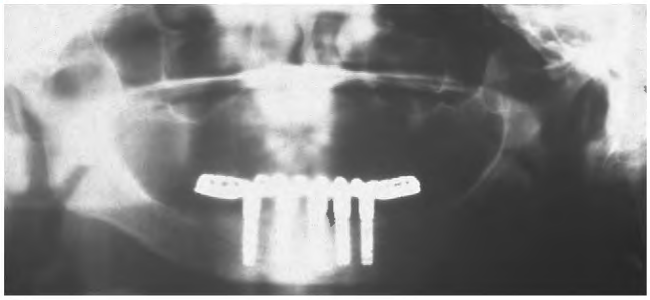

Figure 6-35 As a general rule, the greater the number of opposing teeth, the greater the bite force. When the opposing arch is a denture (as depicted in this panoramic radiograph in the maxilla), the bite forces are less.

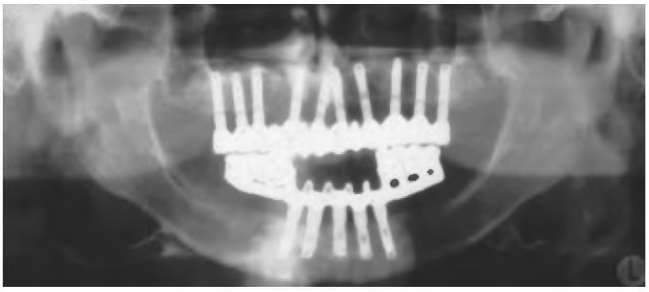

Figure 6-37 When the opposing arch has a fixed implant prosthesis, the bite forces are greatest. The decrease in proprioception results in higher forces during function and parafunction. In this patient, the cantilever should be reduced significantly, especially because the crown height is also large.

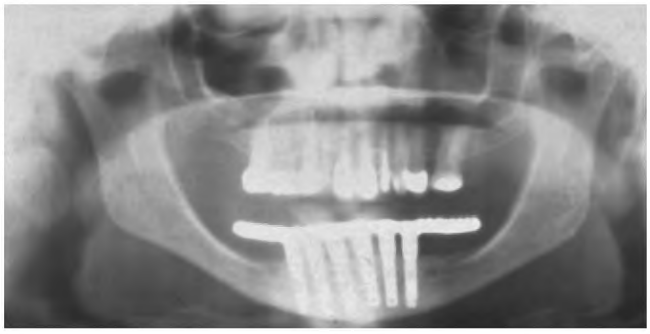

Figure 6-36 The opposing arch consists of natural teeth in this panoramic radiograph. The cantilever length should be reduced or the number of implants increased, compared with an edentulous opposing arch.

Figure 6-38 The opposing arches in this patient are complete implant-supported prostheses. As a general rule, no posterior cantilevers are designed in the maxilla and limited cantilevers are designed in the mandible.

maxilla is the most at-risk arch position, followed by the posterior mandible, then the anterior maxilla. The most ideal region is the mandibular anterior.

OPPOSING ARCH

Natural teeth transmit greater impact forces through occlusal contacts than soft tissue–borne complete dentures. In addition, the maximum occlusal force of patients with complete dentures is limited and may range from 5 to 26 psi.[77] The force is usually greater in recent denture wearers and decreases with time. Muscle atrophy, thinning of the oral tissues with age or disease, and bone atrophy often occur in the edentulous patient as a function of time.[85] Some denture wearers may clench on their prosthesis constantly, which may maintain muscle mass. However, this condition usually accelerates bone loss. Implant overdentures improve the masticatory performance and permit a more consistent return to centric relation occlusion during function. The maximum force generated in an implant prosthesis is related to the amount of tooth or implant supporting the opposing arch[12,77,78] (Figures 6-35 and 6-36).

A complete implant fixed prosthesis does not benefit from proprioception as do natural teeth, and patients bite with a force four times greater than with natural teeth. Thus, the highest forces are created with implant prostheses (Figure 6-37). In addition, premature contacts in occlusal patterns or during parafunction on the implant prostheses do not alter the pathway of closure, as occlusal awareness is decreased with implant prostheses when compared with natural teeth.[17,18] Therefore continued stress increases can be expected to occur with the implant restoration.

Partial denture patients may record forces intermediate between that of natural teeth and complete dentures, depending on the location and condition of the remaining teeth, muscles, and joints. In the partially edentulous patient with implant-supported fixed prostheses, force ranges are more similar to those of natural dentition, but lack of proprioception may magnify the load amount during parafunctional activity.

As a consequence of the opposing arch affecting the intensity of forces applied to an implant prosthesis, the treatment plan may be modified to reduce the risk of overload. Rarely should the opposing arch be maintained in a traditional denture to decrease the stress to the implant arch. Instead, the implant arch should be designed to compensate for the higher stresses expected from an implant-supported opposing arch (Figure 6-38).

WWW.HIGHDENT.IR

SUMMARY

Patient force factors are highly variable from one person to another. An implant foundation should be designed to support the load and resist the stresses while the restoration is in service. An ideal treatment plan may be established relative to the number and position of missing teeth. The treatment plan is then modified dependent on the force factors of the individual patient.

It is far better to overengineer the amount of support necessary for a prosthesis. If just one too few or too small an implant is used, implant bone loss, fracture, and failure may occur. As a general rule, the best way to reduce the risk of biomechanical overload is to add an implant.

The five most important force factors related to patient conditions were presented in this chapter. Of these, parafunction is the predominant element to account for in the treatment plan. On a scale of 1 to 10, severe bruxism is a 10; an excessive CHS can double a force, and therefore is a 7 on the importance scale. Severe masticatory dynamics can also double a force component and result in a 7 on this scale. Position of the abutment in the arch determines the magnitude of force and is a 1 or 2 when in the mandibular anterior region, a 3 or 4 in the maxillary anterior, a 5 in the posterior mandible, and a 6 or 7 in the posterior maxilla (as bone density is most ideal in the anterior mandible and least biomechanically favorable in the posterior maxilla). Direction of load under ideal implant placement conditions is a factor of 3 or 4 in the maxillary anterior regions. The other arch positions may have a more ideal direction of load, unless cantilever loads are positioned on the implant restoration. The opposing arch under typical treatment conditions is the least important force component modifier. A complete implant restoration may be a factor of 3, natural teeth a 2, and an opposing soft tissue–supported denture a 1.

Chapter 7

Bone Density: A Key Determinant for Treatment Planning

Carl E. Misch

Available bone is particularly important in implant dentistry and describes the external architecture or volume of the edentulous area considered for implants. Historically, the available bone was not modified in the implant candidate. Instead, the existing bone volume was the primary factor used to develop a treatment plan. Short implants and fewer implants were used in less available bone and long implants in greater numbers were inserted in larger bone volumes. Today, the treatment plan first considers the final prosthesis options. The patient force factors are then noted. The next consideration is the bone density in the sites of the implant abutments.

The internal structure of bone is described in terms of quality or density, which reflects a number of biomechanical properties, such as strength and modulus of elasticity. The external and internal architecture of bone controls virtually every facet of the practice of implant dentistry. The density of available bone in an edentulous site is a determining factor in treatment planning, implant design, surgical approach, healing time, and initial progressive bone loading during prosthetic reconstruction.[1,2] This chapter presents the aspects of bone density related to overall planning of an implant prosthesis.

INFLUENCE OF BONE DENSITY ON IMPLANT SUCCESS RATES

The quality of bone is often dependent upon the arch position.[3-7] The most dense bone is usually observed in the anterior mandible, followed by the anterior maxilla and posterior mandible, and the least dense bone is typically found in the posterior maxilla. Following a standard surgical and prosthetic protocol, Adell et al.[8] reported an approximately 10% greater success rate in the anterior mandible as compared with the anterior maxilla. Schnitman et al. also noted lower success rates in the posterior mandible as compared with the anterior mandible when the same protocol was followed.[9] The highest clinical failure rates have been reported in the posterior maxilla, where the force magnitude is greater and the bone density is poorer.[5-7,9-13] A range of implant survival has been found relative to arch location.

In addition to arch location, several independent groups have reported different failure rates related to the quality of the bone.[3-20a] Engquist et al. observed that 78% of all reported implant failures were in soft bone types.[16] Friberg et al. observed that 66% of their group's implant failures occurred in the resorbed maxilla with soft bone.[3] Jaffin and Berman, in a 5-year study, reported a 44% implant failure when poor-density bone was observed in the maxilla.[15] The article documented a 35% implant loss in any region of the mouth when bone density was poor. Fifty-five percent of all implant failures within their study sample occurred in the soft bone type. Johns et al. reported 3% failure of implants in moderate bone densities, but a 28% implant failure in the poorest bone type.[17] Smedberg et al. reported a 36% failure rate in the poorest bone density.[18] The reduced implant survival most often is more related to bone density than arch location. In a 15-year follow-up study, Snauwaert et al. reported early annual and late failures were more frequently found in the maxilla.[12] Hermann et al.[13] found implant failures were strongly correlated to patient factors, including bone quality, especially when coupled with poor bone volume (65% of these patients experienced failure). These reported failures are not primarily related to surgery healing, but instead occur after prosthetic loading. Therefore, over the years, many independent clinical groups, following a standardized surgical protocol, documented the indisputable influence of bone density on clinical success (Figure 7-1).*

However, a protocol established by the author, which adapts the treatment plan, implant selection, surgical approach, healing regimen, and initial prosthetic loading, has resulted in similar implant success rates in all bone densities and all arch positions.[21-24] This chapter proposes a scientific rationale for the modification of a

WWW.HIGHDENT.IR

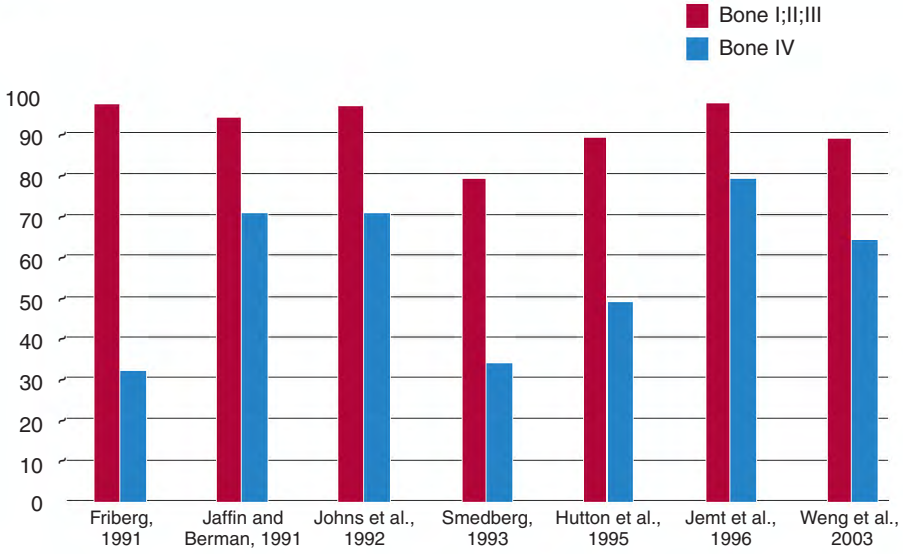

Figure 7-1 Over the years, several clinical reports observed higher success rates in better bone quality and lower survival rates in poor bone quality (Bone IV).

Figure 7-2 The maxilla is a force distribution unit, and the mandible is a force absorption unit.

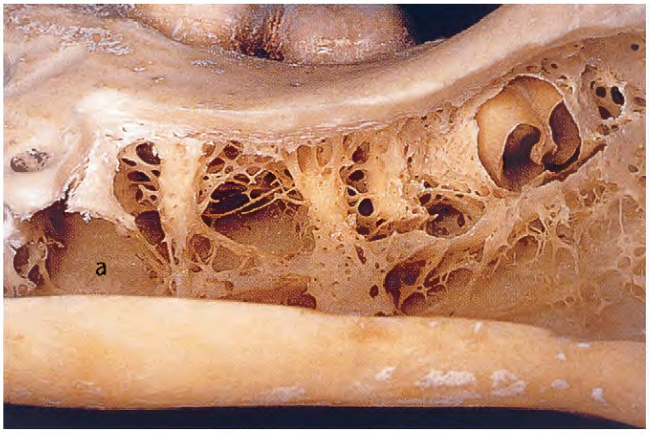

Figure 7-3 The trabecular bone in a dentate mandible is more coarse compared with the maxilla. The mandible, as an independent structure, is a force-absorbing element.

treatment plan in function of implant density to achieve comparable success rates in all bone types.

ETIOLOGY OF VARIABLE BONE DENSITY

Bone is an organ that is able to change in relation to a number of factors, including hormones, vitamins, and mechanical influences. However, biomechanical parameters, such as duration of edentulous state, are predominant.[25-29] Awareness of this adaptability has been reported for more than a century. In 1887, Meier qualitatively described the architecture of trabecular bone in the femur.[30] In 1888, Kulmann noticed the similarity between the pattern of trabecular bone in the femur and tension trajectories in construction beams.[31] Wolff, in 1892, further elaborated on these concepts and published, "Every change in the form and function of bone or of its function alone is followed by certain definite changes in the internal architecture, and equally definite alteration in its external conformation, in accordance with mathematical laws."[32] The modified function of bone and the definite changes in the internal and external formation of the vertebral skeleton as influenced by mechanical load were reported by Murry.[33] Therefore the external architecture of bone changes in relation to function, and the internal bony structure is also modified.

MacMillan[34] and Parfitt[35] have reported on the structural characteristics and variation of trabeculae in the alveolar regions of the jaws. For example, the maxilla and mandible have different biomechanical functions (Figure 7-2). The mandible, as an independent structure, is designed as a force-absorption unit. Therefore, when teeth are present, the outer cortical bone is denser and thicker and the trabecular bone is more coarse and dense

WWW.HIGHDENT.IR

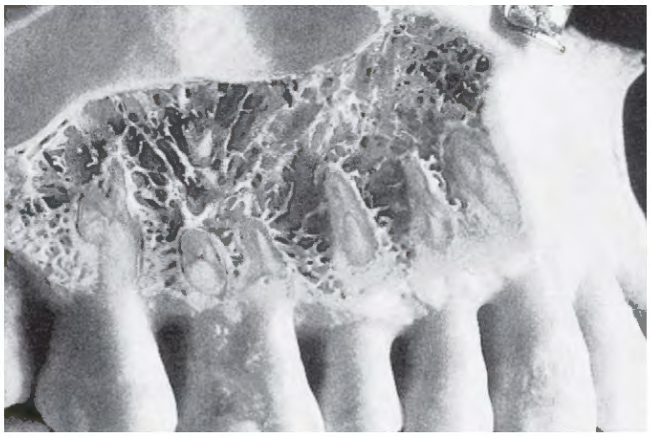

Figure 7-4 The dentate maxilla has a finer trabecular pattern compared with the mandible. The maxilla is a force distribution unit and is designed to protect the orbit and brain.

Figure 7-5 The trabecular bone of each jaw has structural variations. The trabecular bone is most dense next to the teeth, where it forms the cribriform plate. Between the teeth, the bone is usually most dense near the crest and least dense at the apex.

(Figure 7-3). On the other hand, the maxilla is a force-distribution unit. Any strain to the maxilla is transferred by the zygomatic arch and palate away from the brain and orbit. As a consequence, the maxilla has a thin cortical plate and fine trabecular bone supporting the teeth (Figure 7-4). They also noted that the bone is most dense around the teeth (cribriform plate) and more dense around the teeth at the crest, compared with the regions around the apices (Figure 7-5). Alveolar bone resorption associated with orthodontic therapy also illustrates the biomechanical sensitivity of the alveolar processes.[36] Generalized trabecular bone loss in the jaws occurs in regions around a tooth from a decrease in mechanical strain.[37] Orban demonstrated a decrease in the trabecular bone pattern around a maxillary molar with no opposing occlusion, compared with a tooth with occlusal contacts on the contralateral side[38] (Figure 7-6). Bone density in the jaws also decreases after tooth loss. This loss is primarily related to the length of time the region has been edentulous and not loaded appropriately, the initial density of the bone, flexure and torsion in the mandible, and parafunction before

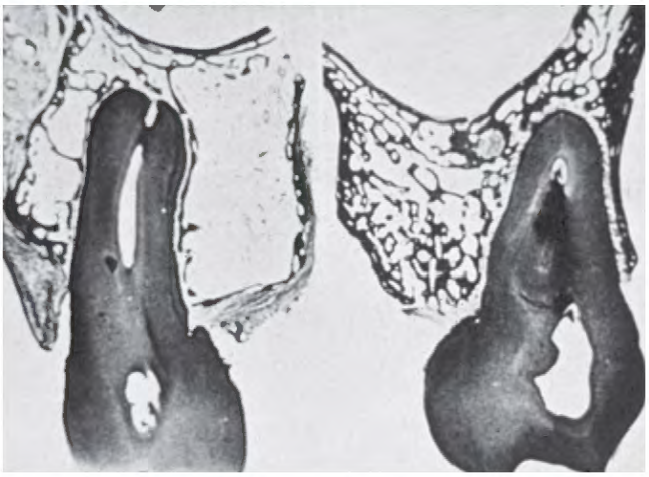

Figure 7-6 On the left, the opposing mandibular tooth was removed. A lack of occlusal contact resulted in loss of trabecular bone around the maxillary tooth. The tooth on the right is from the same monkey, with the opposing mandibular tooth in place. The trabecular bone is much more dense around the tooth. The disuse atrophy observed on the left is from inadequate microstrain conditions to maintain the bone. (*From Orban B*: Oral histology and embryology, *ed 3, St. Louis, 1953, Mosby*.)

and after tooth loss. In general, the density change after tooth loss is greatest in the posterior maxilla and least in the anterior mandible.

Cortical and trabecular bone throughout the body are constantly modified by either modeling or remodeling.[39] Modeling has independent sites of formation and resorption and results in the change of the shape or size of bone. Remodeling is a process of resorption and formation at the same site that replaces previously existing bone and primarily affects the internal turnover of bone, including that region where teeth are lost or the bone next to an endosteal implant.[40,41] These adaptive phenomena have been associated with the alteration of the mechanical stress and strain environment within the host bone.[42,43] Stress is determined by the magnitude of force divided by the functional area over which it is applied. Strain is defined as the change in length of a material divided by the original length. The greater the magnitude of stress applied to the bone, the greater the strain observed in the bone.[44] Bone modeling and remodeling are primarily controlled, in part or whole, by the mechanical environment of strain. Overall, the density of alveolar bone evolves as a result of mechanical deformation from microstrain. Frost proposed a model of four histologic patterns for compact bone as it relates to mechanical adaptation to strain.[45] The pathologic overload zone, mild overload zone, adapted window, and acute disuse window were described for bone in relation to the amount of the microstrain experienced (Figure 7-7). These four categories also may be used to describe the trabecular bone response in the jaws.

The bone in the acute disuse window loses mineral density, and disuse atrophy occurs because modeling for new bone is inhibited and remodeling is stimulated,

WWW.HIGHDENT.IR

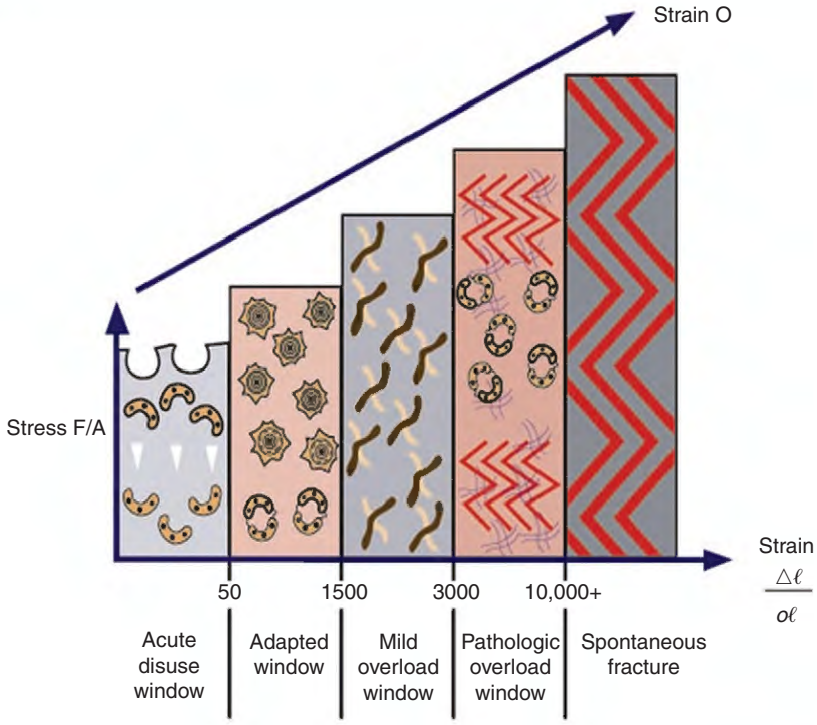

Figure 7-7 Four zones for bone related to mechanical adaption to strain before spontaneous fracture. The acute disuse window is the lowest microstrain amount. The adapted window is an ideal physiologic loading zone. The mild overload zone causes microfracture and triggers an increase in bone remodeling, which produces more woven bone. The pathologic overload zone causes increase in fatigue fractures, remodeling, and bone resorption.

with a gradual net loss of bone. The microstrain of bone for trivial loading is reported to be 0 to 50 microstrain. This phenomenon may occur throughout the skeletal system, as evidenced by a 15% decrease in the cortical plate and extensive trabecular bone loss consequent to immobilized limbs for 3 months.[46] A cortical bone density decrease of 40% and a trabecular bone density decrease of 12% also have been reported with disuse of bone.[47,48] Interestingly, bone loss similar to disuse atrophy has been associated with microgravity environments in outer space, because the microstrain in bone resulting from the earth's gravity is not present in the "weightless" environment of space.[49] In fact, an astronaut aboard the Russian Mir space station for 111 days lost nearly 12% of his bone minerals.[50,51]

The adapted window (50 to 1500 microstrain) represents an equilibrium of modeling and remodeling, and bone conditions are maintained at this level. Bone in this strain environment remains in a steady state, and this may be considered the homeostatic window of health. The histologic description of this bone is primarily lamellar or load-bearing bone. Approximately 18% of trabecular bone and 2% to 5% of cortical bone is remodeled each year[25] in the physiologic loading zone, which corresponds to the adapted window. This is the range of strain ideally desired around an endosteal implant, once a stress equilibrium has been established (Figure 7-8). Bone turnover is required in the adapted window, as Mori and Burr provide evidence of remodeling in regions of bone microfracture from fatigue damage within the physiologic range.[52]

The mild overload zone (1500 to 3000 microstrain) causes a greater rate of fatigue microfracture and increase

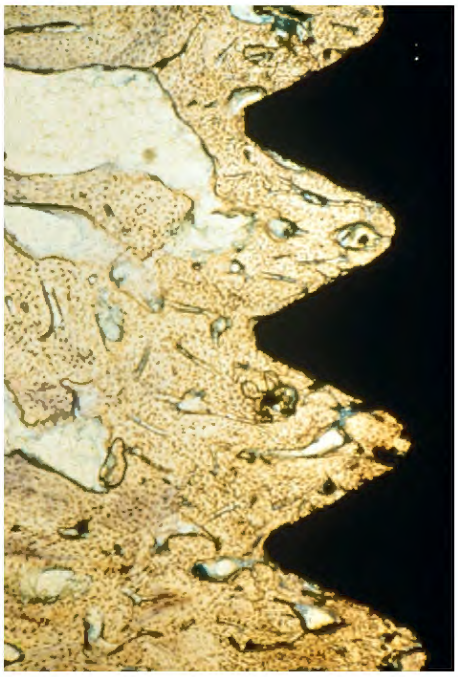

Figure 7-8 An ideal bone-implant interface has organized, lamellar bone next to the implant. The adapted window zone of microstrain balances remodeling and allows the bone to maintain this condition.

in the cellular turnover rate of bone. As a result, the bone strength and density may eventually decrease. The histologic description of bone in this range is usually woven or repair bone. This may be the state for bone when an endosteal implant is overloaded and the bone interface attempts to change the strain environment. During the repair process, the woven bone is weaker

WWW.HIGHDENT.IR

than the more mature, mineralized lamellar bone.[40] Therefore, while bone is loaded in the mild overload zone, care must be taken because the "safety range" for bone strength is reduced during the repair.[41]

Pathologic overload zones are reached when microstrains are greater than 3000 units.[45] Cortical bone fractures occur at 10,000 to 20,000 microstrain (1% to 2% deformation). Therefore pathologic overload may begin at microstrain levels of only 20% to 40% of the ultimate strength or physical fracture of cortical bone. The bone may resorb and form fibrous tissue, or when present, repair woven bone in this zone, as a sustained turnover rate is necessary. The marginal bone loss evidenced during implant overloading may be a result of the bone in the pathologic overload zone. Implant failure from overload may also be a result of bone in the pathologic overload zone.

BONE CLASSIFICATION SCHEMES RELATED TO IMPLANT DENTISTRY

An appreciation of bone density and its relation to oral implantology has existed for more than 25 years. Linkow, in 1970, classified bone density into three categories[53]:

- Class I bone structure: This ideal bone type consists of evenly spaced trabeculae with small cancellated spaces.
- Class II bone structure: The bone has slightly larger cancellated spaces with less uniformity of the osseous pattern.
- Class III bone structure: Large marrow-filled spaces exist between bone trabeculae.

Linkow stated that Class III bone results in a loose-fitting implant; Class II bone was satisfactory for implants; and Class I bone was the most ideal foundation for implant prostheses.

In 1985, Lekholm and Zarb listed four bone qualities found in the anterior regions of the jawbone[54] (Figure 7-9). Quality 1 was composed of homogeneous compact bone. Quality 2 had a thick layer of compact bone surrounding a core of dense trabecular bone. Quality 3 had a thin layer of cortical bone surrounding dense trabecular bone of favorable strength. Quality 4 had a thin layer of cortical bone surrounding a core of low-density trabecular bone. Irrespective of the different bone qualities, all bone was treated with the same implant design and standard surgical and prosthetic protocol.[8] Following this protocol, Schnitman and others observed a 10% difference in implant survival between Quality 2 and Quality 3 bone, and 22% lower survival in the poorest bone density.[3,9,16] Johns et al. reported 3% failure in Type III bone, but 28% in Type IV bone.[17] Smedberg et al. reported a 36% failure rate in Type IV bone.[18] Higuchi and others also experienced a greater failure in the soft bone of the maxilla.* It is obvious that a standardized surgical, prosthetic, and implant design protocol does not yield similar results in all bone densities. In addition, these reports are for implant survival, not the quality of health of surviving implants. The amount of crestal bone loss also has been related to bone density,[56-60] and further supports a different protocol for soft bone.

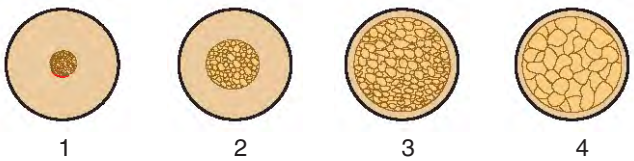

Figure 7-9 Four bone qualities for the anterior region of the jaws. Quality 1 is composed of homogenous compact bone. Quality 2 has a thick layer of cortical bone surrounding dense trabecular bone. Quality 3 has a thin layer of cortical bone surrounded by dense trabecular bone of favorable strength. Quality 4 has a thin layer of cortical bone surrounding a core of low-density trabecular bone. *(From Lekholm U, Zarb GA: Patient selection and preparation. In Brånemark P-I, Zarb GA, Albrektsson T, editors*: Tissue integrated protheses: osseintegration in clinical denistry, *Chicago, 1985, Quintessence.)*

In 1988, Misch proposed four bone density groups independent of the regions of the jaws, based on macroscopic cortical and trabecular bone characteristics.[1,2] The regions of the jaws with similar densities were often consistent. Suggested treatment plans, implant design, surgical protocol, healing, and progressive loading time spans have been described for each bone density type.[23,60,61] Following this regimen, similar implant survival rates have been observed for all bone densities.[21-23]

MISCH BONE DENSITY CLASSIFICATION

Dense or porous cortical bone is found on the outer surfaces of bone and includes the crest of an edentulous ridge. Coarse and fine trabecular bone types are found within the outer shell of cortical bone and occasionally on the crestal surface of an edentulous residual ridge. These four macroscopic structures of bone may be arranged from the least dense to the most dense, as first described by Roberts and Frost[25,45] (Figure 7-10).

In combination, these four increasing macroscopic densities constitute four bone categories described by Misch (D1, D2, D3, and D4) located in the edentulous areas of the maxilla and mandible (Figure 7-11). The regional locations of the different densities of cortical bone are more consistent than the highly variable trabecular bone.

D1 bone is primarily dense cortical bone. D2 bone has dense-to-porous cortical bone on the crest and, within

* References 5-7, 12, 13, 19, 20, 55.

WWW.HIGHDENT.IR

Figure 7-10 The macroscopic structure of bone may be described, from the least dense to the most dense, as (1) fine trabecular, (2) coarse trabecular, (3) porous cortical, and (4) dense cortical.

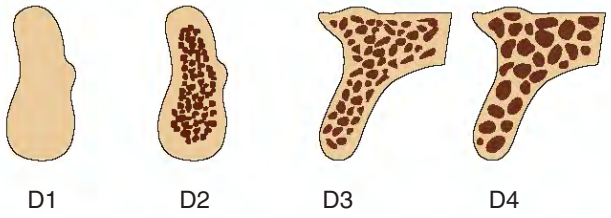

Figure 7-11 Four bone densities found in the edentulous regions of the maxilla and mandible. D1 bone is primarily dense cortical bone; D2 bone has dense to thick porous cortical bone on the crest and coarse trabecular bone underneath; D3 bone has a thinner porous cortical crest and fine trabecular bone within; and D4 bone has almost no crestal cortical bone. The fine trabecular bone composes almost all of the total volume of bone.

Table 7-1 Misch Bone Density Classification Scheme

BONE DENSITY	DESCRIPTION	TACTILE ANALOG	TYPICAL ANATOMICAL LOCATION
D1	Dense cortical	Oak or maple wood	Anterior mandible
D2	Porous cortical and coarse trabecular	White pine or spruce wood	Anterior mandible Posterior mandible Anterior maxilla
D3	Porous cortical (thin) and fine trabecular	Balsa wood	Anterior maxilla Posterior maxilla Posterior mandible
D4	Fine trabecular	Styrofoam	Posterior maxilla

Table 7-2 Usual Anatomic Location of Bone Density Types (% Occurrence)

BONE	ANTERIOR MAXILLA	POSTERIOR MAXILLA	ANTERIOR MANDIBLE	POSTERIOR MANDIBLE
D1	0	0	6	3
D2	25	10	66	50
D3	65	50	25	46
D4	10	40	3	1

the bone, has coarse trabecular bone. D3 bone types have a thinner porous cortical crest and fine trabecular bone in the region next to the implant. D4 bone has almost no crestal cortical bone. The fine trabecular bone composes almost all of the total volume of bone next to the implant (Table 7-1, Figure 7-12). A very soft bone, with incomplete mineralization and large intertrabecular spaces, may be addressed as D5 bone. This bone type is most often immature bone in a developing sinus graft. The bone density may be determined by tactile sense during surgery, the general location, or radiographic evaluation.

BONE DENSITY LOCATION

A review of the literature and a survey of completely and partially edentulous patients postsurgery indicated that the location of different bone densities often may be superimposed on the different regions of the mouth[3-7,11-13,15-20,62-66] (see Tables 7-1 and 7-2). D1 bone is almost never observed in the maxilla and is rarely observed in most mandibles. In the mandible, D1 bone is observed approximately 6% of the time in the Division A anterior mandible and 3% of the time in the posterior mandible, primarily when the implant

WWW.HIGHDENT.IR

Figure 7-12 The four macroscopic bone qualities are, from left to right, D1, D2, D3, and D4. The bone density variance is dependent upon anatomical location and the local strain history of the bone after tooth loss.

Figure 7-13 A cross section of a D2 mandible in the region of the mental foramen. A thick cortical plate exists on the crest and a coarse trabecular bone pattern exists within.

is engaging the lingual cortical plate of bone. In a C–h bone volume (moderate atrophy) in the anterior mandible, the prevalence of D1 bone approaches 25% in males. The C–h mandible often exhibits an increase in torsion, flexure, or both in the anterior segment between the foramina during function. This increased strain may cause the bone to increase in density. D1 bone also may be encountered in the anterior Division A mandible of a Kennedy Class IV partially edentulous patient with a history of parafunction and recent extractions. It may also be observed in the anterior or posterior mandible when the angulation of the implant may require the engagement of the lingual cortical plate.

The bone density D2 is the most common bone density observed in the mandible (Figure 7-13). The anterior mandible consists of D2 bone approximately two thirds of the time. Almost half of patients have D2 bone in the posterior mandible. The maxilla presents D2 bone less often than the mandible. Approximately one fourth of patients have D2 bone, and this is more likely in the partially edentulous patient's anterior and premolar region, rather than the completely edentulous posterior molar areas. Single-tooth or two-tooth, partially edentulous spans in either arch almost always have D2 bone.

Bone density D3 is very common in the maxilla (Figure 7-14). More than half the patients have D3 bone in the upper arch. The anterior edentulous maxilla has D3 bone about 75% of the time, whereas almost half the patients have posterior maxillae with D3 bone (more often in the premolar region). Almost half of the posterior mandibles also present with D3 bone, whereas approximately 25% of the anterior edentulous mandibles have D3 bone.

The softest bone, D4, is most often found in the posterior maxilla (approximately 40%), especially in the molar regions or after a sinus graft augmentation (where almost two thirds of the patients have D4 bone) (Figure 7-15). The anterior maxilla has D4 bone less

WWW.HIGHDENT.IR

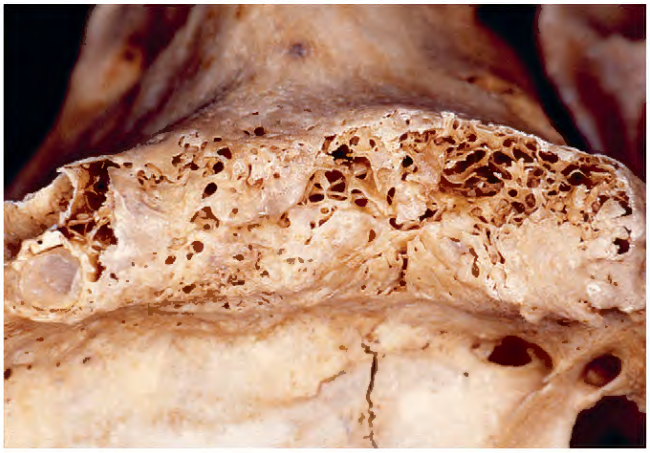

Figure 7-14 A posterior maxilla demonstrating D3 bone with a thin porous cortical plate on the crest with fine trabecular bone underneath.

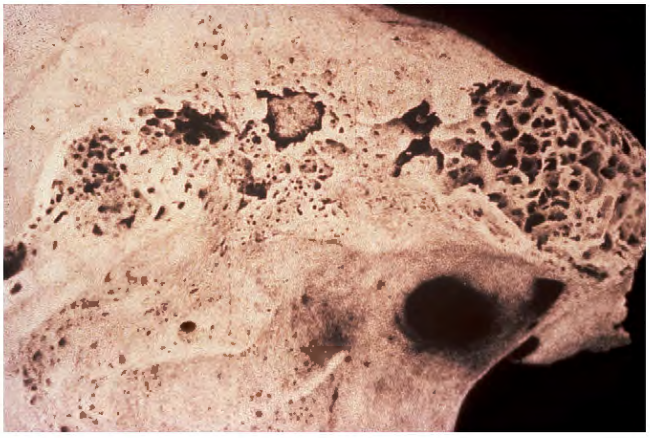

Figure 7-15 In a D4 posterior maxilla, the posterior crestal region has little to no cortical bone on the crest and is composed primarily of fine trabecular bone.

than 10% of the time—more often after an onlay iliac crest bone graft. The mandible presents with D4 bone in less than 3% of the patients. When observed, it is usually Division A bone in a long-term, completely edentulous patient after an osteoplasty to remove the crestal bone.

Generalizations for treatment planning can be made prudently, based on location. The bone density by location method is the first way the dentist can estimate the bone density in the implant sites to develop an initial treatment plan. It is safer to err on the side of less dense bone during treatment planning, so the prosthesis will be designed with slightly more, rather than less, support. Therefore the initial treatment plan before computed tomographic (CT) radiographic scans or surgery suggests the anterior maxilla is treated as D3 bone, the posterior maxilla as D4 bone, the anterior mandible as D2 bone, and the posterior mandible as D3 bone. A more accurate determination of bone density is made with computerized tomograms before surgery or tactilely during implant surgery.

RADIOGRAPHIC BONE DENSITY

Periapical or panoramic radiographs are not very beneficial to determine bone density, because the lateral cortical plates often obscure the trabecular bone density. In addition, the more subtle changes of D2 to D3 cannot be quantified by these radiographs. Therefore the initial treatment plan, which often begins with these radiographs, follows the bone density by location method. Bone density may be more precisely determined by tomographic radiographs, especially computerized tomograms.[67-70] Computed tomography produces axial images of the patient's anatomy, perpendicular to the long axis of the body. Each CT axial image has 260,000 pixels, and each pixel has a CT number (Hounsfield unit) related to the density of the tissues within the pixel. In general, the higher the CT number, the denser the tissue.

Box 7-1 CT Determination of Bone Density

D1:	>1250 Hounsfield units
D2:	850 to 1250 Hounsfield units
D3:	350 to 850 Hounsfield units
D4:	150 to 350 Hounsfield units
D5:	<150 Hounsfield units

CT, Computed tomography.

Modern CT scanners can resolve objects less than 0.5 mm apart. In addition, software is available to electronically position the implant on the CT scan and evaluate to Hounsfield numbers in contact with the implant. In a retrospective study of CT scan images from implant patients, Kirkos and Misch established a correlation between CT Hounsfield units and density at the time of surgery.[69] The Misch bone density classification may be evaluated on the CT images by correlation to a range of Hounsfield units (Box 7-1).[69] The very soft bone observed after some immaterialized bone grafts may be 50 to 200 units.[69] Even negative numbers, suggestive of fat tissue, have been observed with the cortical plates of some jaws, including the anterior mandible. Norton and Gamble also found an overall correlation between subjective bone density scores of Lekholm and Zarb and the CT values.[71] Several studies correlating torque forces at implant insertion with preoperative bone density values from CTs have reported similar conclusions.[72-74] Preoperative CT scan data of areas that lead to successful and unsuccessful implant placement have been reported. In the mandible, failed sites exhibited higher Hounsfield numbers than usual. This was correlated with failure in dense bone, possibly due to the lack of vascularization or overheating during

WWW.HIGHDENT.IR

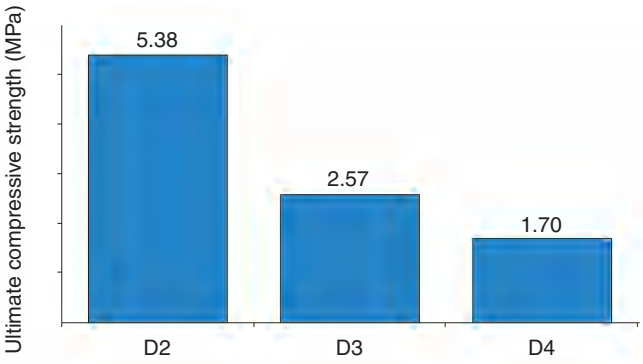

Figure 7-16 The ultimate compressive strength of D2 trabecular bone is greater than D3 trabecular bone. D4 trabecular bone is the weakest.

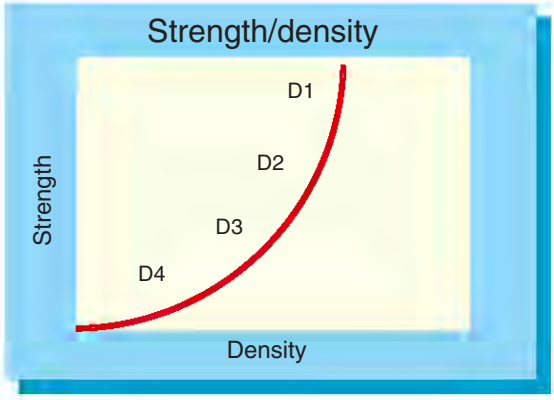

Figure 7-17 The strength of bone is related directly to the density of bone.

surgery. By contrast, in the maxilla, the bone density was low for the failed sites.[68]

The bone density may be different near the crest, compared with the apical region where the implant placement is planned.[75] The most critical region of bone density is the crestal 7 to 10 mm of bone, as this is where most stresses are applied to an osteointegrated bone-implant interface. Therefore when the bone density varies from the most crestal to apical region around the implant, the crestal 7 to 10 mm determines the treatment plan protocol.

BONE DENSITY–TACTILE SENSE

There is a great difference in the tactile sensation during osteotomy preparation in different bone densities, as the density is directly related to its strength.[1,2,74,76] To communicate more broadly to the profession relative to the tactile sense of different bone densities, Misch proposed the different densities of his classification be compared with materials of varying densities.[1,2] Site preparation and implant placement in D1 bone is similar to the resistance on a drill preparing an osteotomy in oak or maple wood. D2 bone is similar to the tactile sensation of drilling into white pine or spruce. D3 bone is similar to drilling into a compressed balsa wood. D4 bone is similar to drilling into a compressed Styrofoam or a light balsa wood. This clinical observation may be correlated to different histomorphometric bone density determinations.[62] When an implant drill can operate at 2000 to 2500 rpm, it may be difficult to feel the difference between D3 and D4 bone. In D4 bone, the drill may be inserted to the full desired depth without the drill rotating. In other words, a bone compression rather than extraction process may be used with the drill. D3 bone is very easy to prepare, but requires the drill to rotate while it is pressed into position. When this tactile method is the primary site, the surgeon should know how to modify the treatment plan if this bone density is different than first estimated when developing the treatment plan.

SCIENTIFIC RATIONALE OF A BONE DENSITY–BASED TREATMENT PLAN

Bone Strength and Density

Bone density is directly related to the strength of bone before microfracture.[77,78] Misch et al. reported on the mechanical properties of trabecular bone in the mandible, using the Misch density classification.[76] A tenfold difference in bone strength may be observed from D1 to D4 bone. D2 bone exhibited a 47% to 68% greater ultimate compressive strength, compared with D3 bone (Figure 7-16). In other words, on a scale of 1 to 10, D1 bone is a 9 to 10 relative to strength. D2 bone is a 7 to 8 on this scale. D3 bone is 50% weaker than D2 bone and is a 3 or 4 on the strength scale. D4 bone is a 1 to 2 and up to 10 times weaker than D1 bone (Figure 7-17). Bidez and Misch performed three-dimensional, finite stress analyses on bone volumes of Division A, B, and C–w patients.[79] Each model reproduced the cortical and trabecular bone material properties of the four densities described. Clinical failure was mathematically predicted in D4 bone and some D3 densities under occlusal loads (Figure 7-18). The bone densities that originally relied on clinical impression are now fully correlated to quantitative objective values obtained from CT scans and bone strength measurements. These values can help prevent failure in specific situations of weak densities.

Elastic Modulus and Density

The elastic modulus describes the amount of strain (changes in length divided by the original length) as a result of a particular amount of stress. It is directly related to the apparent density of bone.[78] The elastic modulus of a material is a value that relates to the stiffness of the material. The elastic modulus of bone is more flexible than titanium. When higher stresses

WWW.HIGHDENT.IR

are applied to an implant prosthesis, the titanium has lower strain (change in shape) compared with the bone. The difference between the two materials may create microstrain conditions of pathologic overload and cause implant failure (Figure 7-19, *A*). When the stresses applied to the implant are low, the microstrain difference between titanium and bone is minimized and remains in the adapted window zone, maintaining load-bearing lamellar bone at the interface (Figure 7-19, *B*).

Misch et al. found the elastic modulus in the human jaw to be different for each bone density[76] (Figure 7-20). As a result, when a stress is applied to an implant prosthesis in D1 bone, the titanium–D1 bone interface exhibits very small microstrain difference. In comparison, when the same amount of stress is applied to an implant in D4 bone, the microstrain difference between titanium and D4 bone is greater and may be in the pathologic overload zone (Figure 7-21). As a result, D4 bone is more likely to cause implant mobility and failure.[79] Several studies using finite element analysis (FEA) models with various implant designs and bone quality have evaluated the stress/strain distribution in the bone around the implants. Conclusions agree with the prior study to show the importance of bone

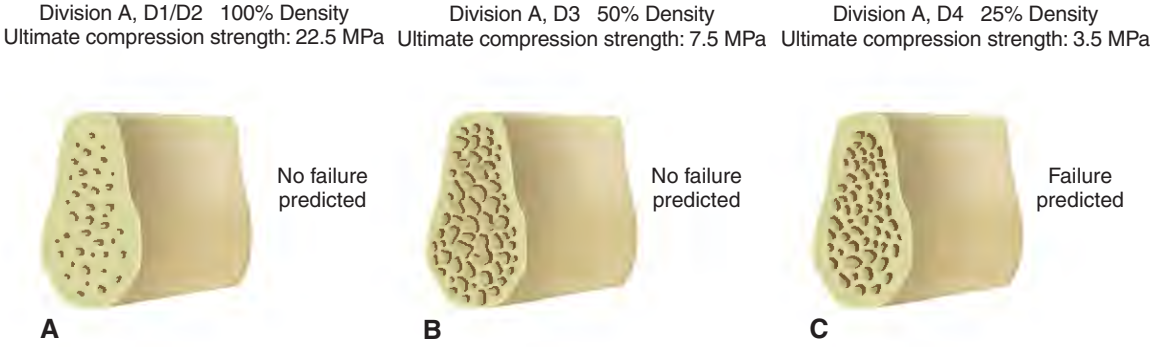

Figure 7-18 **A,** A finite element analysis study of D1 bone with a Division A, B, or C bone volume predicted no implant failure. **B,** In a finite element analysis study of D3 bone of one third the strength, no failure was predicted in Division A bone. **C,** In a finite element analysis study, D4 bone was inadequate in strength for implant success, even in Division A bone volume.

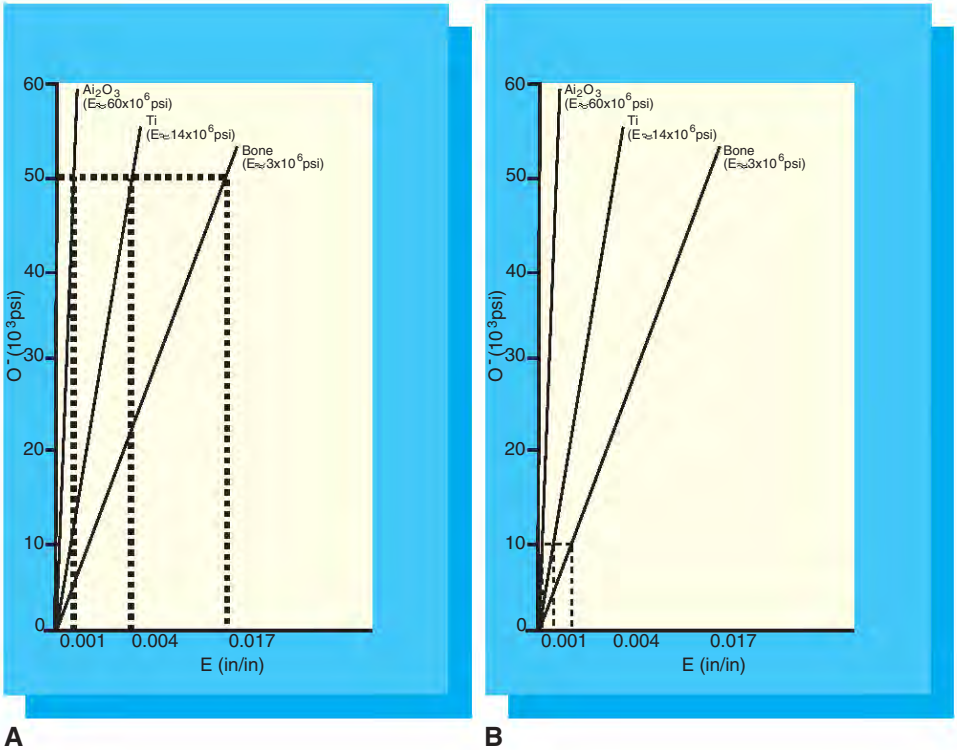

Figure 7-19 **A,** When the microstrain is high (50×10^3 psi in this example), the change in shape difference of titanium and bone is large and may result in a pathologic overload zone. As a result, fibrous tissue at the interface and implant mobility is expected. **B,** When the microstrain is low (10×10^3 psi in this example), the change in shape difference between titanium and bone is small and may result in the ideal adapted window zone. As a result, organized, lamellar bone may remain at the implant interface.

quality in the treatment planning phase for long-term prognosis.[80-85]

Bone Density and Bone-Implant Contact Percentage

The initial bone density not only provides mechanical immobilization of the implant during healing, but after healing also permits distribution and transmission of stresses from the prosthesis to the implant-bone interface. The mechanical distribution of stress occurs primarily where bone is in contact with the implant. Open marrow spaces or zones of unorganized fibrous tissue do not permit controlled force dissipation or microstrain conditions to the local bone cells. Because stress equals force divided by the area over which the force is applied, the less the area of bone contacting the implant body, the greater the overall stress, other factors being equal. Therefore the bone-implant contact percent may influence the amount of stress/strain at the interface.

Misch noted in 1990 that the bone density influences the amount of bone in contact with the implant surface, not only at first stage surgery, but also at the second stage uncovery and early prosthetic loading.[2] The bone-implant contact (BIC) percentage is significantly greater in cortical bone than in trabecular bone. The very dense D1 bone of a C–h resorbed anterior mandible or of the lingual cortical plate of a Division A anterior or posterior mandible provides the highest percentage of bone in contact with an endosteal implant and may approximate more than 85% BIC (Figure 7-22). D2 bone, after initial healing, usually has 65% to 75% BIC (Figure 7-23). D3 bone typically has 40% to 50% BIC after initial healing (Figure 7-24). The sparse trabeculae of the bone often found in the posterior maxilla (D4) offer fewer areas of contact with the body of the implant. With a machined-surface implant this may

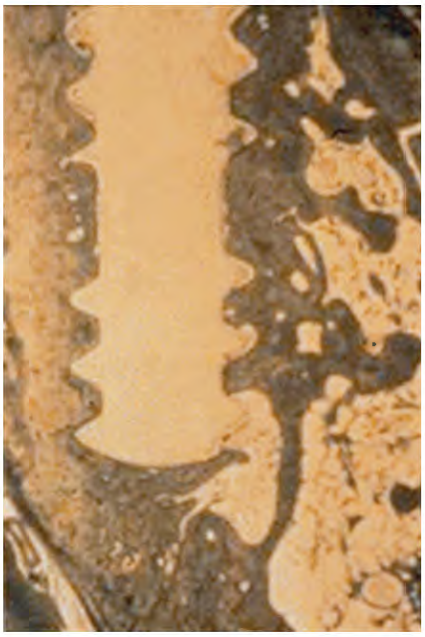

Figure 7-22 D1 bone density has the greatest amount of bone-implant contact. Because stress equals force divided by area, the increase in the area of contact results in a decreased amount of stress.

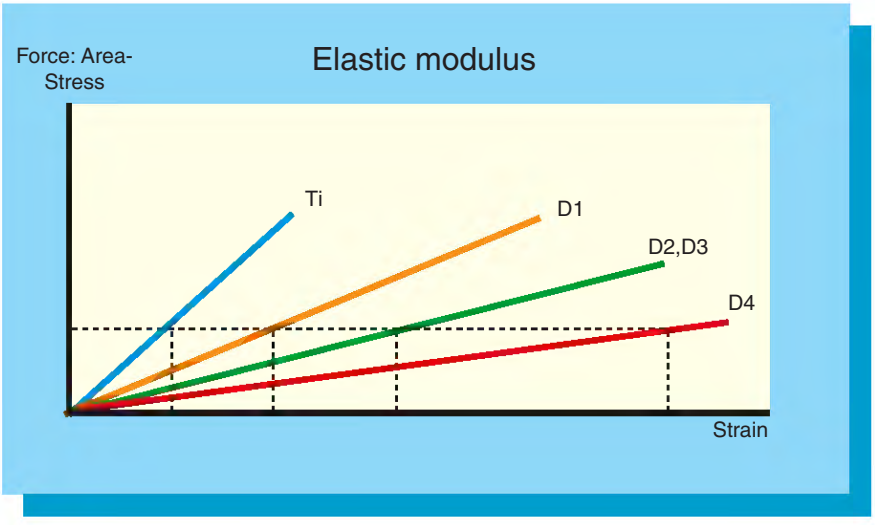

Figure 7-21 The microstrain difference between titanium and D4 bone is great and may be in the pathologic overload zone, whereas at the same stress level, the microstrain difference between titanium and D2 bone may be within the ideal adapted window zone.

WWW.HIGHDENT.IR

Figure 7-23 In D2 bone density, one finds primarily coarse trabecular bone next to the implant. The bone-implant contact is greater than D3 bone but less than D1 bone.

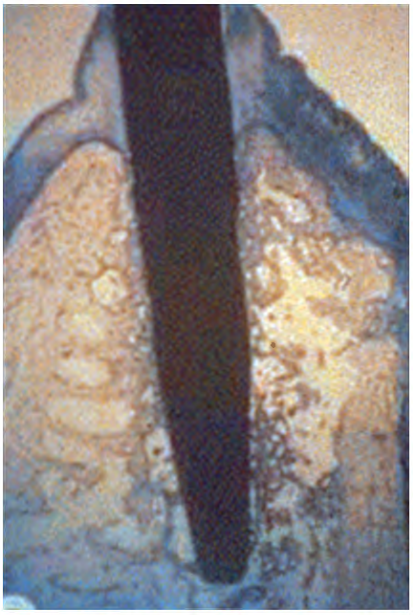

Figure 7-24 The fine trabecular bone of D3 initially heals next to the implant with 40% to 50% bone implant contact.

approximate less than 30% BIC and is most related to the implant design and surface condition (Figure 7-25). Consequently, greater implant surface area is required to obtain a similar amount of bone-implant contact in soft bone, compared with a denser bone quality found around an anterior mandibular implant.

Bone Density and Stress Transfer

Crestal bone loss and early implant failure after loading results may occur from excess stress at the implant-bone interface.[48-51,56-59,80-84] A range of bone loss has been observed in implants with similar load conditions.[59] Misch noted in 1990 that part of this phenomenon may be explained by the evaluation of finite element analysis stress contours in the bone for each bone density.[2] As a result of the correlation of bone density, elastic modulus bone strength, and bone-implant contact percent, when a load is placed on an implant, the stress contours in the bone are different for each bone density. In D1 bone, highest strains are concentrated around the implant near the crest, and the stress in the region is of lesser magnitude. D2 bone, with the same load, sustains a slightly greater crestal strain, and the intensity of the stress extends farther apically along the implant body (Figure 7-26). D4 bone exhibits the greatest crestal strains, and the magnitude of the stress on the implant proceeds farthest apically along the implant body (Figure 7-27). As a result, the magnitude of a prosthetic load may remain similar and yet give one of the following three different clinical situations at the bone-implant interface, based on bone density: (1) physiologic bone loads in the adapted window

Figure 7-25 D4 bone has the least bone-implant contact. As a result, the stress is greatest for the D4 bone-implant interface. Trabecular bone is fine, the strength is poor, and the modulus of elasticity microstrain difference is greatest. The microstrain difference for each bone density is not the same. D4 bone is most at risk, whereas D1 bone is least at risk.

zone and no marginal bone loss, (2) mild overload to pathologic overload bone loads and crestal bone loss, or (3) generalized pathologic overload and implant failure. Therefore, to obtain a similar clinical result in each implant prosthesis, the variables in each patient must be either eliminated or accounted for in the treatment plan. As the myriad of variables cannot be

WWW.HIGHDENT.IR

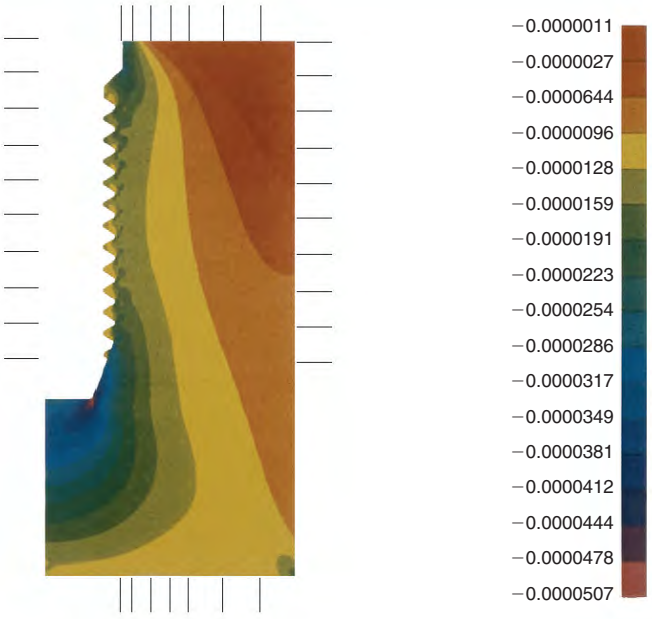

Figure 7-26 Stress transfer around the implant interface is different for each bone density. In this two-dimensional finite element analysis, D2 bone has an intermediate stress intensity around the implant.

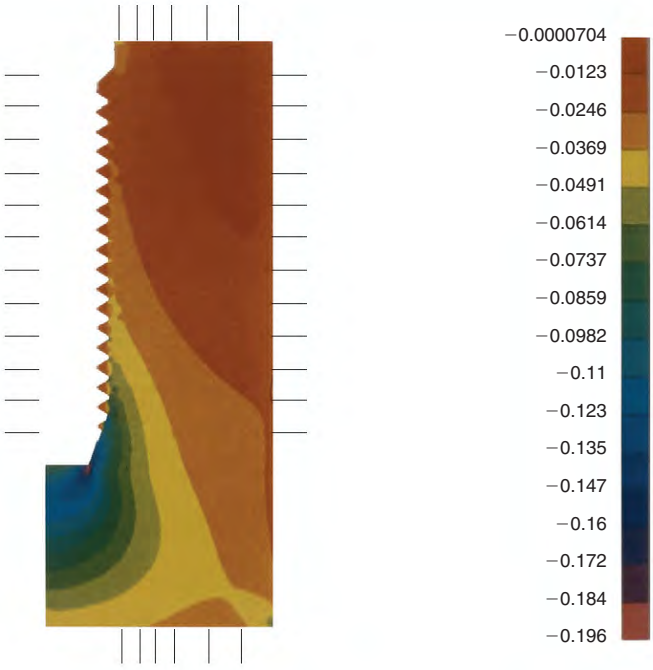

Figure 7-27 A two-dimensional finite element analysis demonstrates that D4 bone has a higher stress intensity around the implant, and the higher intensity even extends to the zone around the apical threads.

eliminated relative to bone density, the treatment plans (including implant number, size, and design) should be modified.

TREATMENT PLANNING

When a patient is first examined, the most common radiographic evaluation is with a panoramic radiograph. The initial treatment plan is presented to the patient using the anatomical location as an index of the bone density: anterior mandible and single tooth replacement is D2, anterior maxilla and posterior mandible is D3, and posterior maxilla is D4. After the following treatment steps are taken into consideration (e.g., implant key position and number, implant size and design, and available bone), a more complete treatment plan relative to bone density is obtained by a CT scan or modified during the surgical procedure using the tactile method to determine bone density.

Four facts form the basis for treatment plan modification in function of the bone quality: (1) each bone density has a different strength; (2) bone density affects the elastic modulus; (3) bone density differences result in different amounts of bone-implant contact percent; and (4) bone density differences result with a different stress-strain distribution at the implant-bone interface. Bone density is an implant treatment plan modifier in several ways—prosthetic factors, implant size, implant design, implant surface condition, implant number, and the need or method of progressive loading.

As the bone density decreases, the strength of the bone also decreases. To decrease the incidence of microfracture of bone, the strain to the bone should be reduced.

Box 7-2 Treatment Plans

Bone density/Treatment plan
Stress = Force/Area
↓ Bone density = ↑ Implant area

- Implant number
- Implant width
- Implant length
- Implant design
- Implant surface condition

Strain is directly related to stress. Consequently, the stress to the implant system should also be reduced as the bone density decreases (Box 7-2). One way to reduce the biomechanical loads on implants is by prosthesis design to decrease force. For example, cantilever length may be shortened or eliminated, narrower occlusal tables designed and offset loads minimized, all of which reduce the amount of load.[44] RP-4 restorations, rather than fixed prostheses, permit the patient to remove the restorations at night and reduce nocturnal parafunctional forces. RP-5 prostheses permit the soft tissue to share the occlusal force and reduce the stress on the implants. Night guards and acrylic occlusal surfaces distribute and dissipate parafunctional forces on an implant system. As the bone density decreases, these prosthetic factors become more important.

The load on the implant may also be influenced by the direction of force to the implant body.[79] A load directed along the long axis of the implant body decreases the amount of stress in the crestal bone

WWW.HIGHDENT.IR

region compared with an angled load. Therefore as the bone density decreases, axial loads on the implant body become more critical. Bone grafting or bone spreading to increase the width of bone and to better position the implant relative to the intended load is considered for soft bone types.

Stress may also be reduced by increasing the functional area over which the force is applied. Increasing implant number is an excellent way to reduce stress by increasing functional loading area. Three implants rather than two may decrease applied implant moments in half and bone reaction forces by two thirds, depending on implant position and size.[44] An implant prosthesis with normal patient forces in the bone should have at least one implant per tooth. In the molar region, two implants for each missing molar may be appropriate. In D2 bone with normal patient forces, a pontic may replace a tooth between two implants. In D3 bone, one implant per tooth is often appropriate.

The surface area of the implant macrogeometry may be increased to decrease stress to the implant-bone interface.[60,86] The width of the implant may decrease stress by increasing the surface area.[60,87] This may also reduce the length requirement. For every 0.5 mm increase in width, there is an increased surface area between 10% and 15% for a cylinder implant, and even more difference is found with threaded-implant body designs. Because the greatest stresses are concentrated at the crestal region of the implant, width is more significant than length for an implant design, once adequate length has been established. D4 bone should often require wider implants compared with D1 or D2 bone. This may require onlay grafts or bone spreading to increase the width of bone, when other stress factors are high. Based on long-term clinical experience of V-shaped threaded implant bodies, the minimum bone height for initial fixation and early loading for D1 bone is 7 mm; for D2 bone, 9 mm; and for D3 bone, 12 mm using the classic V-thread screw implant design and titanium surface condition. D4 bone benefits from relatively longer implants for initial fixation and early loading compared with other bone densities, not only for initial fixation, but also because the stress/strain transfer of occlusal forces extends farther down the implant body. This implant length requirement may require sinus grafts in the posterior maxilla. However, because the crestal region is where pathologic overload of bone most often occurs after prosthetic loading, once initial healing is complete the length of the implant is not as effective to solve crestal bone loss (and the quality of implant health) as other factors (e.g., implant design, implant width).

The macro design affects the magnitude of stresses and their impact on the bone-implant interface[10,80,88,89] and can dramatically change the amount and contour of the bone strains concentrated at the interface. Different implant design criteria respond to different bone densities. Bone densities exhibit a tenfold difference in strength, and the elastic modulus is significantly different between D1 and D4. Implants designed for D4 bone should have the greatest surface area. For example, a classic V-thread screw design has 30% more surface area than a cylinder implant. A thread design with more threads has more surface area than one with fewer threads. The depth of the thread is also a variable that may be controlled, based on the surface area desired. The deeper the thread depth in the implant body, the more functional surface area for the bone-implant contact. An implant body designed for the soft bone should have more and deeper threads than an implant body designed for hard bone (Figure 7-28). A D1 implant, on the other hand, may be designed for easy surgical placement, as the strains under load are minimized, but the surgical failure rates are greater.

Figure 7-28 Several features may be incorporated in the implant design to decrease stress after loading. The implant on the right has more threads than the implant on the left. The thread depth may be greater to increase surface area. A rough surface condition will also increase bone-implant contact. As a result, the implant on the right (BioHorizons D4 Maestro Implant) has more functional surface area than the implant on the left (BioHorizons D2 Maestro Implant). In soft bone types, the implant on the right has a loading advantage.

Coatings or the surface condition on an implant body can increase the bone-implant contact percentage and therefore the functional surface area. A rougher surface is strongly suggested in soft bone and has resulted in improved short-term survival rates when compared with machined titanium.[11] After 1 to 2 years, the mechanical load on the overall implant design is more critical to the amount and type of bone contact compared with the surface condition on the implant body. Rough surface conditions also may have some disadvantages. Plaque retention when exposed above the bone, contamination, and increased cost are a few of the concerns with roughened surfaces. The benefit and risk of surface conditions suggests the roughest surfaces are most often used in only softer bone types.

Progressive bone loading provides for a gradual increase in occlusal loads, separated by a time interval

WWW.HIGHDENT.IR

to allow the bone to mature and accommodate to the local strain environment.[2] Over time, progressive loading changes the amount and density of the implant-bone contact. The increased density of bone at the implant interface improves the overall support system mechanism. The softer the bone, the more important the need for progressive loading.[1,2]

SUMMARY

A key determinant for clinical success is the diagnosis of the bone density in a potential implant site. The strength of bone is directly related to bone density. The modulus of elasticity is related to bone density. The percentage of bone-implant contact is related to bone density, and the axial stress contours around an implant are affected by the density of bone. As a consequence, past clinical reports that did not alter the protocol of treatment related to bone density had variable survival rates. To the contrary, altering the treatment plan to compensate for soft bone types has provided similar survival rates in all bone densities. Once the prosthetic option, key implant position, and patient force factors have been determined, the bone density in the implant sites should be evaluated to modify the treatment plan. The treatment plan may be modified by reducing the force on the prosthesis or increasing the area of load by increasing implant number, implant position, implant size, implant design, or implant body surface condition.

Chapter 8

Treatment Plans Related to Key Implant Positions and Implant Number

Carl E. Misch

In the past, treatment planning for implant dentistry was primarily driven by the existing bone volume in the edentulous sites. As a result, distal cantilevers were extended from anterior implants or shorter implants were placed in the posterior regions of the mouth. A second historical phase of treatment planning has since developed based on esthetics. In this scheme, implant positions were primarily controlled by the teeth being replaced.

The primary causes of complications in implant dentistry are related to biomechanics.[1] For example, early loading failures outnumber surgical healing failures, especially in soft bone, when forces are greater than usual or implant sizes are shorter than 10 mm. Misch developed a treatment plan sequence to decrease the risk of biomechanical overload, consisting of following[2]:

1. Prosthesis design
2. Patient force factors
3. Bone density in the edentulous sites
4. Key implant positions and number
5. Implant size
6. Available bone in the edentulous sites
7. Implant design

This chapter will consider the key implant positions for a prosthesis, followed by the overall number of implants to support the restoration.

ABUTMENT OPTIONS

Several treatment options are available for the adequate restoration of an edentulous segment. As a general rule, implant-supported prostheses independent from natural adjacent teeth are designed whenever possible. This concept reduces the risk of decay on the natural tooth margin next to the adjacent pontic or abutment. The incidence of decay on a tooth splinted in a fixed partial denture accounts for 22% of the complications within 10 years, whereas individual crowns have less than 1% risk of decay within this time frame.[3] Unrestored natural teeth have less risk of decay, and implants do not decay at all. A second common complication of teeth-supported fixed prosthetic restorations is endodontic-related factors that occur in approximately 15% of cases within 10 years. Implant abutments do not require endodontic procedures, and unsplinted natural tooth crowns have less endodontic procedures. Independent implant prostheses may also reduce or eliminate pontics, while simultaneously increasing the number of abutments and distributing forces more effectively. The increase in abutment number decreases the risk of an unretained restoration, which is the third most common fixed prosthesis complication supported by natural teeth. Therefore independent implant prostheses cause fewer complications and exhibit greater long-term success rates of the prosthesis and greater survival rates of the adjacent teeth.[4] However, when an implant restoration is joined to a natural tooth, an increased risk of abutment screw loosening, implant marginal bone loss, and unretained restoration occurs. In addition, the distribution of occlusal forces is optimized when independent implant prostheses are designed. As a result, the ideal treatment plan for a partially edentulous patient includes an independent implant restoration.

Key Implant Positions

Some implant positions are more critical than others in regard to force reduction. There are four general guidelines to determine key implant positions (Box 8-1):

1. Cantilevers on the prosthesis should be reduced and preferably eliminated; therefore the terminal abutments in the prosthesis are key positions.

Box 8-1 Guidelines for Key Implant Positions

No cantilevers
No three adjacent pontics
Canine-molar rule
Arch dynamics

WWW.HIGHDENT.IR

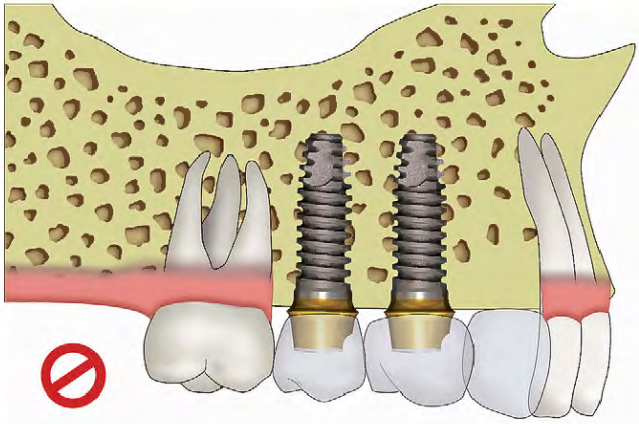

Figure 8-1 Ideal key implant positions include the terminal abutment positions when adjacent teeth are missing. Without a terminal abutment, a cantilever exists on the restoration, which increases complications. This is particularly important when a lateral load or heavy bite force is applied to the cantilever.

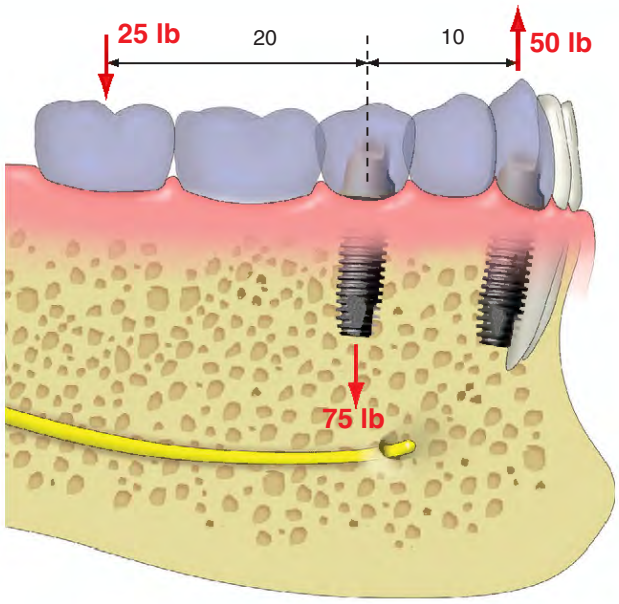

Figure 8-2 A cantilever on two implants may be considered a Class 1 lever. When the center of each implant is 10 mm apart, with a 20-mm cantilever, a mechanical advantage of 2 is created. Therefore the load on the cantilever will be multiplied by 2 on the far implant, and the implant close to the cantilever receives the total stress of the two loads.

2. Three adjacent pontics should not be designed in the prosthesis.
3. The canine and first molar sites are key positions, especially when adjacent teeth are missing.
4. An arch is divided into five segments. When more than one segment of an arch is being replaced, a key implant position is at least one implant in each segment.

No Cantilevers

The first rule for ideal key implant positions is that no cantilever should be designed in the prosthesis (Figure 8-1). Cantilevers are force magnifiers to the implants, abutment screws, cement or prosthesis screws, and implant-bone interface. Cantilevers on fixed partial dentures supported by teeth have a higher complication rate than prostheses with terminal abutments, including unretained restorations. This is especially noted with parafunction or reduced crown height spaces.[5] Therefore the ideal key implant positions include the terminal abutment positions when adjacent teeth are missing.

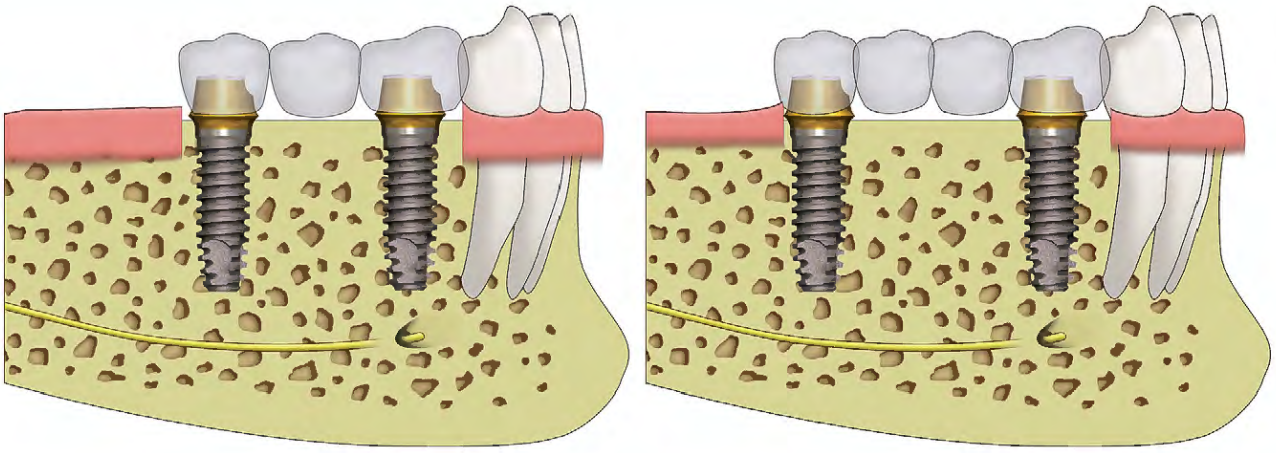
The length of the cantilever is directly related to the amount of the additional force placed on the abutments of the prosthesis. Therefore when a 25-lb force is placed along the long axis of an implant, the implant system (i.e., crown, cement, abutment, abutment screw, implant body, implant marginal bone, and implant bone interface) receives a 25-lb load. When a force of the same magnitude (25 lb) is applied on a 10-mm cantilever, the moment force on the abutment is increased to a 250-lb millimeter force. As a result, any part of the implant system is at an increased risk of biomechanical failure (e.g., porcelain fracture, uncemented prosthesis, abutment screw loosening, crestal bone loss, implant failure, implant component or body fracture).

A cantilevered restoration on multiple implants may be compared with a class I lever. The extension of the prosthesis from the last abutment is the *effort arm* of the lever. The last abutment next to the cantilever acts as a fulcrum when a load is applied to the lever. The distance between the last abutment and the farthest abutment from the end of the cantilever represents the *resistance arm* and may be called the anteroposterior distance or A-P spread of the implants. The length (usually in millimeters) of the cantilever (effort arm) divided by the resistance arm represents the *mechanical advantage.* Therefore, when two implants are 10 mm apart with a cantilever or extension of 20 mm, the mechanical advantage is two (20 mm/10 mm). In this example, a 25-lb force on the cantilever results with a 50-lb force on the farthest abutment from the cantilever (25 lb × 2 = 50 lb). The abutment closest to the cantilever (fulcrum) receives a force equal to the sum of the other two forces, or, in this example 75 lb (25 lb + 50 lb) (Figure 8-2). Therefore cantilevers magnify forces to all the abutments supporting the prosthesis.

To enforce the rule of no cantilever, the key implant positions when one or two adjacent teeth are missing indicate one implant per tooth. When 3 to 14 adjacent teeth are missing, the key implant positions include the two terminal abutments, one on each end of the prosthesis. A three- to four-unit prosthesis may be fabricated with only these abutments, when nearly all the force factors are low and the bone density is favorable (Figure 8-3). Restorations of 5 to 14 units require additional abutments.

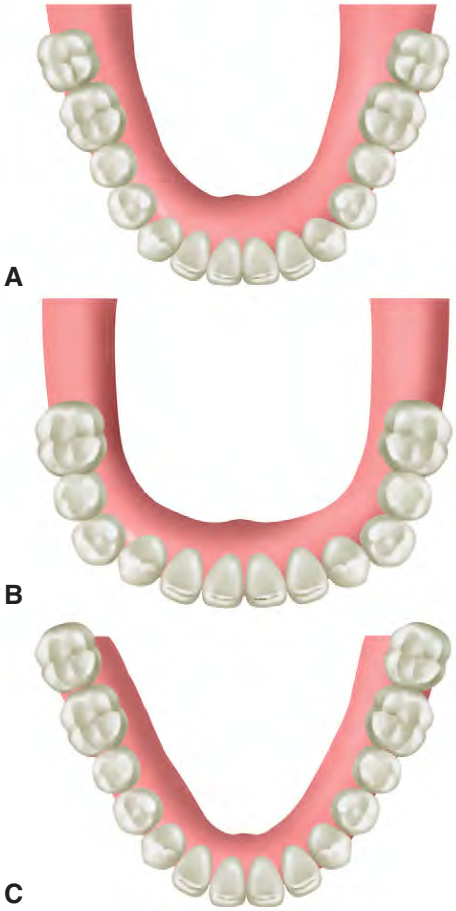
The ideal treatment plan should eliminate cantilevers. However, in some clinical conditions, a cantilever is the most prudent treatment option. For example, in

WWW.HIGHDENT.IR



A B

Figure 8-3 **A,** When three adjacent teeth are missing, the terminal abutments are key implant positions. When all patient force factors are low and bone density is good, these abutments may be adequate to replace the three missing teeth. **B,** When four adjacent teeth are missing, the terminal abutments are key implant positions. Rarely are these two implants sufficient to replace four posterior teeth.



A B C

Figure 8-4 The anteroposterior distance (A-P spread) of five implants in the mandible is measured from the distal of the last two implants to the mid position of the most anterior implant. Because these splinted implants form an arch, the cantilever may extend up to 2.5 times the A-P distance (when patient force factors are low and bone density is good). Arch shape affects the A-P distance. The ovoid arch form **(A)** often has an A-P distance of 6 to 8 mm. A square arch form **(B)** often has an A-P dimension of 2 to 5 mm. A tapered arch form **(C)** has the greatest A-P distance, larger than 8 mm.

an edentulous mandible, available bone in the posterior regions may be insufficient for root form implant placement, without advanced procedures (e.g., nerve repositioning, iliac crest bone grafts). An alternative treatment plan may be to cantilever pontics from anterior implants. However, when terminal abutments are not designed in the treatment plan and a cantilever is planned, other force and surface area factors should compensate for the increase in force. When this option is considered, the force factors of parafunction, crown height, masticatory dynamics, implant location, and opposing arch are closely scrutinized. In addition to force modifiers, the A-P distance (A-P spread) of the distal and anterior implants is also a factor. When the implants are in one plane, the cantilever should rarely extend farther than the A-P distance, regardless of how low the patient force factors (see Figure 8-1). When the force factors are unfavorable, the cantilever length should be reduced or eliminated, the implant number increased, the implant size increased, or the implant design surface areas increased. When five or more implants are positioned around an arch, and several different plans exist because of the arch form of the splinted implant, the cantilever may extend as far as 2.5 times the A-P distance when force factors are low and density is favorable (Figure 8-4). However, more than two pontics are not indicated on a posterior cantilever, even under ideal conditions.

When the cantilever on the prosthesis is represented by only a lateral incisor, the ideal implant position may not include the lateral incisor position when bite forces are low to moderate. The lateral incisor is the smallest tooth in the arch, so the cantilever is limited. The anterior bite forces are lowest in the central and lateral incisor region. The occlusal contact on the pontic may be eliminated and further reduce risk of overload.

WWW.HIGHDENT.IR

When a pontic replaces the lateral incisor, the soft tissue drape may be improved compared with an implant. As a result, the ideal implant position based on force and esthetics may be a larger-diameter implant in the canine position (i.e., 5-mm versus 4-mm diameter) and a cantilever pontic to replace the lateral incisor.

The fact that, on occasion, a cantilever may be acceptable when force factors are low and bone density is favorable does not negate the ideal goal that no cantilever should be designed in the prosthesis. Therefore when three or more adjacent teeth are missing, the terminal abutments at each end of the prosthesis are first designed in the treatment plan. When this option is not readily available, additional implants, larger implant sizes, and greater implant surface area design are indicated. In addition, the forces to the cantilevered portion of the prosthesis should be reduced.

No Three Adjacent Pontics

In most prostheses designs, three adjacent pontics are contraindicated on implants, just as they are contraindicated on natural abutments.[6] The adjacent abutments are subjected to considerable additional force when they must support three missing teeth, especially in the posterior regions of the mouth. In additions, all pontic spans between abutments flex under load. The greater the span between abutments, the greater the flexibility of the metal in the prosthesis. The greater the load, the greater the flexure. This metal flexure places shear and tensile loads on the abutments (see Chapter 25).[7] The greater the flexure, the greater the risk of porcelain fracture, uncemented prostheses, and abutment screw loosening.

A one-pontic span exhibits little flexure—8 µm or less with precious metal under a 25-lb load.[8] A two-pontic span flexes eight times more than a one-pontic span, all other variables being equal. A three-pontic span flexes 27 times more than a one-pontic span (Figure 8-5).[7-9] As a result, not only is the magnitude of the force increased to the adjacent abutments when the prosthesis has three pontics (because they are supporting two abutments and three pontics), but the flexure of the metal increases to a point that the incidence of complications make the treatment plan contraindicated, especially when forces are greater (as in the posterior region).

The flexure of materials in a long span is more of a problem for implants than natural teeth. Because natural roots have some mobility both apically and laterally, the tooth acts as a stress absorber and the amount of material flexure may be reduced. Because an implant is more rigid than a tooth (and also has a greater modulus of elasticity than a natural tooth), the complications of increased load and material flexure are greater for an implant prosthesis. Therefore because three posterior pontics are contraindicated in a natural tooth–fixed prosthesis, it is even more important not to have three pontics in an implant restoration. Angled forces magnify the amount of the force to the implant system; therefore most maxillary anterior prostheses should also limit the number of pontics in the restoration.

The span of the pontics in the ideal treatment plan should be limited to the size of two premolars, which is 13.5 to 16 mm. When a molar is one of the teeth missing between existing teeth, the missing molar space may be 10- to 14-mm long. Therefore when the span is greater than 14 mm, two pontics should be considered to replace the molar. As a result, when a second premolar and first molar are missing, this span is often treatment-planned to replace three teeth, rather than two. In other words, a missing tooth span is often related to the missing number of roots in the mandible and number of buccal roots in the maxilla. This is especially appropriate for greater patient forces (i.e., moderate to severe parafunction) or softer bone types (i.e., D3 and D4) (Figure 8-6). As a result of these

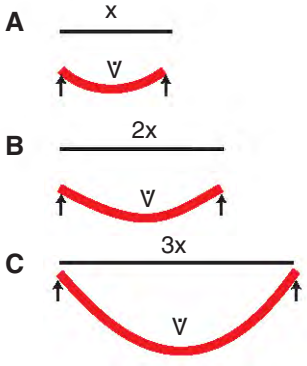


Figure 8-5 Metal flexure is related to the cube of the distance. **A,** When one pontic is present, the metal flexes (x). **B,** When the fixed prosthesis has two pontics ($2x$), the metal flexes $2 \times 2 \times 2 = 8$ times more. **C,** When three pontics exist ($3x$), the metal flexes $3 \times 3 \times 3 = 27$ times more than a one-pontic restoration.

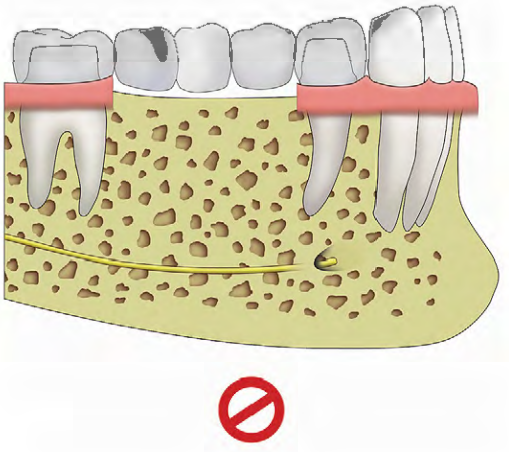

Figure 8-6 When adjacent missing posterior teeth include a molar, the missing molars may be regarded as two premolar teeth when the space is 14 mm or more. Therefore when a first molar and second premolar are missing, the treatment plan may consider replacement of three adjacent teeth.

WWW.HIGHDENT.IR

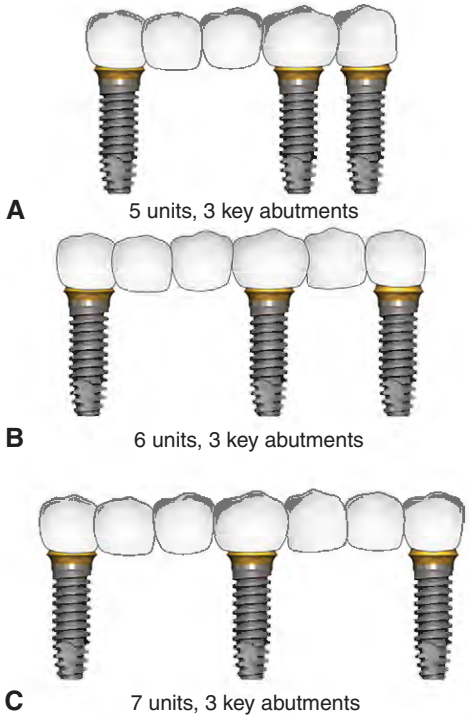

Figure 8-7 A five- to seven-unit fixed prosthesis has three key positions for the abutments. The terminal abutment follows Rule 1 (no cantilever), and a one-pier abutment is positioned following Rule 2 (no three adjacent pontics). Rarely are these three abutments sufficient to support the prosthesis in the long term. Additional abutments are required when force factors are moderate to severe or bone density is poor around the implant.

guidelines, an edentulous arch missing 14 natural teeth may have 18 potential implant sites. Rarely are second molars replaced; therefore when 12 natural teeth are considered in an edentulous arch, 14 potential implants sites are present.

To limit the effect of the complications of three adjacent premolar size pontics, additional key implant positions are indicated in prostheses missing more than four adjacent teeth. To have three potential pontics in a restoration, at least four adjacent posterior teeth or five adjacent anterior and premolar teeth must be missing (when terminal abutments are present). Therefore, when 4 to 14 missing adjacent teeth are to be replaced, key implant positions are located in the terminal abutments and additional pier or intermediary abutments are indicated to limit the pontic spans to 2 premolar-sized pontics or less. Following this rule, a five to seven premolar-sized unit prosthesis has three key abutments (two terminal and one pier) (Figure 8-7). An 8 to 10 premolar-sized unit prosthesis has 4 key implant positions (2 terminal and 2 pier). An 11- to 13-unit prosthesis has 5 key abutments (2 terminal and 3 pier), and a 14-unit prosthesis has 6 key abutment positions. In addition to these key abutments, additional abutments are usually needed to address force factors and bone density. Rarely is the force factor situation favorable and bone density ideal enough to be fulfilled with solely key abutments for a fixed prosthesis.

Canine and First Molar Sites

A fixed restoration replacing a canine is at greater risk than nearly any other restoration in the mouth. The maxillary or mandibular adjacent incisor is one of the weakest teeth in the mouth, and the first premolar is often one of the weakest posterior teeth. A traditional fixed prosthetic axiom indicates it is contraindicated to replace a canine and two or more adjacent teeth.[6,10] Therefore if a patient desires a fixed prosthesis, implants are required whenever the following adjacent teeth are missing in either arch: (1) the first premolar, canine, and lateral incisor; (2) the second premolar, first premolar, and canine; and (3) the canine, lateral, and central incisors (Figure 8-8). Whenever these combinations of teeth are missing, implants are required to restore the patient because: (1) the length of the span is three adjacent teeth, (2) the lateral direction of force during mandibular excursions increase the stress, and (3) the magnitude of the bite force is increased in the canine

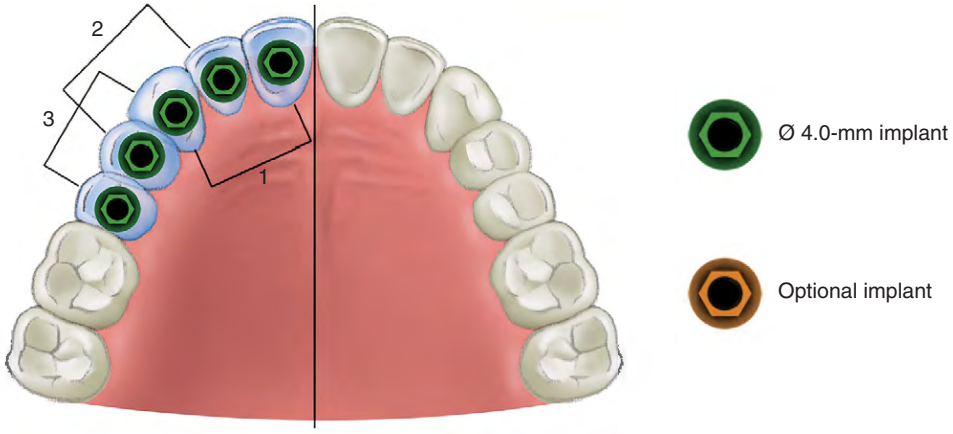

Figure 8-8 Whenever the canine and three adjacent teeth are missing, implants are required to support a fixed prosthesis. Therefore when *(1)* the canine, lateral, and central; *(2)* the lateral, canine, and first premolar; or *(3)* the canine, first, and second premolar teeth are missing, implants are indicated for a fixed prosthesis.

region compared with the anterior region. Therefore, under these conditions, at least two key implant positions are required to replace these three adjacent teeth, usually in the terminal positions of the span (especially when one of the terminal abutments is the canine position) (Box 8-2; Figures 8-9 and 8-10).

When the three adjacent teeth are the first premolar and canine and lateral incisors, the key implant positions are the first premolar and the canine. These positions result in an anterior cantilever to replace the lateral incisor. However, because the lateral incisor is the smallest tooth in the arch and in the anterior region has the least bite force, the cantilever is of limited negative impact. In addition, the canine implant is usually larger than a lateral incisor implant for the esthetic requirements of the restoration. This further reduces the effect of the cantilever (Figure 8-11). In addition, the occlusion is modified so that no occlusal contact is present on the lateral incisor pontic in centric occlusion or excursions of the mandible. When force factors are greater than usual, a small-diameter implant may also be used to support the lateral incisor, and three implants with no cantilever reduce the increased force factor risks.

When there are multiple missing teeth and the canine edentulous site is a pier abutment position, the canine position is a key implant position to help disocclude the posterior teeth in mandibular excursions. As a

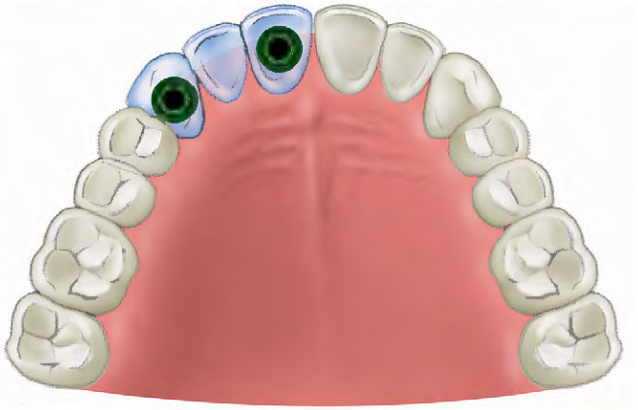

Figure 8-10 When the canine, lateral, and central incisor teeth are missing, key implant positions are in the central and canine positions to support these three teeth.

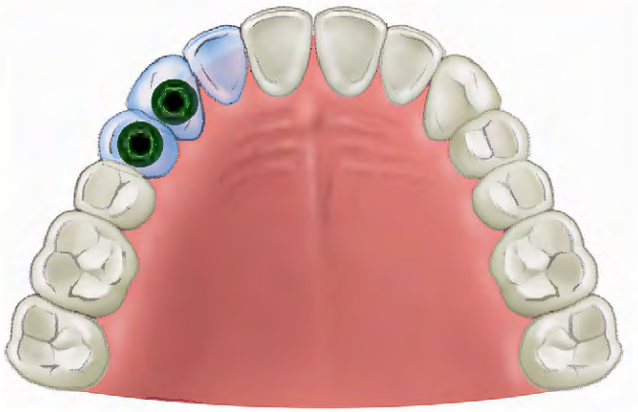

Figure 8-11 When the first premolar, canine, and lateral incisors are missing, the key implant positions are the first premolar and canine position. Although this may result in a cantilever on the restoration, the lateral incisor is the smallest tooth, the anterior region has less bite force, and the canine implant may be larger than the lateral incisor implant for esthetic requirements.

result, when four or more adjacent teeth are missing, including a canine and at least one adjacent posterior premolar tooth, the key implant positions are the terminal abutments, the canine position, and additional pier abutments, which limit the pontics spans to no more than two teeth (Figure 8-12).

The first molar is also a key implant position when three adjacent posterior teeth are missing. The bite force doubles in the molar position compared with the premolar position in both the maxilla and mandible. In addition, the edentulous span of a missing first molar is 10 to 12 mm, compared with a 7-mm span for a premolar. As a result, when three or more adjacent teeth are missing, including a first molar, the key implant positions include the terminal abutments and the first molar position (Figure 8-13). For example, in a patient missing the second premolar, first molar, and second molars, three key implant positions are needed to restore the full contour of the missing molars teeth: the

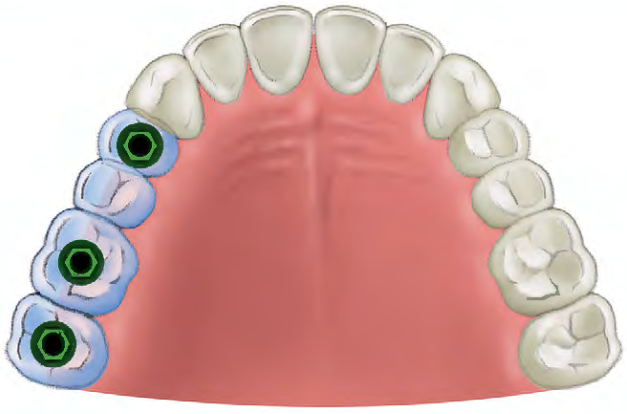
Figure 8-12 **A,** When the central, lateral, canine, and first premolar are missing, the ideal key implant positions are the central and first premolar (Rule 1, no cantilever) and the canine position (Rule 3, the canine and first molar position). **B,** When the central, lateral, canine, first premolar, second premolar, and first molar are missing, the three key implants positions are the central and first molar sites (Rule 1), and the canine site (Rules 2 and 3, no three adjacent pontic and canine and first molar position). **C,** When the central, central, lateral, canine, first premolar, and second premolar are missing, there are three key implant positions: the central and second premolar (Rule 1, no cantilever) and the canine position (Rule 3, the canine and first molar position). **D,** When eight adjacent teeth are missing from second premolar to the opposite canine, there are four key implant positions: The canine and second premolar position (Rule 1), the opposite canine (Rule 3), and one of the central incisor positions (Rule 2). **E,** When 10 adjacent teeth are missing from second premolar to second premolar, there are 5 key implant positions: the 2 second premolar sites (Rule 1), the 2 canine sites (Rule 3), and one of the central incisor positions (Rule 2).

second premolar and second molar terminal abutments and the first molar pier abutment (Figure 8-14). When one implant replaces a molar (for a span of less than 13 mm), the implant should be at least 5 mm in diameter. When a smaller-diameter implant is selected, the molar may be considered the size of two premolars.

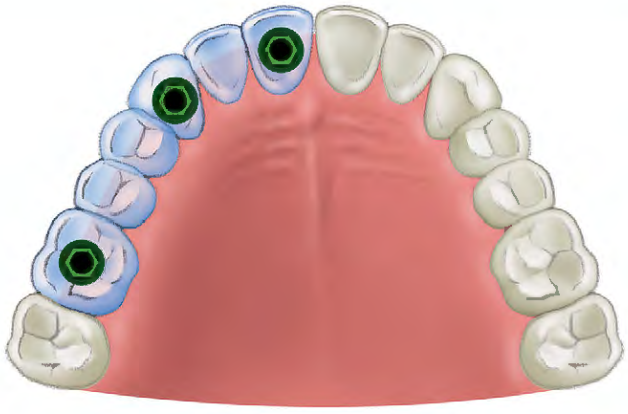
Key Arch Positions

An arch may be divided into five segments, similar to an open pentagon (Figure 8-15). The two central and two lateral incisors are one segment, the canines are independent segments, and the premolars and molars on each side form a segment. In other words,

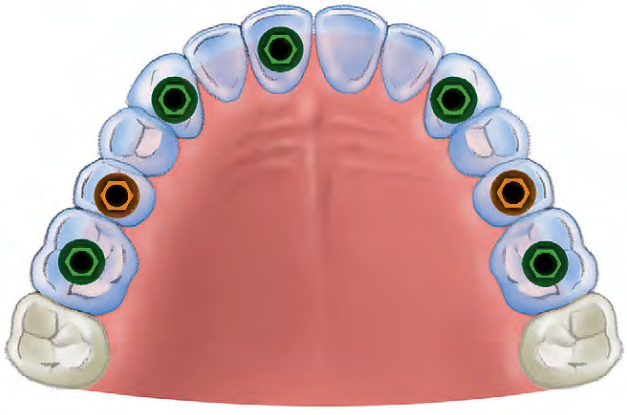
WWW.HIGHDENT.IR



A



B



C

Figure 8-13 **A,** When the patient is missing four teeth from the first premolar to second molar, there are three key implant positions to replace the four teeth: the first premolar and second molar sites (Rule 1) and the first molar position (Rule 3). **B,** When the patient is missing six adjacent teeth from the central incisors to the first molar, there are three key implant positions: The central and first molar position (Rule 1) and the canine position (Rule 3). When a larger implant cannot be inserted into the molar site, an additional implant is required to follow Rule 2. **C,** When the patient is missing teeth from first molar to first molar, there are five key implant positions: The two first molars (Rule 1), the two canines (Rule 3), and a central incisor (Rule 2). Additional implants in the posterior region are indicated when a larger-diameter implant is not positioned in the first molar sites (Rule 2). Implants in the second premolar site are also usually indicated when force factors are moderate or bone density is D3. Even more implant support is suggested when force factors are severe or bone density is D4.

each segment is essentially a straight line, with little inherent biomechanical advantage to a lateral force. However, when two or more segments of an arch are connected, the tripod effect is greater, and, as a benefit, an A-P distance (A-P spread) is created from the most distal terminal abutments to the most anterior pier abutment.

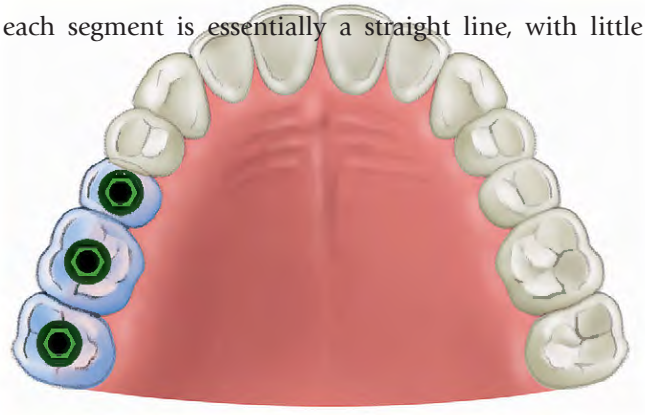


Figure 8-14 In a patient missing the second premolar and first molar and second molars, three key implant positions are needed to restore the full contour of the missing molars teeth: the second premolar and second molar terminal abutments and the first molar pier abutment.

When multiple adjacent missing teeth extend beyond one of the open pentagon segments, a key implant position needs to be situated within each segment. Therefore if the patient is edentulous from first premolar to first premolar, the key implant positions include the terminal abutments (the two first premolars), the two canines, and either of the central incisor positions (Figure 8-16). These implant positions follow the rules of: (1) no cantilever, (2) no three adjacent pontics, (3) the canine position, and (4) at least one implant in each edentulous segment of an arch.

IMPLANT NUMBER

In the past, the number of implants most often was determined in function of the amount of available bone in the mesiodistal dimension. For example, in an edentulous arch, six implants were used in abundant bone between the mental foramina anterior to the maxillary sinuses for a full-arch fixed prosthesis, whereas four implants were used in moderate to severe resorption for a fixed full-arch prosthesis (Figure 8-17).[11] However, this treatment option does not consider the force magnifiers of crown or height space or the A-P

WWW.HIGHDENT.IR

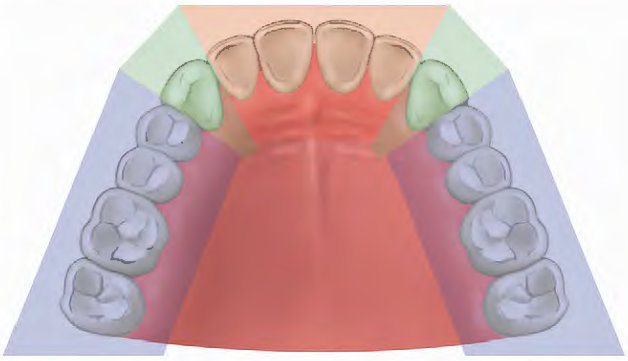

Figure 8-15 An arch may be considered as an open pentagon: the two premolar and molar sites, the two canine sites, and the central and lateral incisors represent the five sides.

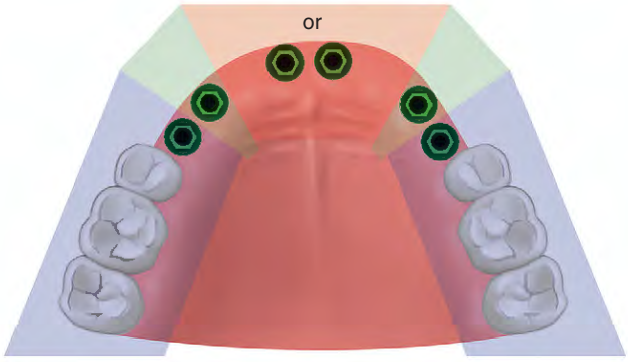

Figure 8-16 When a patient is missing eight teeth from first premolar to first premolar, there are five key positions: the first premolar sites (Rule 1, no cantilever and Rule 4, one implant in each open pentagon segment), the two canines (Rule 3, the canine and first molar rule and Rule 4, an implant in each pentagon segment), and an implant in one of the central incisor positions (Rule 2, no three adjacent pontics and Rule 4, an implant in each open pentagon segment).

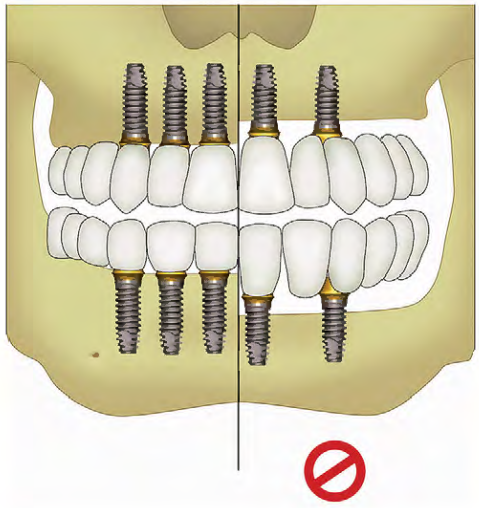

Figure 8-17 In the past, an edentulous arch used six implants to support a fixed prosthesis in abundant bone situations and four implants to support a complete full-arch prosthesis when minimal bone volumes were present.

Table 8-1 Implants versus Prosthesis Success: Four Implants per Prosthesis for 25 Patients (100 Implants for 25 Prostheses)

IMPLANT NUMBER (SUCCESS RATE)	FOUR IMPLANTS PER PROSTHESIS	PROSTHESIS SUCCESS RATE

90 (90%)	15	60%
80 (80%)	5	20%
75 (75%)	0	0%

distance (A-P spread) of the implants in relationship to the bilateral posterior cantilevers replacing the posterior teeth.

When four implants support a 12-unit fixed prosthesis, the position of the implants cannot follow the four key implant position rules, and include either four pontics between the anterior implants or three pontics cantilevered from the most distal implants. In addition, the number of implants in a treatment plan should rarely use a minimum number. There is no safety factor if an implant fails. For example, if 25 patients receive four implants to support a fixed prosthesis, there would be 25 fixed prostheses and 100 implants. If each patient lost one implant, there would only remain three implants and, as a result, nearly all 25 fixed prostheses would be at risk of overload failure. If 20% of the implants fail (with 1 failure per patient), only five of the 25 patients would have 4 implants to support the restoration (20% prosthesis success). This type of treatment planning may initially be less expensive for the patient, but an implant failure any time after implant surgery places the patient's restoration at considerable risk (Table 8-1).

If the 25 edentulous patients have eight implants to support a full-arch, 12-unit fixed prosthesis, the risks of prosthesis failure is significantly reduced (Table 8-2). If each patient loses one implant, most likely all patients would still be able to function with their original prosthesis. Even if all 25 patients lost two implants, the 25 prostheses may still function without risk (depending on the implant failure location). The additional implants also reduce the cantilever length or reduce the number of pontics in the prosthesis, providing more abutments for greater retention of the restoration, with reduced risk of screw loosening or uncemented prosthesis.

The key implant positions are often not enough support for the implant restoration, unless all patient force factors are all low (e.g., parafunction, masticatory dynamics, crown height) and the bone density is good (D1, D2). Therefore most often additional implants (besides the key implants) are added to the treatment plan.

WWW.HIGHDENT.IR

175 (87.5%)	25	100%
150 (75%)	25	100%

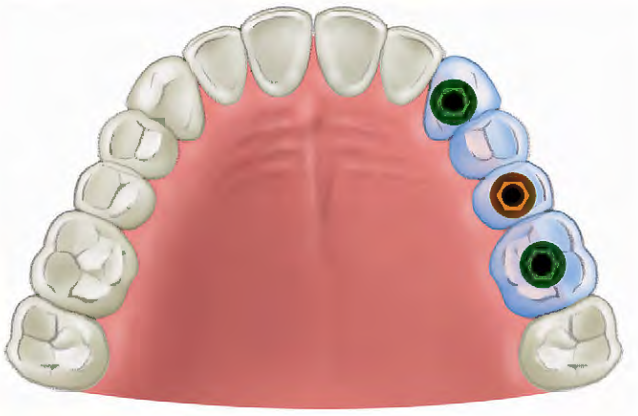

Figure 8-18 When four adjacent teeth are missing from the canine to first molar, the two terminal key implant positions are usually inadequate to support the prosthesis. One or two additional implants are required in most clinical situations (depending on patient force factors and bone density). The additional implant of choice is in the second premolar site, especially when a larger-diameter implant is not placed in the molar site.

One of the most efficient methods to increase surface area and decrease stress is to increase the implant number. For example, only two implant key positions as terminal abutments for a four-unit implant prosthesis in the canine and posterior region represent inadequate implant support, unless patient force factors are low, bone density is ideal, and implant size is not compromised. In most situations, three implants to replace four missing teeth is an ideal implant number. When force factors are high and bone density is poor (i.e., posterior maxilla), four implants to replace four teeth is often appropriate (see Figure 8-13; Figure 8-18).

Previous studies have shown that three abutments for a five-tooth span distribute stress more favorably than do two abutments for the same span. The one additional implant may decrease the implant reaction force by two times and reduce metal flexure fivefold. In addition, in the three-abutment scenario, moment forces are reduced.[12,13] In full-arch prostheses, studies comparing six implants and four implant abutments show better distribution and reduced stress on the six-implant system components (crown, cement, abutment, abutment screw, marginal bone, implant-bone interface, and implant components).[14]

The decision on the number of implants in the treatment plan begins with the implants in the ideal key positions. Additional numbers are most often required, and primarily related to the patient force factors or to bone density in the edentulous sites. Therefore in a young, large male who bruxes severely, with greater than normal crown height space in the posterior regions of the mouth, opposing an implant restoration will require one implant for each missing root (two implants for each molar). Likewise, patients with moderate force factors and poor bone density (D4 bone) in the implant sites may also require this many implants.

As a general observation, the number of implants to replace all of the mandibular teeth range from five to nine, with at least four between the mental foraminae. When fewer than six implants are used, a cantilever must be designed in a fixed prosthesis as a result of the mandibular flexure. Cantilevers in the mandible should ideally be projected in only one posterior quadrant to increase the A-P distance and reduce the force to the implants (Figure 8-19, *A*). When implants are positioned in four of the five open pentagon positions in the mandible, a cantilever is at a reduced risk of overload because of favorable dynamics of an arch, increased large A-P distance, and favorable bone density. When seven or more implants are used, two separate restorations may be fabricated with no posterior cantilever to permit mandibular flexure and torsion (Figure 8-19, *B*). Usually the second molar is not replaced in the edentulous mandible. A greater number of implants are generally required in the maxilla to compensate for the less dense bone and more unfavorable biomechanics of the premaxilla, and range from 7 to 10 implants with at least 3 implants from canine to canine (Figure 8-20).

In most situations, an implant should be positioned at least 1.5 mm from an adjacent natural tooth and 3 mm from an adjacent implant.[15-21] Using these guidelines, each 4-mm-diameter implant requires 7 mm of mesiodistal space (Figure 8-21). Therefore the maximum number of implants between adjacent teeth can be calculated by taking the crest module of an implant (e.g., 4.0 mm) and adding these dimensions (Figure 8-22). For example, an edentulous span of 21 mm is required for three adjacent implants 4 mm in diameter and 28 mm for four adjacent implants between two teeth. As a general rule, it is better to err on the side of safety in numbers than on the side of too few implants. Therefore, when in doubt, add an additional implant to the treatment plan.

Commonly, implant-supported crowns in the posterior regions of the mouth are the size of premolars. This concept often permits the placement of two implants to replace an intratooth molar, when the span is at least 14 mm for 4-mm-diameter implants (3 mm between each implant and 1.5 mm from the adjacent teeth). When the missing molar is the most distal in the arch,

WWW.HIGHDENT.IR

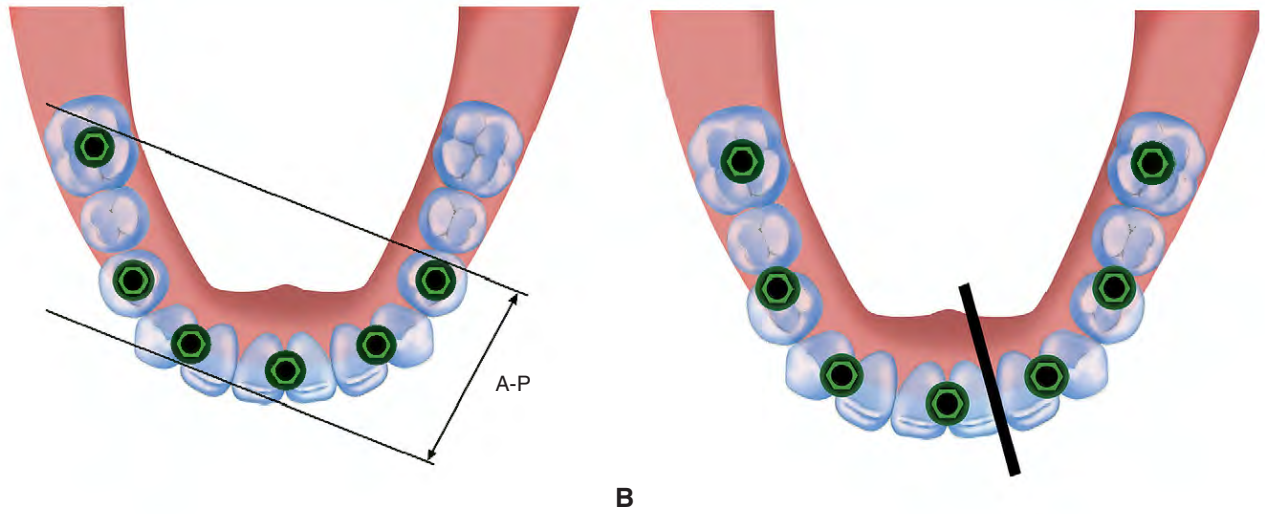

Figure 8-19 **A,** When six or more implants are positioned in the mandible (first molar, two first premolar, two canine, and one central incisor) a cantilever may be designed in the mandible because of the dynamics of an arch, with four of the five sections of an open pentagon joined, the large anteroposterior distance, and the favorable mandibular bone density. **B,** When seven or more implants are placed in an edentulous mandible, two separate prostheses with no posterior cantilever may be designed. The mandible flexure and torsion is free to occur when the separation between the two prostheses is between the mental foraminae. *A-P,* Anteroposterior distance.

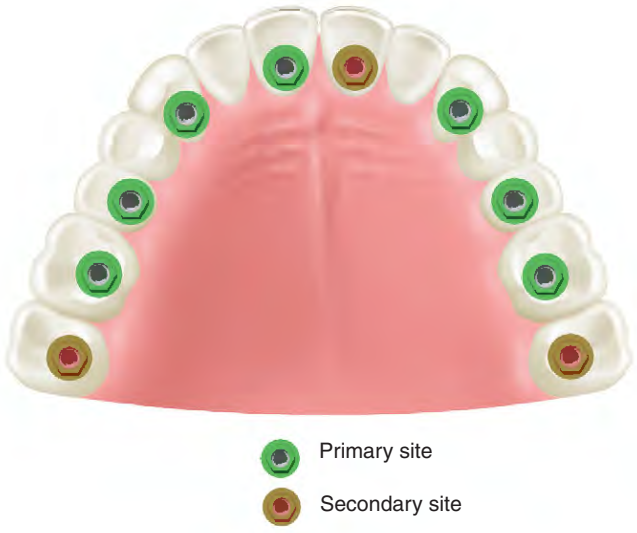

Figure 8-20 The ideal seven-implant positioning for a maxillary edentulous arch includes at least one central incisor position, bilateral canine positions, bilateral second premolar sites, and bilateral sites in the distal half of the first molars. In the case of heavy stress factors, an additional anterior implant and bilateral second molar positions (to increase the anteroposterior distance) may be of benefit.

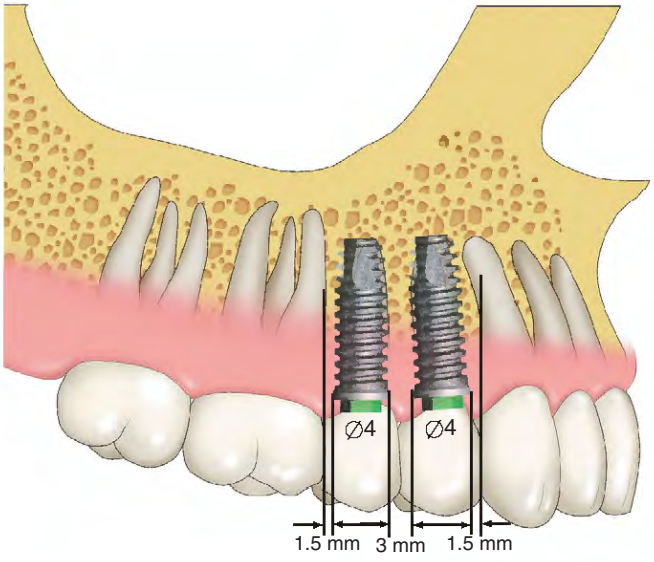

Figure 8-21 The minimum mesiodistal dimension for two standard 4-mm diameter implants is 1.5 mm + 4 mm + 3 mm + 4 mm + 1.5 mm = 14 mm.

a 12.5-mm span is required for two 4-mm-diameter implants (3 mm between each implant and 1.5 mm from the anterior tooth), because the 1.5-mm distance from the last tooth is no longer required.

There are several advantages of a 7- to 8-mm-wide premolar and a molar-sized crown. More implants may be used to restore the missing teeth. Implants may range from 4 to 5 mm in diameter, which are the most common sizes, and often the available bone has adequate buccolingual bone dimension in this region. The emergence of the crown contours on implants of this dimension permit sulcular probing. In addition, the occlusal table width decreases mesial and distal moment forces compared with a molar-sized crown.[22]

SPLINTED IMPLANTS

The primary advantage of restornig implants as independent units would be interproximal hygiene. However, this concept is not relevant with implants for two reasons. First, a very low percentage of the population flosses regularly.[23] Therefore this advantage would, at best, affect 1 or 2 of 10 patients. Because the implants are usually 3 mm or more apart, if a patient does wish

WWW.HIGHDENT.IR

to perform interproximal hygiene, most aids (e.g., floss threader, proxy brush) could easily clean this region.

A second advantage of separate dental units is the ability to replace a single unit to repair porcelain fracture. However, when dental implants are splinted together, the crown marginal ridges between the implants are supported by metal connectors; therefore the porcelain is placed under compression. As independent units, the margins of porcelain-to-metal crowns are most often placed under shear loads, which increase the risk of porcelain fracture. In addition, splinted dental units provide greater prosthesis retention and transfer less force to the cement interface. As a result, the restoration is less likely to become uncemented. This is especially significant when the abutments are short or lateral forces are present.

A third reason for independent crowns is primarily related to natural teeth. A single crown has a caries risk of less than 1% within 10 years. However, when natural teeth are splinted together, decay at the interproximal margin often occurs at a rate of approximately 22%.[24] In addition, the endodontic risk is increased when crowns are splinted. A single crown has an endodontic risk of 3% to 5.6%. Splinted teeth have an endodontic risk of 18%.[3] Therefore independent units reduce the incidence of complications and allow the practitioner to more readily treat these complications. However, implants do not decay or need endodontic therapy. As a result, independent units would not be required to address these complications.

On the other hand, there are many advantages to splinting implants together. To maximally benefit from an increased number of implants, the implants should be splinted together. Splinted implants increase functional surface area of support, increase the A-P distance (A-P spread) to resist lateral loads, increase cement retention of the prosthesis, decrease the risk of abutment screw loosening, decrease the risk of marginal bone loss, and decrease the risk of implant component fracture. In other words, the entire system benefits.[25-28]

In addition to biomechanical reasons, if an independent implant fails over time, the implant is removed, the site bone is grafted, the site is reimplanted, and a new crown is fabricated. When multiple splinted implants have an implant that fails, the affected implant may often be cut below the crown, and the implant or crown site converted to a pontic using the same prosthesis. As a result, rather than several surgical and prosthetic procedures over an extended period when independent units are restored, the problem may be solved in one relatively short appointment when the crowns are splinted together.

The splinted implants distribute less force to the implant bodies, which decreases the risk of marginal bone loss or implant body fracture. In a report by Sullivan, a 4-mm single implant replacing a molar had implant body fracture in 14% of the cases.[29] In comparison,

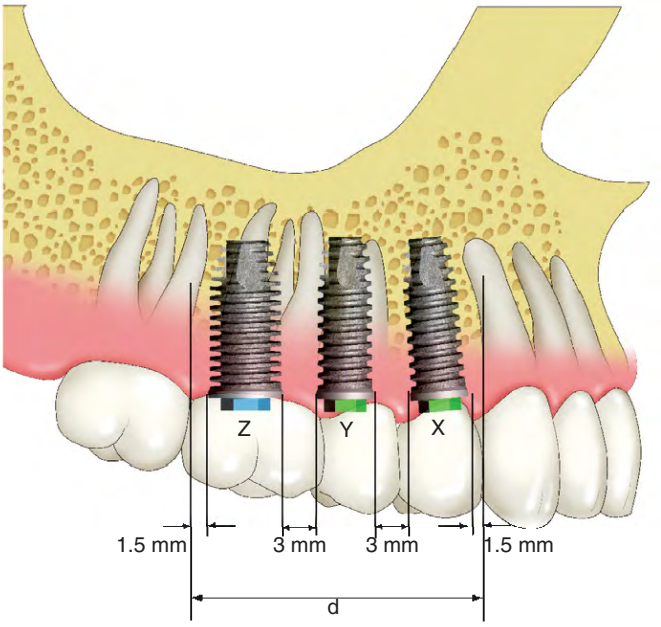

Figure 8-22 When three adjacent teeth are missing (two premolars and first molar), the mesiodistal dimension averages 7.1 mm + 6.6 mm + 10.4 mm = 24.1 mm. In this situation, planning 4-mm-diameter implants to fabricate two premolars of 7 mm each (1.5 mm + 4 mm + 1.5 mm) and one 5-mm-diameter implant for the first molar allows more bone around each implant.

multiple implants splinted together had a 1% implant body fracture.[1] Splinted implants reduce the risk of screw loosening. The highest prosthetic complication with single-tooth implants is abutment screw loosening. In a report by Balshi, single-tooth implants replacing a molar had 48% screw loosening over a 3-year period.[30] When two implants were splinted together to replace a molar, the incidence of screw loosening was reduced to 8% over the same period.

The exception to the splinted implant rule is a full-arch mandibular implant prosthesis. The body of the mandible flexes distal to the foramen on opening and has torsion during heavy biting with potential clinical significance for full-arch implant prostheses.[31,32] As a result, a full-arch implant prosthesis replacing the first or second molars should not be splinted to molars on the opposite side. Therefore full-arch mandibular restorations should have a cantilever or be made in two or three sections to accommodate the mandibular dynamics during function. The concept of flexure and torsion does not affect the maxilla, where all implants often are splinted together, regardless of their positions in the arch.

SUMMARY

A biomechanical-based treatment plan reduces complications after implant loading with the prosthesis. To

WWW.HIGHDENT.IR

reduce stress conditions, there are key implant positions for a prosthesis replacing missing teeth: (1) no cantilevers should be ideally designed on the restoration, (2) three adjacent pontics should be eliminated, (3) the canine and first molar sites are important positions in an arch, and (4) an arch is divided into five segments. When more than one segment of an arch is being replaced, a key implant position is at least one implant in each missing segment.

Increasing the number of implants is the most efficient method to increase surface area and reduce overall stress. Therefore, after the key implant positions are selected, additional implants are indicated to reduce the risks of overload from patient force factors or implant sites with reduced bone density. When in doubt of the number of implants required, add an additional implant.

Chapter 9

Implant Body Size: A Biomechanical and Esthetic Rationale

Carl E. Misch

The initial treatment plan for implant dentistry should include the ideal implant size, based primarily on biomechanic and esthetic considerations. In traditional prosthetics, when a tooth is replaced, the abutment teeth are already provided by nature with wide posterior abutments for posterior teeth. When teeth are replaced with dental implants, the implant team should preselect the ideal abutment size, based on the ideal size for an esthetic restoration within biomechanical guidelines.

The size of an implant used to be determined primarily by the existing bone volume in height, width, and length. The surgeon would select longer implants in the anterior regions of the mouth and shorter ones in the posterior areas because of the limits of the mandibular canal and maxillary sinus. The width of the implant, also determined at surgery, would relate to the existing width of available bone, and one diameter implant (4 mm) would be used in most all situations.[1]

Over the years, dental implant treatment plans incorporating biomechanics have been advocated by Misch to decrease the most common complications—those related to stress.[2] The prosthesis first is planned, including whether the restoration is fixed or removable, how many teeth are replaced, and the esthetic demands. The patient force factors are then considered to evaluate the magnitude and type of force applied to the restoration. The bone density is evaluated in the regions of the potential implant placement. The key implant positions and the implant number are then selected in relation to the patient force factors and the bone density in the implant sites. For example, when the patient has parafunction or the bone is less dense or when a cantilever is present, the greater force exerted on the implant abutments will transmit greater stresses to the implant-bone interface. The next consideration in this ideal treatment plan sequence is the implant size.[1]

Dental implants function to transfer loads to surrounding biological tissues.[3,4] Biomechanical load management is dependent on two factors: the character of the applied force and the functional surface area over which the load is dissipated.[5] The implant size directly affects the functional surface area that distributes a load transferred through the prosthesis. A comprehensive approach to the overall dental implant size begins with the identification of clinical problems to be addressed. Fundamental scientific principles related to force and surface area are then combined with engineering principles to pursue the desired clinical goals. When relevant, esthetic considerations in regards to implant size are part of the evaluation. This chapter will build on and apply basic biomechanics and demonstrate how these principles also relate to the ideal dental implant size to support a prosthetic load. The esthetic guidelines related to implant size will also be addressed.

CHARACTER OF FORCES APPLIED TO DENTAL IMPLANTS

Stress and Strain

The presence of fibrous tissue has long been known to decrease the long-term survival of a root form implant.[1] Excessive loads on an osteointegrated implant may result in mobility of the supporting device, even after a favorable bone-implant interface has been obtained.[6] Although several conditions may cause crestal bone loss, one of these may be prosthetic overload.[7] Excessive loads on the bone result in increased strain conditions in the bone.[8] These microstrains on the bone may affect the bone remodeling rate and cause pathologic overload, which results in the loss of bone. The amount of bone strain is directly related to the amount of stress applied to the implant-bone interface. The greater the stresses throughout the implant-bone interface, the greater the risk factor for crestal bone loss and subsequent implant failure.[9] Therefore the stress and strain relationship has been shown to be an important parameter for crestal bone maintenance and implant survival.

Forces applied to dental implants may be characterized in terms of five distinct (although related) factors: magnitude, duration, type, direction, and magnification.[5] Each factor should be considered within the physiologic constraints on implant size. In addition, there are surgical and prosthetic considerations related to implant size.

WWW.HIGHDENT.IR

For example, the increase in stress to an implant body also increases the risk of abutment screw loosening or implant body fracture. As a result, a relative risk factor for different implant sizes may be established.

Force Magnitude

The physiology of the stomatognathic system imposes a range on the magnitude of forces that may be applied to an implant in the oral environment. The magnitude of bite force varies as a function of anatomical region and state of the dentition.[10] Average bite forces can range from 10 to 350 lb. The magnitude of force is greater in the molar region (200 lb), less in the canine area (100 lb), and least in the anterior incisor region (25 to 35 lb).[11] These average bite forces increase with parafunction to magnitudes that may approach 1000 lb in the posterior regions.[12]

After sustained periods of edentulism, the bone foundation often becomes less dense. Studies on dentate and edentulous jaws illustrate greater trabecular bone density in the anterior regions compared with the premolar or molar regions.[13] The bone's ultimate strength is highly dependent on its density.[14] As such, less dense bone may no longer be able to support normal physiologic bite forces on a dental implant. Careful treatment planning, including appropriate implant size selection, is imperative to lower the magnitude of loads imposed on the vulnerable implant-bone interface under these less ideal conditions. Thus the posterior regions with higher bite forces and lower bone densities should use a different parameter for implant size compared with the anterior regions. In addition, the anterior regions are more often in the esthetic zone and may influence the size of the implant as a consequence.

Force Duration

The duration of bite forces on the dentition has a wide range. Under ideal conditions, the teeth come together during swallowing and eating for only brief contacts. The total time of those brief episodes is less than 30 minutes per day. Patients who exhibit bruxism, clenching, or other parafunctional habits, however, may have their teeth in contact several hours each day.[12] Fatigue fractures increase in direct relationship to the amount of the force and the number of cycles of load. Therefore an increase in force duration directly increases the risk of fatigue load to the implant body when the force is higher than the endurance limit of these entities.[15] The implant body width is directly related to the strength of an implant, and wider diameter implants reduce the risk of fatigue fracture.

The duration of a force may also alter the implant-bone interface. Fatigue damage to cortical bone has been reported under relatively high-frequency loading rates (e.g., shin splints in runners).[16] Although fatigue damage to alveolar bone has not yet been reported in the literature, it is unlikely the alveolar bone reacts differently to parafunctional loads. Roberts et al. report the bone around an implant may be remodeled at a rate of 500% each year after loading, compared with normal trabecular physiologic remodeling around a tooth of 20% to 40% per year.[17] The dramatic increase in remodeling rates may eventually lead to fatigue damage and resultant bone loss.[18]

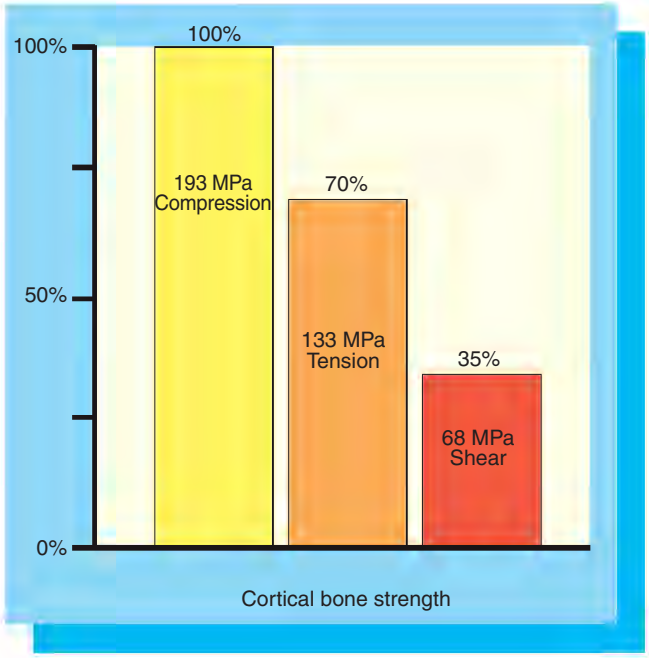

Figure 9-1 Bone is strongest under compression forces, 30% weaker to tensile forces, and 65% weaker to shear forces.

Force Type

Three types of forces may be imposed on dental implants within the oral environment: compression, tension, and shear. Bone is strongest when loaded in compression, 30% weaker when subjected to tensile forces, and 65% weaker when loaded in shear (Figure 9-1).[19] Therefore an attempt should be made to limit shear forces on bone, because it is least resistant to fracture under these loading conditions. This is most important in regions of decreased bone density, because the strength of bone is also directly related to its density.[14] An increased width of an implant may decrease offset loads and increase the amount of the implant-bone interface placed under compressive loads.

Force Direction

The forces to an implant body are typically greatest at the crestal bone interface.[20] Angled loads to the implant prosthesis produce angled loads to the crest module of the implant. The implant angulation is important to consider. For example, given an occlusal load with a 25-lb magnitude, the direction of the load has a significant effect on the magnitude of compressive and lateral load components. By increasing the angle of the

WWW.HIGHDENT.IR

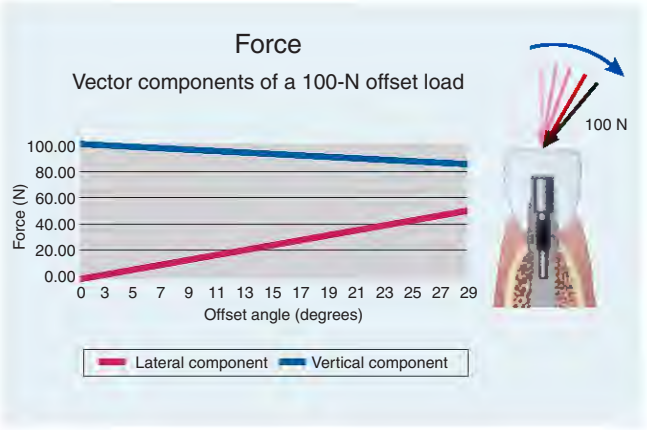

Figure 9-2 The force applied to an implant body with an angled load or angled direction of force is increased in direct relation to the force angle.

load by only 6 degrees, the lateral component of that load is increased by 233%. In addition, every degree of angled load greatly increases the damaging shear load component experienced by the implants, which is the most damaging component of the load (Figure 9-2).

Angled loads increase the amount of shear loads to the bone, and the bone is weakest to shear-type loads[21] (Table 9-1). Therefore, under ideal conditions, the implant body should be oriented to provide long axis compressive loads to the implant and to decrease shear loads to the crestal bone region. Occlusal loads in centric occlusion occur where the occlusal forces are usually the greatest. As such, the implant should be inserted perpendicular to the curve of Wilson and curve of Spee. Additionally, axial alignment places less stress on the overall implant system (i.e., abutment and abutment screw components) and decreases the risk of screw loosening and fatigue fractures of the implant or its components.

The anatomy of the mandible and maxilla places significant constraints on the ability to surgically place root form implants suitable for loading along their long axis. Bone undercuts further constrain implant placement and thus load direction imposed on the implant. Most all undercuts occur on the facial aspects of the bone, with the exception of the submandibular fossa in the posterior mandible.[22] Therefore implant bodies are often angled to avoid perforation of the lingual/facial bony undercut during insertion. Resorptive patterns after prolonged edentulism also exacerbates the normally occurring angulation challenges.[23]

The maxillary anterior region does not permit an ideal implant position, even under ideal conditions. The natural maxillary anterior teeth are 12 to 15 degrees off the long axis of load, and the bone of the premaxilla is in a similar relationship after tooth loss. Therefore implants in this region are often positioned with a greater relative angle to occlusal loads than any other region.[21] To decrease the effect of an angled load on the implant, the implant body may be increased in diameter.

Force Magnification

Force magnification increases the stress beyond the usual conditions of load; for example, a cantilevered prosthesis, a crown height greater than normal, or parafunction.[5] Multiple force magnifiers, such as a patient with parafunctional habits and an excessive crown height, may exceed the capability of any dental implant to withstand occlusal loads. Careful treatment planning with special attention to the implant position, implant number, occlusal loading, and an increase in implant size to increase functional surface area is indicated when a clinical case presents the challenge of force magnifiers.

A magnifier of force around an individual implant is also affected by the density of bone. Four distinct bone density categories within the maxilla and mandible exhibit a broad range of biomechanical strengths (i.e., ability to withstand physiologic loads).[13,14] Significantly

Table 9-1 Cortical Bone Strength Related to Angle of Load

TYPE OF FORCE	STRENGTH (MPa)	STANDARD DEVIATION	DIRECTION OF LOAD
Compressive	193	13.9	Longitudinal
	173	13.8	30 degrees off-axis
	133	15.0	60 degrees off-axis
	133	10.0	Transverse
Tensile	133	11.7	Longitudinal
	100	8.6	30 degrees off-axis
	60.5	4.8	60 degrees off-axis
	51.0	4.4	Transverse
Shear	68.0	3.7	Torsion

WWW.HIGHDENT.IR

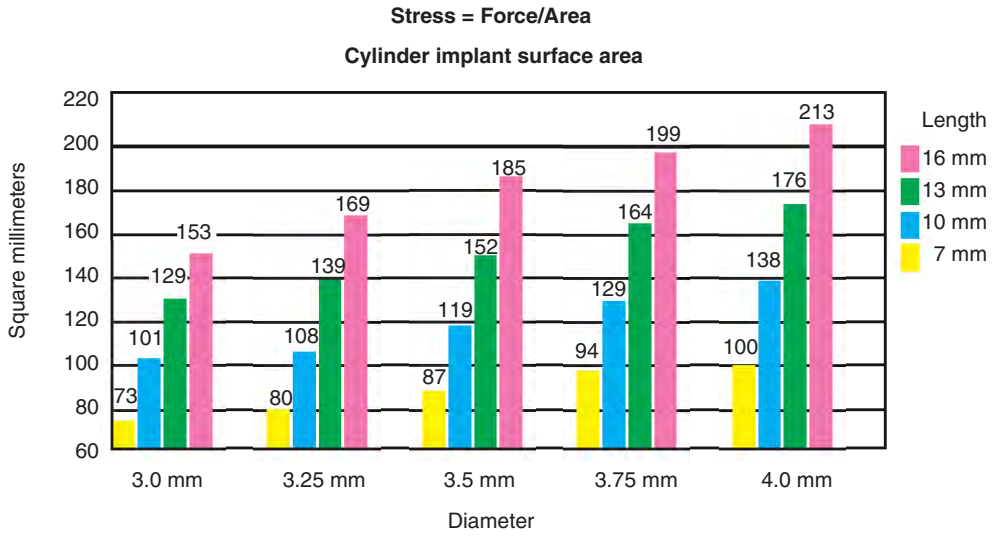

Figure 9-3 The length of a dental implant is directly related to its overall surface area. For every 3-mm increase in length, a cylinder implant has a 30% increase in surface area for shorter sizes and 20% for longer sizes.

increased clinical failure rates in poor-quality, porous bone compared with denser bone have been documented worldwide by multiple independent clinical investigators for more than a decade, with failure rates as high as 35% with implants in D4 (Type IV) bone.[24-28] Bone density is directly related to bone strength, and D4 bone may be more than 10 times weaker than D1 bone and 70% weaker than D2 bone.[14] Most implant failures in soft bone are from occlusal overload from a decrease in bone strength, a decreased bone-implant contact percentage, and the type of load transfer to the implant-bone interface on functional loading.[14,29] Therefore the effect of a resultant force is magnified as to its clinical result when placed in softer bone types.

Considerable effort should be made in the treatment plan to decrease the negative effects of compromised bone density, including implant size. The most important factor to decrease stress to the implant-bone interface is usually an increase in implant number, which dramatically increases the effective surface area over which the occlusal loads are dissipated, and in turn decreases stress. Implant number also relates to implant position, which can effectively reduce cantilever lengths and subsequent harmful bending loads and shear stresses. After the implant number has been increased in the treatment plan, the next beneficial step to decrease the risk of overload is to increase the implant size.

SURFACE AREA

The surface area over which the occlusal forces are applied is very relevant and is inversely proportional to the stress observed within the implant system (stress = force/surface area). It can be clearly seen from this basic engineering equation that, to reduce stress, the force must decrease or the surface area must increase. Therefore an increase in implant size is beneficial to decrease the stress applied to the system. The size of an implant may be modified in either length or diameter.

Rationale for Longer Implant Length

The length of the implant is directly related to the overall implant surface area, when all other variables are constant. A 10-mm–long cylinder implant increases surface area by approximately 30% over a 7-mm-long implant and has about 20% less surface area than 13-mm–long implants (Figure 9-3).[30,31] As a result, a common axiom has been to place an implant as long as possible. The length of the implant used for prosthetic support often corresponds to the height of available bone in the edentulous site.

Conventional thinking suggests that longer implants provide maximum functional surface area in a healed implant interface. However, when the length axiom is reevaluated, several challenges ensue. The available bone height is greater in the anterior regions of the mouth, especially the anterior mandible. Yet the bite forces are lower and the bone density is greater in these regions, especially in the mandible. The posterior regions have less bone height and the implant cannot engage the dense opposing cortical plate, because it is either nonexistent (maxilla) or beyond anatomical limits (neurovascular canal in the mandible). The posterior maxilla often has less height than the mandible, and the bone is less dense. As a result, poorer survival rates are reported for posterior implants, with the posterior maxilla associated with the highest failure rate (Figure 9-4).

WWW.HIGHDENT.IR

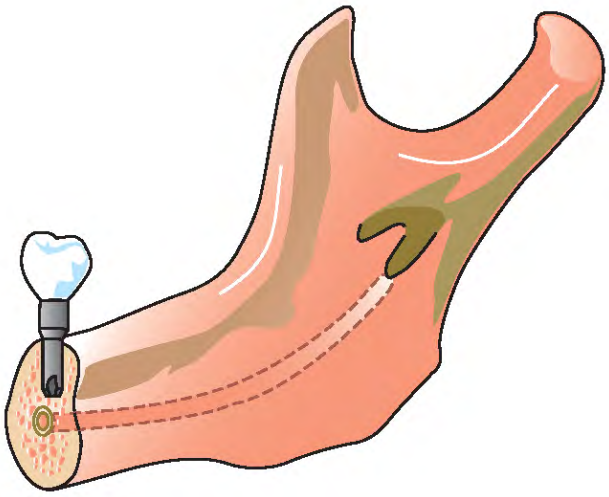

Figure 9-4 The longest implants are most often placed in the anterior mandible, followed by the anterior maxilla. The shortest implants are often placed in the posterior maxilla or mandible (or cantilevered from anterior implants). The survival rate of implants is related to length and anatomical location.

Implants longer than 15 mm have been suggested to provide greater stability under lateral loading conditions. However, reports suggest that increasing the length beyond a certain dimension may not reduce force transfer proportionately.[20,32] Finite element analysis provides an analytical means to investigate the influence of implant length relative to functional surface area under such extreme loading conditions. Misch and Bidez placed cylindrical implants of different lengths in a computer bone model with ideal bone density and volume (see Chapter 11). The embedded implant body lengths were 5, 10, 15, 20, and 30 mm. A 10-mm crown height was designed above the level of bone, and a lateral force of 50 N was applied to the top of the 10-mm crown. For these loading conditions, the percentage of maximum stress was plotted against the percentage of embedded length (Figure 9-5). Peak stresses were not completely dissipated in the 5-mm-long implant model, with approximately 30% of the maximum stress still present at the apex of the implant. The 5-mm implant model, therefore, did not provide sufficient length for lateral force dissipation in spite of good bone density and volume. In the 10-mm implant model, 80% of maximum stress was dissipated in approximately 95% of the embedded length. For the 15- and 20-mm lengths, 80% of the maximum stress was dissipated in approximately 90% of the embedded length. For the 30-mm length, 80% of the maximum stress was dissipated in approximately 70% of the embedded length. Therefore the length of the implant in favorable bone quality and crown height may range from 10 to 15 mm, and 12 mm is usually ideal. All implant lengths exhibited 80% to 100% of the stress in the crestal 40% of the implant length. The results of this analysis point to the fact that the majority of the maximum stress generated by a lateral load can be dissipated as well by implants in the range of 10 to 15 mm in length, compared with implants in the range

WWW.HIGHDENT.IR

of 20 to 30 mm in length. In addition, the highest stresses were observed in the crestal bone regions, regardless of the implant length. This biomechanical analysis supports the opinion that longer implants are not necessarily better in good bone volume and density, such as that found in the anterior regions of the mandible. An implant length of 12 mm is usually ideal under most patient force and bone density conditions and up to 15 mm is suggested in softer bone types.

Bicortical stabilization, a rationale often cited for longer implants, is not needed in D1 bone, which is primarily homogenous cortical bone.[13] Because bone overheating is a primary cause of surgical failure, attempting to engage the opposing cortical plate and preparing a longer osteotomy may result in overheating the bone when it is D1 or D2.[33] A threaded implant may not readily engage the denser bone of the apical cortical plate, and the implant threads may strip along the rest of the osteotomy, especially if D3 or D4 trabecular bone types. In addition, after the implant-bone interface is formed, excessively long implants do not transfer stress to the apical region, because most of the stresses are transmitted within the crestal 7 to 9 mm of bone (except in the softest bone types) and therefore are often not needed.[20] A further analysis relative to implant length is suggested, especially in good-quality bone.

D3 and D4 bone are primarily present in the posterior regions of the jaw, where less available bone height is observed compared with the anterior regions. Nerve repositioning is cited as an acceptable clinical treatment to facilitate placement of longer implants in the posterior mandible. However, this advanced surgical procedure represents an increased risk for paresthesia and is often not indicated, especially when other implant options are available.[34] To place the longest implants in the maxillary posterior regions, a sinus graft is often required. Sinus grafts have been shown to grow bone into the graft from the surrounding walls of bone, and bone does not form under the sinus mucosa. The apical end of longer implants will not benefit from the sinus bone graft procedure for some time, and the crest of the bone below the graft will remain at greater risk. Therefore increasing surface area primarily by length in the posterior regions of the jaws requires advanced grafting or nerve repositioning surgery and, in spite of this, does not benefit the primary regions of increased stress (i.e., the crestal bone region). However, implants from 12 to 15 mm in length are usually considered ideal for most situations.

Disadvantages of Short Implants

Different risk factors for implant longevity have emerged over the years. A review of the literature related to implant failure and implant length was published by Goodacre et al. in 2003.[35] In the majority of articles addressing implant length, implants 10 mm or smaller have increased failure rates. In the reports summarized, the failure rates of short implants were 10%, compared with a 3% failure rate of longer implants. The failure is even more apparent when the literature reviews implants smaller than 10 mm in the posterior regions of partially edentulous patients. Less than half the clinical reports had survival rates higher than 90%, and more than half of the reports had implant failure higher than 19.7% (Tables 9-2 and 9-3).[36-46]

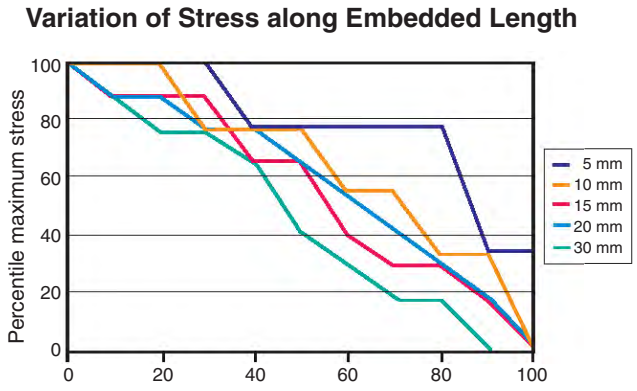

Figure 9-5 A computer bone model with implant lengths of 5, 10, 15, 20, and 30 mm was loaded with a lateral force of 50 N applied to the top of a 10-mm crown extension. Almost 80% of the stress was found in the crestal 40% of the implant, regardless of the length.

A review of several of the larger, multicenter reports of short implants is noteworthy. Minsk et al. reported the results of a training center in 1996, with 80 different operators using 6 different systems over a 6-year period.[27] Implants 7 to 9 mm in length were reported to have a 16% failure rate. The overall survival rate of all longer lengths was 95%. Winkler et al. published a multicenter report over a 3-year period in 2000.[37] The implant survival was directly related to the length of the implant. The 7-mm-long implants had a 26.4% failure rate, whereas 16-mm implants demonstrated only a 2.8% rate of failure. Implants of 8 mm had a 13% failure rate, whereas 10-mm implants in the report failed at a rate of 10.9%, and the 13-mm implants failed 5.7% of the time.

A multicenter report by Weng et al. in 2003 found 60% of all failed implants were 10 mm or less in length.[38] The overall failure rate of all implants in the study was 9%, yet the 7-mm implant failed 26% of the time and the 8.5-mm implant had a 19% failure rate[39] (Figure 9-6). Naert et al. reported in the literature on clinical outcomes of short dental implants.[6] Implants shorter than 10 mm had a survival rate average of 81.5%, whereas longer implants had a survival rate higher than 95%.

It should be noted the failure rates in most all these reports are not surgical failures or failures to osseointegrate. The failures associated with short implants often occurred after prosthetic loading. In other words, the surgical success was not affected by implant length. However, after the prostheses were

in function, an increase in early loading failure was observed, especially within the first 12 to 18 months.

When an implant of 12 mm or more is unavailable without advanced surgical procedures to gain height, a shorter implant may be considered. However, four reasons linked to biomechanics may explain why the posterior short implant may have a higher failure rate after loading compared with longer implants[48]:

1. Higher bite forces
2. Bone density in the region
3. Increased crown height
4. Implant design considerations

IDEAL IMPLANT SIZE

To obtain predictable success in situations with most patient force factors or bone densities, there is a minimum implant length, depending on the implant body width and the implant design[49] (Figure 9-7). The softer the bone, the greater the implant body length and diameter suggested[50]. The literature observes a wide range of implant studies reporting higher implant survival rates when the implant is at least 12 mm in length. Shorter implants usually increase the risk of failure and therefore are not initially treatment planned as a first option. Rather than establish an ideal treatment

WWW.HIGHDENT.IR

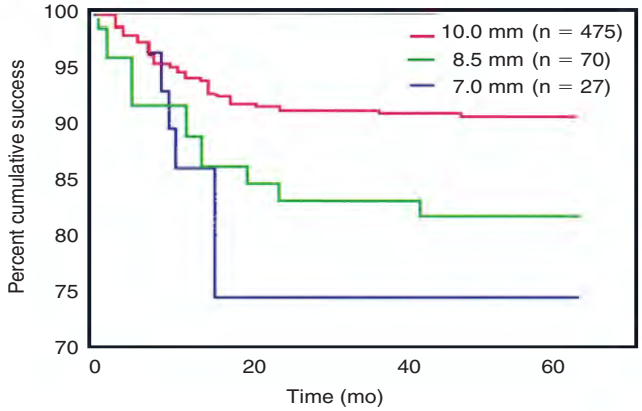

Figure 9-6 The 7-mm implant failed 26% of the time and the 8.5-mm-long implant had a 19% failure rate. Nearly all the failures occurred within 18 months after the initial loading period. (*Data from Weng D, Jacobsen Z, Tarnow D et al: A Prospectiv multicenter clinical trial of 3: machined-surface implants: results after 6 years of follow-up*, Int J Oral Maxillofac Implants *18:417-423, 2003*.)

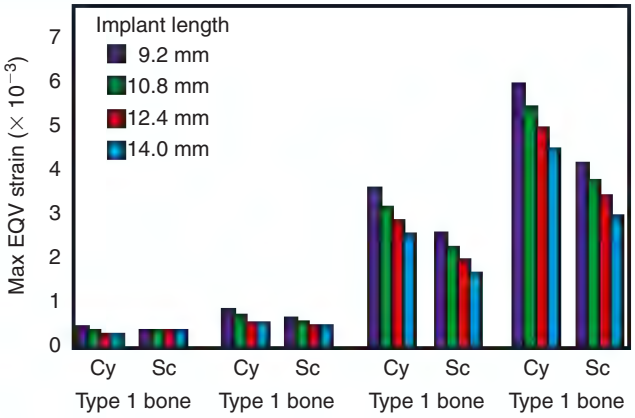

Figure 9-7 A finite element analysis found the strain increase around an implant was greatest in softer bone types (Type 3 and Type 4 bone). Longer implants had less strain than shorter implants and screw type implants less strain than cylinder implant in softer bone types. *(Data from Tada S, Stegariou R, Kitamura E et al: Influence of implant design and bone quality on stress/strain distribution in bone around implants: a 3-dimensional finite element analysis,* Int J Oral Maxillofa Implants *18:357-368, 2003.)*

plan that may be deficient in surface area, the minimum length of an implant for an unloaded healing protocol is usually 12 mm or more for most implant designs. Therefore, after the ideal treatment plan determines the key implant positions and implant number, the implant length selected for most treatment plan options is at least 12 mm long.

Rationale for a Shorter Implant Length

The height of existing available bone is often used by the implant dentist to determine the implant length after adequate width and mesiodistal space are confirmed. The height of available bone is measured from the crest of the edentulous ridge to the opposing landmark. The posterior regions of the jaws usually have the least height of existing bone, because the maxillary sinus expands after tooth loss and the mandibular canal is 10 mm or more higher than the inferior border of the mandibular body.[22] A radiographic study of 431 partially edentulous patients revealed that the posterior existing available bone height was 6 mm or greater in only 38% of maxillae and 50% of the mandibles.[34] The bite forces in the posterior regions of the mouth are greater than the anterior section.[11] As a result, in the posterior regions of the mouth with the highest bite forces, without sinus grafts or advanced surgical procedure, the implants are often shorter when compared with the anterior edentulous sites.

Implant length does affect the overall surface area of the implant body and is therefore theoretically desirable. However, unlike what occurs for a natural tooth and its periodontal membrane, stresses around implants during function and parafunction are typically concentrated on the marginal bone at the crest of the ridge.[9] Three-dimensional analysis demonstrate that for an implant with a direct bone contact, the greatest magnitude of stress is concentrated in the crestal 5 mm of the bone-implant interface[20,32] (Figure 9-8). Stresses

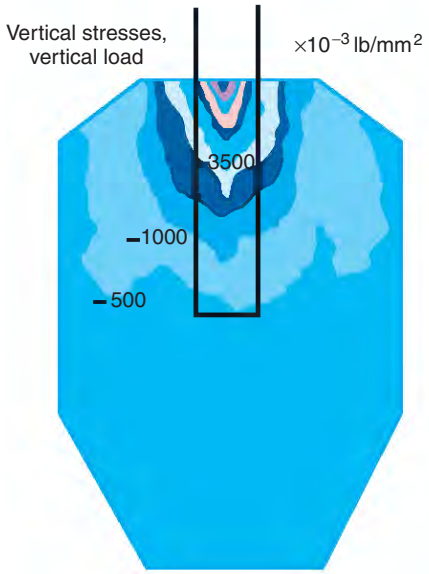

Figure 9-8 Three-dimensional finite element analysis demonstrates the highest strain conditions are around the crestal region of an implant.

distributed to the apical third of an implant are of much less magnitude than those in the crestal third. As a result, under some clinical conditions, stress transfer patterns to the bone may be similar between a short and a longer implant.[51]

Advantages of Short Implants

Shorter implants may offer several advantages compared with longer implants.[52] Bone grafting before and in conjunction with implant placement is not as frequent when short implants are used. The surgical procedure is reduced in complexity with decreased risk of overheating the bone and subsequent ease of site preparation and implant insertion. Therefore there

WWW.HIGHDENT.IR

Box 9-1 Advantages of Short Implants

1. Less bone grafting in height
   a. Less time for treatment
   b. Less cost of treatment
   c. Less discomfort
2. Less surgical risk of:
   a. Sinus perforation
   b. Paresthesia
   c. Osteotomy trauma from heat
   d. Damage to adjacent tooth root
3. Surgical ease
   a. Decreased interarch spaces
   b. Less inventory/cost

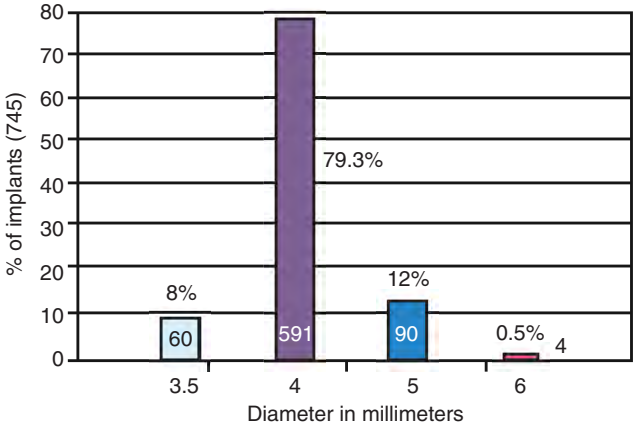

Figure 9-9 The implant diameters in this report were 3.5, 4, 5, and 6 mm. Of 745 implants, 79.3% were 4 mm wide, and the fewest in the report were 6 mm wide (0.5%). *(Data from Misch CE, Steigenga J, Barboza E et al: Short dental implants in posterior partial edentulism: a multicenter retrospective 6-year case series study,* J Periodontol *77: 1340-1347, 2006.)*

is less surgical risk of sinus perforation during the grafting procedure in the posterior maxilla and less risk of mandibular canal violation and paresthesia in the lower posterior jaw. When an adjacent tooth root presents apical dilacerations, the shorter implant may be inserted above the apex of the tooth apex without compromising the implant position. In ridges with undercuts or fossae or when basal bone and the original alveolar ridge are not in the long axis of the missing teeth, a shorter implant may be inserted at a better angulation for occlusal load. From a surgeon's standpoint, less inventory and overhead in the office are additional benefits (Box 9-1).

In 2006, Misch et al. reported on a retrospective multicenter 6-year case series study,[46] during which 273 consecutive patients received 745 implants, either 7- or 9-mm long. These implants supported 338 restorations, all in the posterior regions of the mouth. There were 102 single tooth implants and 236 fixed restorations supported by multiple implants. In this multicenter report, the short implant dimension was dealt with by reducing biomechanical factors. Incisal guidance eliminated lateral forces in excursions. Multiple implants were always splinted together. Additional implants or wider implants were used when possible.

Box 9-2 Implant Size: Short versus Long

Guidelines

- Increase diameter
- Splint together
- Decrease crown height
- Decrease cantilever
- Increase surface area design
- OD versus FPD
- Minimize lateral force
- Improve bone density

OD, Overdenture; *FPD,* fixed partial denture.

From Stage I to Stage II healing, there were six failures (99.2% success rate). During the fabrication of the restorations, there were two implant failures (99.7% success rate). The 737 successful implants and 338 restorations were followed from 1 to 6 years after prosthesis delivery. A total of 140 implants were evaluated for at least 5 years and 263 implants for more than 4 years. No implants lost after prosthesis delivery. Therefore the early loading success rate after prosthesis delivery was 100% for up to 5 years (Figures 9-9 to 9-11). Therefore, when a biomechanical approach to decrease stress or increase area is followed, an implant survival similar to other reports may be obtained, at least in this report (Box 9-2).[46] Other recent reports in the literature also support the use of short implants, provided proper force orientation and load distribution are favorable.[43-45,52,53]

IMPLANT DIAMETER

Over several decades, implants have gradually increased in width. The pin implants of Scialom in the 1960s and 1970s were less than 2 mm wide (Figure 9-12).[54] Brånemark first introduced an implant body diameter of 3.75 mm.[1] An implant body of 4 mm in diameter was also available and was primarily used as a rescue or "back up" implant when the initial implant inserted lacked stability during surgical placement. In the late 1990s, several implant manufacturers provided implants with diameters as great as 8 mm. These larger diameter implants were primarily used to improve the emergence profile of the crown. It was rationalized that if the implant was similar in diameter to the replacement tooth size, the crown would be more esthetic.

The wide-diameter implant presents surgical, loading, and prosthetic advantages. The surgical advantages relate to the use of a wide implant as a rescue implant, when the regular body size does not adequately fixate to the surrounding bone (Box 9-3). The regular implant may be removed and replaced with the wide-body

WWW.HIGHDENT.IR

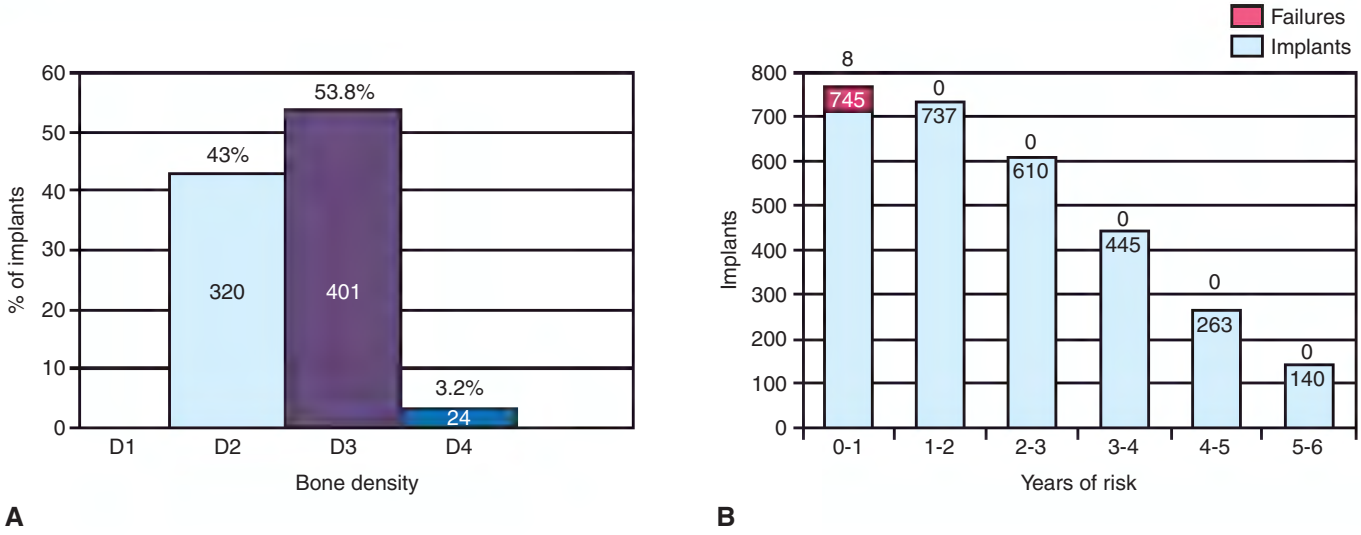

Figure 9-10 **A,** The majority of implant sites in the posterior regions were D3 bone (53.8%). The least-often observed bone types in this report were D1 and D4 bone, with 0% and 3.2% respectively. **B,** A total of 745 implants were surgically inserted during this study. There were eight implants lost (six implants from Stage I to Stage II surgery and two implants from Stage II to the prosthetic delivery). A total of 337 implants were followed after prosthetic delivery for as long as 6 years, with 263 implants having longer than a 4-year evaluation period.

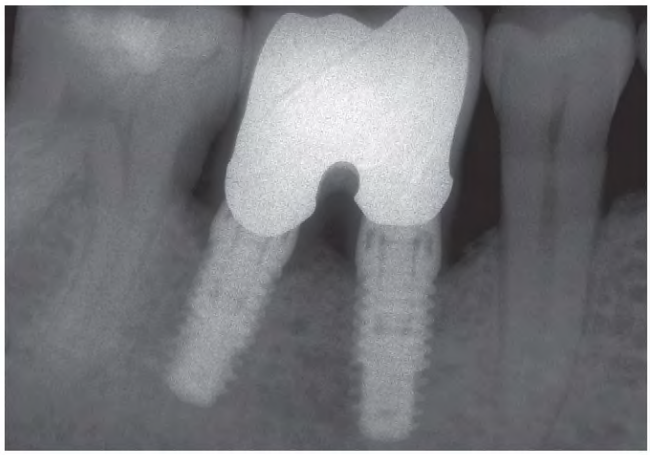

Figure 9-11 Short implants in the posterior regions were splinted together, with no lateral forces in excursions and no cantilevers less than 2 mm in diameter, to achieve clinical success.

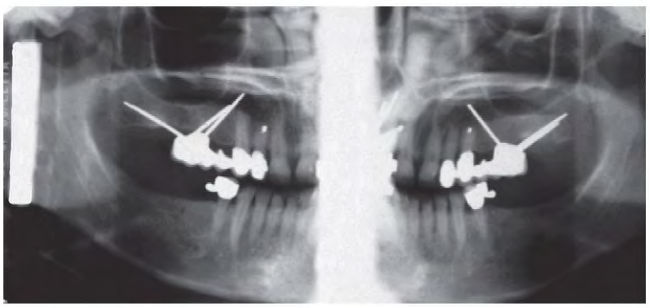

Figure 9-12 The pin implants of Scialom were used in a tripod approach to support fixed prostheses in the 1960s and 1970s.

Box 9-3 Surgical Advantages of Wide-Diameter Implants

- Surgical rescue implant
- Failed implant/immediate
- Tooth extraction/immediate

implant. When an implant fails, because of lack of osteointegration or fracture, the implant may be removed and the wide-body implant immediately inserted.[55] This eliminates the need for bone grafting, the time for bone augmentation healing, and the additional surgery to replace the implant. The same concept may be used for the immediate placement of an implant after the extraction of a tooth.[56] Because the diameter of most teeth are larger than 4 mm, a wider diameter implant has less space between the walls of the extraction site and the wide implant body.

The logical method to increase functional surface area in this region is to increase the implant diameter, because the opposing landmarks limit the implant length. Wider root form designs exhibit a greater area of bone contact than narrow implants of similar design, in part from an increase in circumferential bone contact. This trend is also noted in natural teeth to compensate for increased force; molar teeth are wider than incisors. For each millimeter implant diameter increase, the functional surface area is increased by 30% to 200%, depending on the implant design (i.e., cylinder versus thread) (Figure 9-13).

The loading advantages relate to a greater surface area, especially in the crestal region of the implant (Box 9-4). The greater surface area is a benefit when the patient force factors are greater; for example, parafunction, increased crown height, increased masticatory dynamics, and the molar regions in the posterior of the mouth.

WWW.HIGHDENT.IR

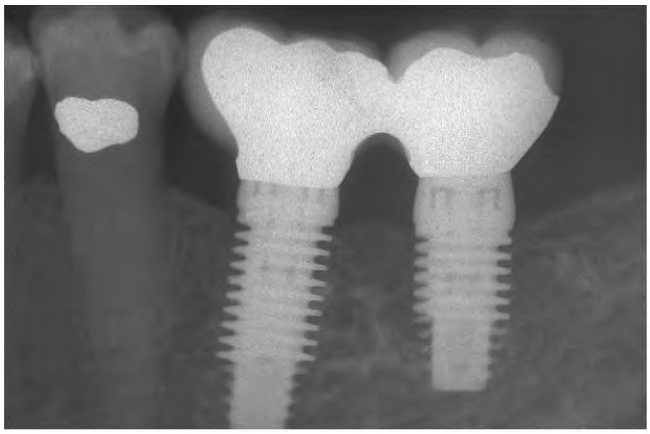

Figure 9-13 A wider diameter cylinder implant has a 5% to 8% greater surface area for every 0.25-mm increase in diameter. Therefore a 1-mm larger diameter cylinder implant may have a 30% increase in surface area.

Box 9-4 Loading Advantages of Wide-Diameter Implants

- Increase surface area
- Compensate unfavorable patient force factors
- Minimize cantilevers for angled implant
- Compensate for poor bone density
- Enhance surface for short implants

The greater surface area is an advantage when a cantilever is necessary to restore the dentition, either in a mesiodistal or facial-lingual direction. For example, the most distal implant with a posterior cantilever acts as a fulcrum and receives the greatest force. The wider diameter reduces the risk of overload. An angled load to the implant body increases the magnitude of the force at the crestal marginal bone and to the abutment screw of the implant. A larger diameter implant reduces the magnitude of forces to the entire implant system. In situations of poor bone density, there may be overload even with occlusal forces within physiologic limits. Wider diameter implants distributing forces over a greater surface area may decrease this risk.

An implant, smaller than 10 mm long, is often used in the posterior regions of the mouth. Under such conditions, the wide-diameter implant may compensate for the less than ideal implant length. Because occlusal stresses to the implant interface are concentrated at the crest of the ridge, width appears more important than height after a minimum height has been obtained for initial fixation and resistance to torque and bending loads. A comparative evaluation on strains in the alveolar crest of implants with different diameters was performed by Petrie and Williams.[57] In this three-dimensional finite element analysis, there was as much as 3.5-fold reduction in stress when wider diameter implants (up to 6 mm) were compared with narrow diameters (3.5 mm). In 2004, Himmlova et al. confirmed the findings on a three-dimensional computer model evaluating implant lengths and diameters from 2.9 to 6.5 mm.[58] The stresses were primarily at the marginal bone levels at the crest of the implant. The greatest decrease in stress was found between 3.6-mm and 4.2-mm implants (31.5%), whereas the 5-mm implant compared with the 4.2-mm diameter reduced the stress by half as much (16.4%). The length of the implant also reduced the amount of stress, but was not as pronounced as the diameter. A study by Aparicio and Orozco in 1998 used Periotest values to clinically confirm less stress transferred to the implant-bone complex.[59] The observed Periotest values from 5-mm-wide implants in the maxilla and mandible were 1.1 and 0.6 units lower than for 3.75-mm-diameter implants in the same patients.

Several studies in the literature report a similar or improved implant survival rates compared with the regular diameters. Graves et al., in 1994, reported 96% survival over a 2-year period with 268 wide implants in 196 patients.[60] All failures occurred before Stage II surgery from nonintegration of the implant. In 2000, Winkler et al. reported on the influence of implant diameter and length related to implant survival.[37] The survival of implants 3.0 to 3.9 mm in diameter was 90.7%, whereas the survival rate of implants from 4.0 to 4.9 mm was 94.6% over a 3-year period.

The 5.5-mm-wide Frialit-2 implant was evaluated by Krennmair and Waldenberger in 2004 with 121 implants in 114 patients.[61] The study yielded a 98.3% overall survival, with 100% in the mandible and 97.3% in the maxilla. Griffin and Cheung reported on short, wide implants in posterior areas with reduced bone height for 168 HA-coated implants 6 mm in diameter and 8 mm long in 167 patients.[52] There were 128 single crowns supported by these implants. The overall cumulative survival rate for up to 68 months (mean 34.9 months) after loading was 100%. Anner et al. in 2005, found a 100% survival rate in 45 implants with a mean loading period of 2 years with a 6-mm-wide, tapered, HA-coated implant.[62] In 2006, Misch et al. compared 4-mm and 5-mm implants that were 7- and 9-mm long, respectively, in the posterior maxilla and mandible.[46] The 5-year retrospective study yielded 100% implant success for the 5-mm implant and a 98% survival for the 4-mm implant. Therefore these later reports seem to indicate that larger diameter implants can achieve similar implant survival to the standard 3.75-mm-diameter implant body.

The prosthetic advantages of the wide-diameter implant include an improved emergence profile for the crown (Box 9-5). The larger the implant diameter, the more closely the emergence profile resembles the natural tooth, especially in the posterior region of the jaws. Most natural roots are greater than 4 mm in cross-section. The closer the implant diameter to the root diameter, 2 mm below the cement-enamel junction

WWW.HIGHDENT.IR

Figure 9-14 A molar implant crown has an improved emergence profile with a larger diameter implant. This may decrease food impaction in the interproximal region.

(CEJ) ideal crestal bone level (in ideal conditions), the more similar the crown emergence. This is especially noted in the maxillary first molar region, because the root diameter approaches 8 mm, or twice the size of a 4-mm implant (Figure 9-14). The wider crown contour may also decrease the interproximal space and decrease the incidence of food impaction during function. The wide-diameter implant may also improve sulcular daily oral hygiene by improving the crown emergence and avoiding the need for a ridge lap. This allows access to the sulcus for periodontal probing depths or sulcus cleaning.[52]

In 1997, Jarvis emphasized the biomechanical advantage of wide-diameter implants, particularly in reducing the magnitude of stress delivered to the various parts of the implant.[63] The diameter of the implant is related to the bending fracture resistance or moment of inertia, and the increase in diameter decreases the risk of fracture to the power of four, provided all other geometric features remain the same. Therefore, based on force factors, an implant placed in a young, bruxing male should be larger in diameter than an implant for an older, nonparafunctional female.

- Improve emergence profile
- Decrease screw loosening
- Minimize component fracture
- Facilitate oral hygiene

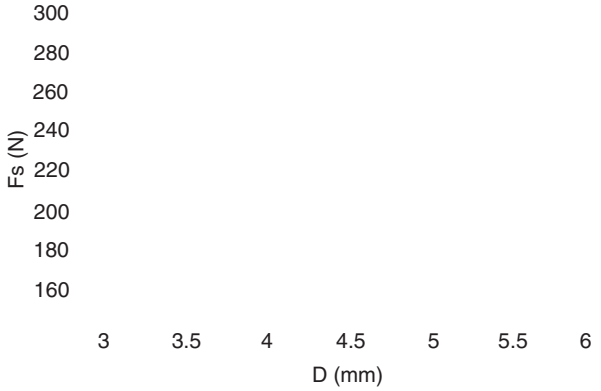

Figure 9-15 A larger diameter implant distributes less force to the abutment screw compared with a narrower diameter implant.

The force on an abutment screw is reduced with a large-diameter implant. A decrease in force to the abutment screw (and less screw loosening) and an increase in the strength of the implant body decrease the risk of fracture. The large-diameter implants, which have a larger prosthetic platform, exhibit less force transmission and stress to the abutment screw and therefore demonstrate less screw loosening (Figure 9-15).

By modeling the implant assembly as an engineering assembly, the following formula can be derived:

$$Fs = \frac{(P(H) - R2(h))^2}{D}$$

Where:

Fs = load on abutment screw
P = lateral load on the abutment
H = abutment height
R2 = reaction force on external hex
h = external hex height of the implant
D = platform diameter of the implant
Point A = point of abutment rotation (see Figure 9-16)

Therefore, by increasing *D* (platform diameter), the force on the screw is decreased. When a smaller abutment diameter is placed on an implant (platform switching), the force on the screw will increase, along with the risk of screw loosening (Figure 9-16).[64] In a clinical article by Cho et al. in 2004, wide-diameter

- Bone trauma—drill sequence
- Decreased facial bone thickness may lead to recession
- Stress shielding
- Increased surgical failure rate
- Too close to adjacent tooth, PDL encroachment

PDL, Periodontal ligament.

implants had 5.8% screw loosening compared with 14.5% for standard-diameter implants.[65] When a larger diameter implant can not be inserted in the molar region, two regular-diameter implants rather than one wide-diameter implant is advantageous.[66-68]

Disadvantages of Wide-Bodied Implants

The disadvantages of a wide-bodied implant are primarily related to the surgical aspects and early healing period (Box 9-6). Several reports indicate a higher failure rate, not from loading failure, but during the early healing period.[69-72] It is hypothesized that the failure rate is related to the use of the implant as a rescue device in less than optimal conditions, such as when the regular size implant is not fixated or after extraction of a failed implant or tooth.

Alternatively, the higher bite forces and lower bone density of the posterior regions may not always be able to be addressed adequately by primarily implant width. The wider diameter, short implants in some of the literature had a higher failure rate than standard-diameter implants. For example, Ivanoff et al. in 1999, found 6-mm-long implants with a 5-mm diameter had a failure rate of 33% in the mandible and 10% in the maxilla.[70] The 8-mm-long, 5-mm-diameter implant failed 25% of the time in the maxilla and had a 33% failure rate in the mandible. In this study, the longer implants of 10-mm and 12-mm implants that were 5 mm in diameter reported 0% mandibular failure and a 10% failure in the maxilla. Therefore the increase in implant diameter was not enough to compensate for the shorter implants in this report.

There are other reports in the literature that question the use of wider diameter implants of any length. Eckert et al. in 2001 found 19% implant loss in the mandible and 29% in the maxilla of 85 wide-platform MK II implants in 63 patients.[71] In 2003, Attard and Zarb compared the success rate of the standard-diameter 3.75-mm-implant at 15 years and the 5-year survival of the wide-platform, 5-mm-diameter implant replacing posterior teeth. The standard-diameter implant had a 91.6% implant survival, whereas the 5-mm implant had a 76.3% rate.[72] In 2004, Shin et al. found an 80.9% survival rate of 5-mm-diameter, wide-bodied implants compared with 96.8% for the regular-diameter implant over a 5-year period.[73] These reports on the wide-body implant emphasized an elevated risk of failure compared with regular-diameter implants and the need for additional clinical trials. Ivanoff et al. stated the higher failure rate may be caused by an early learning curve, implants used in poor bone quality and the use of the wide-diameter implant as a rescue implant when the standard diameter did not reach stability or failed.[70]

A wide-bodied implant may be closer than 1.5 mm to the adjacent tooth or result with less than 1.5 mm of

WWW.HIGHDENT.IR

facial or palatal bone. As a result, the bone loss around the platform a "biologic width," microgap position, smooth metal below the bone, or loading bone loss from shear forces may cause bone loss on the adjacent tooth or facial bone loss and gingival recession.[67,73,74] Therefore abundant bone volume is necessary for wide-diameter implants to prevent these occurrences.

Stress shielding occurs when insufficient stress is transferred to the implant-bone interface, which results in disuse atrophy of the bone, similar to a condition when no strain is transferred to bone after tooth loss. Implants 6 mm or wider in the anterior regions of the mouth were initially inserted, because a central incisor root is approximately 6 mm at the cement-enamel junction. However, these implants often exhibited crestal bone loss and were too close to the adjacent labial incisors. As a result, bone loss and gingival recession were common. In the posterior regions, 8-mm-diameter implants were used in the molar sites. Again, the implant is so wide that the bone was often not strained enough to maintain a lamellar pattern. Instead, the lack of strain resulted in disuse atrophy and bone loss (titanium has 5 to 10 times the modulus of elasticity of cortical bone). The bending fracture resistance of an 8-mm-diameter implant is 16 times more than a 4-mm-diameter implant, and as a result, the stimulation of the interface may be too low to maintain bone. Therefore an implant should not be wider than 5 mm in the anterior when adequate mesiodistal space is present and force magnitude is also observed, and the implant should not be greater than 6 mm in the posterior, again when adequate forces exist to stimulate the bone.

NATURAL TEETH

The roots of the natural dentition optimize the amount and direction of forces found with the mouth. The periodontal ligament complex is a very effective organ that distributes occlusal loads over a large bone surface area, thereby reducing the stress on the bone and distributing the load away from the crestal bone and along the entire root surface. This is evidenced by the cribriform plate, which is cortical bone and disappears after the tooth loss.

The smallest diameter roots are in the mandibular anterior region, where the forces are less and the direction of force is along the long axis of the root. The maxillary anterior teeth have larger roots and a different cross-section shape to compensate for the off-axis loading that increases lateral forces on the structure. The canines have a greater root surface area in response to the higher bite forces (90 lb/in^2 compared with 35 lb/in^2) and the direction of force during mandibular excursions. The premolars have less surface area than the canine, because they do not receive a lateral load in excursions. The molars have multiple roots splinted together in one crown. The maxillary posterior region has the least bone density, whereas the mandibular counterpart has coarser trabecular bone. The maxillary molars have more roots than the mandibular components and therefore have more surface area to dissipate loads in the fine trabecular bone located in this region of the mouth. The molar crowns are almost twice as large in diameter and the root surfaces are twice those of the premolars. This compensates for the amount of load increase by two to three times and decreases the risk of damaging stresses.

The natural tooth roots may serve as an indicator for implant width requirements for prosthetic loads (Figures 9-17 and 9-18). In this light, the mandibular incisors regions and the maxillary lateral incisor may be replaced with 3- to 3.5-mm-diameter implants; the maxillary anteriors, premolars in both arches, and mandibular canine may use 4-mm-diameter implants. The molars may be restored with 5- or 6-mm-diameter implants in both arches. When larger diameter implants cannot be used in the molar region, two 4-mm-diameter implants for each molar should be considered.

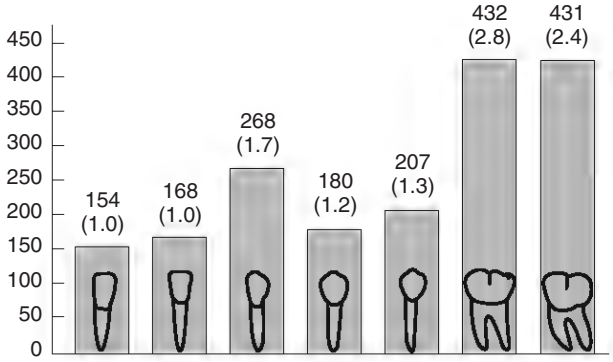

Figure 9-17 The implant diameter may be related to the natural teeth diameters, with narrower implants in the anterior and wider implants in the posterior regions.

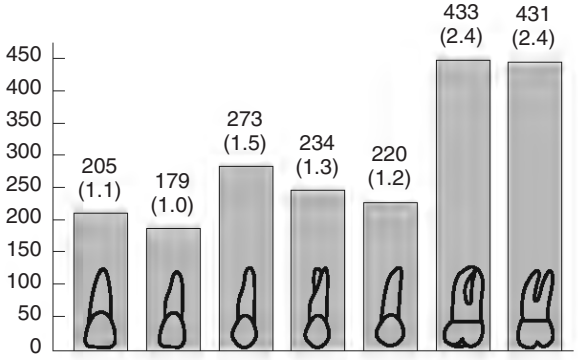

Figure 9-18 The maxillary molars have a larger diameter and surface area compared with any teeth in the mouth.

Box 9-7 Implant Diameter Criteria

Esthetics

- Size of tooth (minimum implant size)
- Adjacent tooth-interproximal bone (maximum implant size)
- Faciopalatal bone (maximum implant size)

Function

- Functional surface area
- Fatigue strength

IMPLANT SIZE BASED ON ESTHETICS

Anterior Tooth Replacement

The average mesiodistal dimension for a central incisor is 8.6 mm for a male and 8.1 mm for a female, a lateral incisor is 6.6 mm for a male and 6.1 mm for a female, and a canine is 7.6 mm for a male and 7.2 mm for a female. However, the implant body should not be as wide as the natural tooth or clinical crown it replaces. Otherwise, the emergence contour and interdental papillae region cannot be established properly. The teeth become narrower as they proceed apically. The mesiodistal dimension of the maxillary central incisor at the cervix of the CEJ averages 6.4 mm, the lateral incisor dimension is 4.7 mm, and canine natural teeth at the cervix are 5.6 mm (Box 9-7).[75,76] This dimension is also too wide for an implant to restore the soft tissue and emergence profile of a crown associated with the implant. The bone level on natural teeth is 2 mm below the CEJ. The natural tooth dimensions at this bone level are reduced to 5.5 mm for central incisors, 4.3 mm for lateral incisors, and 4.6 mm for canines. Therefore the latter dimensions most closely approximate the widest implant diameter to mimic the emergence profile of a natural tooth as it emerges from the soft tissue drape.

The second factor that determines the mesiodistal ideal implant diameter to replace a tooth is the necessary distance from an adjacent tooth root or implant. The horizontal dimension of a wedge-shaped bone defect around an implant at the crest of the ridge from the biological width, implant design, or occlusal overload is about 1.4 mm wide.[77] When the implant is closer than 1.5 mm to an adjacent root of a tooth, the wedge-shaped vertical defect may become a horizontal defect, creating bone loss on the adjacent tooth root. Initial vertical bone loss around an implant during the first year of loading varies and ranges from 0.5 to more than 3 mm. This effect is of utmost importance because the interseptal bone height in part determines the incidence of presence or absence of the interdental papillae between the teeth or implants.[78] As a result, an implant should be at least 1.5 mm from the adjacent teeth whenever possible. Natural tooth roots are often closer than 1.5 mm to each other.

Therefore the ideal mesiodistal implant size is usually less than the natural root dimension. Most often, the ideal implant diameters used to replace the average size anterior tooth correspond to a 4.2-mm implant for a central incisor, a 3- to 3.5-mm implant for a lateral incisor, and a 4.2-mm implant for an average canine.

In summary, two conditions determine the ideal anterior tooth implant size in the mesiodistal dimension. The ideal diameter most often corresponds to the width of the missing natural tooth, 2 mm below the CEJ. In addition, the implant diameter plus 1.5 mm on each side should be equal to or less than the mesiodistal dimension between the two natural roots at the level of the crest of the residual ridge (see Box 9-7).

The implant dimension in question is the size of the crest module, not the implant body dimension. For example, a 4.1-mm crest module (on a 3.75-mm implant body) needs 7.1 mm of mesiodistal crestal bone, a 3.5-mm crest module (on a 3.25-mm implant body) is indicated for 6.5 mm of bone, and a 5.2-mm crest module requires 8.2 mm of bone.

The difference in the emergence profile between a 4-mm-diameter implant and a 5-mm-diameter implant is often not clinically relevant and provides a zone of safety related to the available bone around the implant. Therefore, when in doubt, a smaller size diameter implant should be selected. As such, a 4-mm-diameter implant often is used in the central implant position for a single-tooth replacement. Likewise, a 3-mm-diameter implant often is used for a lateral incisor single-tooth restoration. The exceptions to this rule may be in a bruxing patient. The wide-diameter implant will decrease abutment screw loosening, crestal bone loss, and risk of long-term implant body failure.

Multiple Anterior Implants

When implants are placed adjacent to each other, a minimum distance of 3 mm is suggested, especially when crestal bone loss is expected around the implants, to accommodate for eventual crestal bone loss and maintain interseptal bone levels. This distance permits a 1.5-mm defect to form on adjacent implants, without the vertical wedgelike defect becoming a horizontal defect and increasing the risk of tissue shrinkage between the implants.

The size dimension of two adjacent anterior implants should most often be reduced compared with the ideal dimensions of a single-tooth implant. The smaller implant diameters increase the amount of bone on the facial, increase the amount of soft tissue interdentally, and decrease the risk of esthetic complications.

Posterior Tooth Replacement

The natural maxillary first and second premolar teeth have an average mesiodistal size of 7.1 and 6.6 mm,

WWW.HIGHDENT.IR

respectively. The dimensions of these teeth at the CEJ are 4.8 and 4.7 mm.[75,76,79,80] At a distance of 2 mm below the CEJ, the teeth are also similar in size and average 4.2 and 4.1 mm. Therefore, although the first premolar is often slightly larger than the second premolar at the occlusal surface, both teeth are similar at the level of the bone.

The ideal implant size in the posterior maxilla depends on four criteria (Box 9-8):

1. The implant dimension should correspond to the natural tooth (2 mm below the CEJ).
2. The implant should be at least 1.5 mm from the adjacent teeth.
3. The implant should be at least 3 mm from an adjacent implant.
4. The implant should be at least 4 mm in diameter.

In this way, bone loss on one implant will not affect the adjacent tooth or implant, and the implant is strong enough to resist fatigue fracture and screw loosening under higher bite forces in the posterior region of the mouth.

The natural maxillary molars have the greatest diameter and largest surface area of any teeth (Figure 9-18). The maxillary molars have a 200% increase in surface area compared with the premolar teeth. The first molar is 10.4 mm in mesiodistal dimension, and the second molar is 9.8 mm. The CEJ dimensions of these teeth are 7.9 mm and 7.6 mm, respectively, and 2 mm below the CEJ these teeth are both 7 mm. However, the ideal implant diameter is 5 to 6 mm for the maxillary molars. Because titanium is 5 to 10 times more rigid than natural teeth, the modulus of elasticity for an implant of sizes greater than 6 mm may be too great and cause stress shielding in the bone-implant interface. As a result, bone loss around the implant may occur from inadequate stimulation of the bone. In addition, the 6-mm diameter should not be used in the anterior regions because the magnitude of the force is not large enough to strain the bone within the ideal physiologic zones next to such a wide-diameter implant.

When the diameters of molar implants do not provide sufficient surface area, the number of implants should be increased. Rather than two implants replacing the first and second molars, three or even four implants may be considered. Treatment plans for implant number to compensate for implant size may be used for very soft bone types or unfavorable force factors (i.e., parafunction). When multiple adjacent posterior teeth are missing, increasing the number of implants affects the overall surface area than the implant size.

SUMMARY

The ideal size of the implant body should be incorporated into a treatment plan, rather than the surgeon determining this dimension at the time of surgery. The initial size of an implant is determined in both length and diameter. In a two-stage healing protocol, the ideal implant length should be 12 to 16 mm. The softer the bone, the longer the implant requirements. The greater the bite force, the longer the implant dimension. Therefore the shortest implant length may be treatment planned in the anterior mandible, the anterior maxilla should have a slightly longer implant, the posterior mandible a longer implant, and the longest implant requirement for an ideal treatment plan is usually found in the posterior maxilla.

Box 9-8 Implant Size Selection Criteria in Posterior Maxilla

- Natural tooth 2 mm below cement-enamel junction
- 1.5 mm from adjacent tooth
- 3 mm from adjacent implant
- 4-mm-diameter minimum, for posterior maxilla

The diameter of the implant is also an important part of an ideal treatment plan. The diameter of an implant has a surgical, loading, and prosthetic consideration. In the initial treatment plan, the loading and prosthetic components are most important. The width of the implant is directly related to the overall functional surface area. Therefore, where the forces are greater or the bone is less dense, the implant is wider, ranging from 3 to 6 mm. As a general rule, the narrowest implant is found in the anterior mandible, followed by the anterior maxilla and the posterior mandible; the widest diameter requirements are found in the molar region of the posterior maxilla.

The prosthetic aspects of the implant width are primarily related to the esthetics of the emergence profile, the force on an abutment screw and the strength of the implant components. As a result, wider diameter implants are selected in the molar regions; standard diameters in the canines, premolars, and maxillary central incisors; and the smallest size implants in the maxillary lateral and mandibular incisors.

The natural dentition follows the guidelines established in the implant size treatment plan considerations. The correlation is most likely found because of the biomechanical relationship of the amount and type of the forces in the location of the jaws and the type of the bone in the region. Therefore, in the maxilla, fine trabecular bone is used to dissipate forces. The angle of the force to the premaxilla is 12 to 15 degrees, and the amount of force is the greatest in the molar region. The mandible is a force-absorbing unit and has coarse trabeculae and dense cortical bone. The tooth size difference is reflected in the diameter of the tooth, not in the overall length dimension. These guidelines are consistent when engineering principles determine tooth size.

Chapter 10

Available Bone and Dental Implant Treatment Plans

Carl E. Misch

Long-term success in implant dentistry requires the evaluation of more than 50 dental criteria, many of which are unique to this discipline.[1] However, the doctor's training and experience and the amount and density of available bone in the edentulous site of the patient are arguably primary determining factors in predicting individual patient success. In the past, the available bone was not modified and was the primary intraoral factor influencing the treatment plan. Today the prosthodontic needs and desires of the patient should be first determined, relative to the number and position of missing teeth. After the intended prosthesis is designed, the patient force factors and bone density are then evaluated. The key implant positions, implant number, and size are determined. After these factors are considered, the most important element in the implant region is the available bone. Greenfield already appreciated its importance in 1913.[2] This chapter describes the three-dimensional concept of available bone and the implant treatment options for each type of bone anatomy.

Figure 10-1 Maxillary and mandibular atrophy after tooth loss was documented by J. Misch in 1922.

LITERATURE REVIEW

The process of bone volume atrophy after tooth loss and loss of alveolus has been fully documented (Figure 10-1).[3-19] Characteristic bone volume changes after tooth loss were evaluated in the anterior mandible by Atwood (Figure 10-2).[4-6] The six residual ridge stages are beneficial to appreciate the shapes and range of bone loss. Tallgren reported the amount of bone loss occurring the first year after tooth loss is almost 10 times greater than the following years.[7] The posterior edentulous mandible resorbs at a rate approximately four times faster than the anterior edentulous mandible.[8] It has been suggested that, in the mandibular synthesis, females present higher total reduction and more rapid bone loss during the first 2 years.[9] More recent studies in complete denture wearers have confirmed the higher rate of resorption in the first year of edentulouness.[10,11] The anterior maxilla resorbs in height slower than the anterior mandible. However, the original height of available bone in the anterior mandible is twice as much as the anterior maxilla. Therefore the resultant maxillary atrophy, although slower, affects

Figure 10-2 Atwood presented a classification of bone loss after tooth loss in the anterior mandible in 1963.

WWW.HIGHDENT.IR

the potential available bone for an implant patient with equal frequency.[7] The changes in the edentulous anterior maxillary ridge dimension can be dramatic in height and width (up to 70%), especially when multiple extractions are performed.[12] In addition, many patients lose additional bone by simultaneous alveolectomy procedures after tooth extraction before the delivery of a maxillary denture.[13] Although slight differences exist between different alveolectomy techniques, all are detrimental to the ridge volume.[14]

The residual ridge shifts palatally in the maxilla and lingually in the mandible as related to tooth position, at the expense of the buccal cortical plate in all areas of the jaws, regardless of the number of teeth missing.[15-19] However, after the initial bone loss, the maxilla continues to resorb toward the midline, whereas the mandibular basal bone is wider than the original alveolar bone position and results in the late mandible resorption progressing facially. This, in addition to a marked change in mandibular position, leads to the classical appearance of the denture wearer with a protruding chin and a mandibular lip.[20] The posterior maxilla loses bone volume faster than any other region. Not only does periodontal disease cause initial bone loss before the loss of teeth, the crestal bone loss is substantial after tooth extraction. In addition, the maxillary sinus after tooth loss expands toward the crest of the edentulous ridge. As a result, the posterior maxilla is more often indicated for bone augmentation compared with any other intraoral location.

Weiss and Judy[21] developed a classification of mandibular atrophy and its influence on subperiosteal implant therapy in 1974. Kent presented a classification of alveolar ridge deficiency designed for alloplastic bone augmentation in 1982.[22] Another bone volume classification was proposed by Lekholm and Zarb in 1985 for residual jaw morphology related to the insertion of Brånemark fixtures.[23] They described five stages of jaw resorption, ranging from minimal to extreme (Figure 10-3). The mandibular resorption was only described in loss of height. All the five stages of resorption in either arch used the same implant modality, surgical approach, and type of final prosthesis. In addition, as the bone volume decreased, the number of implants decreased.

A maxillary alveolar process of resorption after tooth loss after Atwood's description for the mandible was presented by Fallschüssel in 1986.[24] The six resorption categories of this arch ranged from fully preserved to moderately wide and high, narrow and high, sharp and high, wide and reduced in height, and severely atrophic. The classifications of Atwood, Zarb and Lekholm, and Fallschüssel do not describe the actual resorption process in chronological order and are more descriptive of the residual bone.[25] Another bone resorption classification, which included the expansion of the maxillary sinuses, was also proposed by Cawood and Howell in 1988.[26] Although similar to other categories, the bone volume changes are not reflective of the changes required for implant placement or bone grafting procedures.

In 1985, Misch and Judy established four basic divisions of available bone for implant dentistry in the edentulous maxilla and mandible, which follow the natural resorption phenomena of each region, and determined a different implant approach to each category.[1,27-33] The angulation of bone and crown height were also included for each bone volume, because they affect the prosthetic treatment. These original four divisions of bone were further expanded with two subcategories to provide an organized approach to implant treatment options for surgery, bone grafting, and prosthodontics (Figure 10-4). The ability to organize the available bone of the potential implant site into specific related categories of common treatment options and conditions is of benefit to both the beginning and experienced clinician alike. Improved communication among health professionals and the collection of relevant specific data for each category are also beneficial. The Misch-Judy bone classification has facilitated these processes during the past two decades

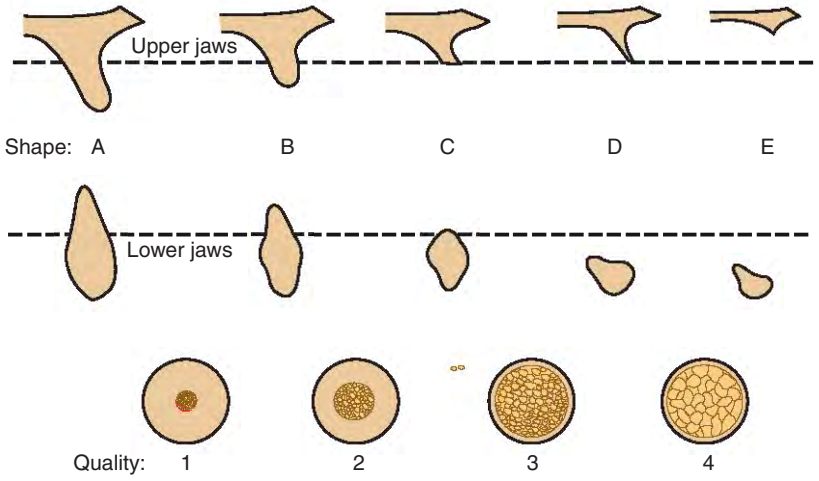

Figure 10-3 Lekholm and Zarb presented a classification of bone loss in the edentulous jaws in 1985.

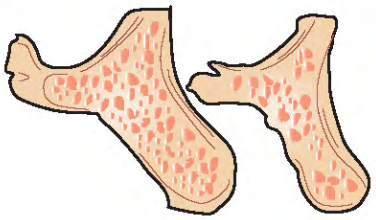

Figure 10-4 In 1985, Misch and Judy presented a classification of available bone (Divisions A, B, C, D), which is similar in both arches in 1985. Implant, bone grafting methods, and prosthodontic related treatment was suggested for each category of bone. *h*, Inadequate height; *w*, inadequate width.

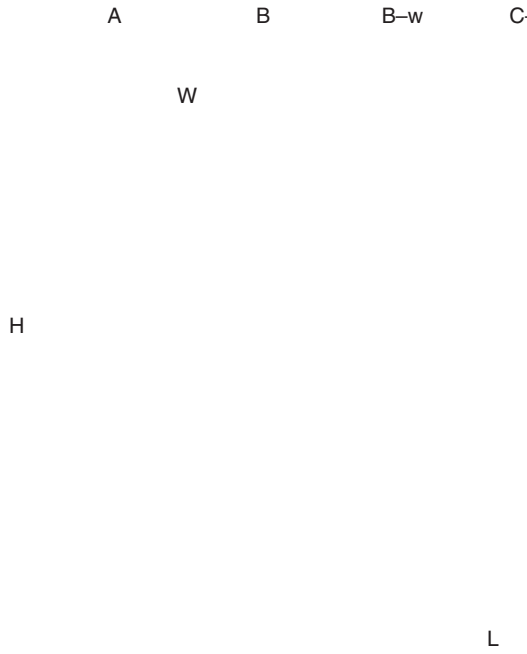

Figure 10-5 Available bone is measured in height *(H)*, width *(W)*, and length *(L)*. Also considered are crown height space and angulation of bone (direction of force to the implant body).

within the profession, universities, implant programs, and international implant societies.

AVAILABLE BONE

The category and design of the final prosthesis and key implant positions are first determined after a patient interview and evaluation of existing medical and dental conditions. The patient force factors and bone density are of particular note. The abutments necessary to support the restoration are then established in implant number and size and without initial regard to the available bone conditions.

Available bone describes the amount of bone in the edentulous area considered for implantation. It is measured in width, height, length, angulation, and crown height space (Figure 10-5). Historically, the available bone was not modified and dictated the implant position and size. Today, if the bone is inadequate to support an ideal abutment for the intended prosthesis or bone grafting, the ideal site is often indicated or an alternative site may be considered.

As a general guideline, 1.5 to 2 mm of surgical error is maintained between the implant and any adjacent landmark. This is especially critical when the opposing landmark is the mandibular inferior alveolar nerve. However, the implant may be placed without complication through the cortical plate of the maxillary sinus or inferior border of the mandible. The implant may also be positioned closer to the cribriform plate of a natural tooth. If the implant should become mobile or affected by periimplant disease, the adjacent landmark may be adversely involved. Likewise, if the sinus becomes infected or the adjacent tooth suffers from periodontal disease, the implant may be affected.

Manufacturers describe the root form implant in dimensions of width and length. The implant length corresponds to the height of available bone. Therefore this text refers to root form implant height or length. The width of a root form implant is most often related to the diameter and mesiodistal length of available bone. Most root form implants have a round cross-sectional design to aid in surgical placement; therefore the diameter of the implant corresponds to the implant width. Many manufacturers propose implants with a crest module wider than the implant body dimension.

WWW.HIGHDENT.IR

Yet the often stated dimension of the manufacturer is the smaller body width. For example, the Nobel Biocare 3.75-mm-diameter implant has a 4.1-mm-crest module. The clinician should be knowledgeable of all implant dimensions, especially because the crestal dimension of bone (where the wider crest module dimension is placed) is usually the narrowest region of the available bone and where the implant is closest to an adjacent tooth.

All teeth are not equal when considered as abutments for a prosthesis. The restoring dentist knows how to evaluate the surface area of the natural abutment roots. A healthy maxillary first molar with more than 450 mm^2 of root surface area constitutes a better abutment for a fixed prosthesis than a mandibular lateral incisor with 150 mm^2 of root support. The larger diameter teeth correspond to the regions of the mouth with greater bite force. It is interesting to note the increase in surface area for natural teeth is most dependent upon diameter and a change in design, more so than length.

Implant Width

All sizes and designs of implants do not have the same surface area and should not be considered as equals for prosthetic abutments. With a greater surface area of implant-bone contact, less stress is transmitted to the bone, and the implant prognosis improved. For a generic cylinder root form implant design, each 0.25-mm increase in diameter corresponds to a surface area increase of approximately 5% to 8%. Therefore a cylinder root form implant 1 mm greater in diameter will have a total surface area increase of approximately 20% to 30%. Because stress *(S)* equals force *(F)* divided by the functional area *(A)* over which it is applied *(S = F/A)*, the greater diameter decreases the amount of stress at the crestal bone implant interface. Because early bone loss relates to the crestal bone regions and prosthetic complications may be related to the crest module size of an implant, the width of the implant is much more critical than its height, after a minimum height has been obtained.

Implant Height

The height of the implant also affects its total surface area. A cylinder root form implant 3 mm longer provides 20% to 30% increase in surface area. The advantage of increased height does not express itself at the crestal bone interface but rather in initial stability of the implant, the overall amount of bone-implant interface, and a greater resistance to rotational torque during abutment screw tightening. The increased height of an implant in an immediate extraction site larger in diameter than the implant also increases the initial bone contact percent, which can decrease the initial risk of movement at the interface. In addition, the crestal bone and opposing anatomical landmark are often composed of cortical bone, which is denser and stronger than trabecular bone. As a result, it may help stabilize the implant while the trabecular woven bone forms. In this way, a direct bone-implant interface is encouraged. This may be of particular advantage when an immediate-loading protocol of implants is used for a transitional prosthesis. However, after the implant has healed, the crestal region is the zone that receives the majority of the stress. As a result, implant length is not as effective as the width to decrease crestal loads around an implant.

The minimum height for endosteal implants, long-term survival is in part related to the density of bone. The more dense bone may accommodate a shorter implant (i.e., 8 mm), and the least dense, weaker bone requires a longer implant (i.e., 12 mm). After the minimum implant height is established for each implant design and bone density, the width is more important than additional length. This chapter primarily presents the volume of bone requirements for ideal bone density situations or D2, which is coarse trabecular bone surrounded by porous to dense cortical bone.

Available Bone Height

The available bone height is first estimated by radiographic evaluation in the edentulous ideal and optional regions, where implant abutments are required for the intended prosthesis. A panoramic radiograph is the most common method for the preliminary determination of the available bone height.

The height of available bone is measured from the crest of the edentulous ridge to the opposing landmark. The anterior regions are limited by the maxillary nares or the inferior border of the mandible. The anterior regions of the jaws have the greatest height, because the maxillary sinus and inferior alveolar nerve limit this dimension in the posterior regions. The maxillary canine eminence region often offers the greatest height of available bone in the maxillary anterior.[34] In the posterior jaw region, there is usually greater bone height in the maxillary first premolar than in the second premolar, which has greater height than the molar sites because of the concave morphology of the maxillary sinus floor. Likewise, the mandibular first premolar region is usually anterior to the mental foramen and provides the most vertical column of bone in the posterior mandible. However, on occasion, this premolar site may present a reduced height compared with the anterior region, because of the anterior loop of the mandibular canal (when present) as it passes below the foramen and proceeds superiorly, then distally, before its exit through the mental foramen (Figure 10-6).

The dilemma of available bone in implant dentistry involves the existing anatomy of the edentulous mandible and maxilla. The initial mandibular bone

WWW.HIGHDENT.IR

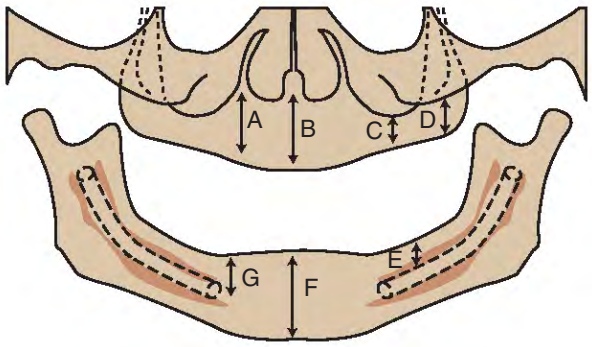

Figure 10-6 The height of available bone is measured from the crest of the edentulous ridge to the opposing landmark. The opposing landmark may be in the maxillary canine region *(A)*, floor of the nares *(B)*, maxillary sinus *(C)*, tuberosity *(D)*, mandibular canine region *(G)*, anterior mandible *(F)*, or bone above the inferior mandibular canal *(E)*.

height is influenced by skeletal anatomy, with angle Class II patients having shorter mandibular height, and angle Class III patients exhibiting the greatest height. The initial edentulous anterior maxillary available bone height is less than the mandibular available bone height. The opposing landmarks for the initial available bone height are more limiting in the posterior regions. The posterior mandibular region is reduced because of the presence of the mandibular canal, approximately situated 12 mm above the inferior border of the mandible. As a result, in the areas where greater forces are generated and the natural dentition has wider teeth with two or three roots, shorter implants, if any, are often used and in insufficient number because of the anatomical limiting factors. A study of 431 patients revealed that in the partially edentulous maxilla and mandible, the placement of posterior implants at least 6 mm in length was possible in only 38% and 50%, respectively. The anterior regions of edentulous arches could receive implants 55% and 61% of the time, respectively.[35] The existing bone anatomy of the implant patient often requires modification to enhance long-term implant success. For example, sinus grafts in the posterior maxilla permit the placement of posterior endosteal implants into restored bone height.

The suggested minimum bone height for predictable long-term endosteal implant survival approaches 12 mm. Before 1981 the Brånemark screw–type implant body and osteointegrated approach was provided as a single diameter (3.75 mm) and was used only in the completely edentulous anterior maxilla and mandible.[36] The implant drills cut 10 mm deep, and the "10-mm" implant was 9 mm in length. By 1990 this philosophy had been expanded to all jaw regions and many implant sizes. However, failure rates reported in the literature for implants shorter than 9 mm tend to be higher independently from the manufacturer design, surface characteristic, and type of application.[37-52] Therefore the initial implant length should approximate 12 mm, because the ideal treatment plan should first be designed. The inexperienced dentist may wish to have 14 mm of bone height to place a 12-mm-high implant body before proceeding with the surgery. This precaution allows 2-mm surgical error or permits an osteoplasty to gain additional width of bone. The 12-mm height minimum applies to most screw-shape endosteal implant designs in good-density (D2) bone. This minimum implant height requirement may be reduced in the very dense bone (D1) in the symphysis of an atrophic mandible, when the prosthesis has fewer forces (as an overdenture) or when the shorter dimension can be compensated by implant number, width, or design.[53-55]

The available bone height in an edentulous site is the most important dimension for implant consideration, because it affects both implant length and crown height. Crown height affects force factors and esthetics. In addition, bone augmentation is more predictable in width than height, so even when the width is inadequate for implant placement, bone grafting may be used to create a site ideal for restorative and implant insertion requirements.

Available Bone Width

The width of available bone is measured between the facial and lingual plates at the crest of the potential implant site. The crest of the edentulous ridge is most often supported by a wider base. In most areas, because of this triangular-shaped cross section, an osteoplasty provides greater width of bone, although of reduced height. However, the anterior maxilla often does not follow this rule, because most edentulous ridges exhibit a labial concavity in the incisor area, with an hourglass configuration. Crest reduction affects the location of the opposing landmark, with possible consequences for surgery, implant height selection, appearance, and the design of the final prosthesis. This is particularly important when an FP-1 prosthesis is planned, with the goal of obtaining a normal contour and proper soft tissue drape around a single tooth replacement.

After adequate height is available, the next most significant criterion affecting long-term survival of endosteal implants is the width of the available bone. Root form implants of 4-mm crestal diameter usually require more than 6 mm of bone width to ensure sufficient bone thickness and blood supply around the implant for predictable survival. These dimensions provide more than 1 mm of bone on each side of the implant at the crest. Because the bone usually widens apically, this minimum dimension rapidly increases. For root form implants, the minimum bone thickness is located in the midfacial and midlingual contour of the crestal region exclusively (Figure 10-7). The crestal aspect of the residual ridge is often cortical in nature and exhibits greater density than the underlying trabecular bone regions, especially in the mandible. This mechanical advantage permits immediate fixation

WWW.HIGHDENT.IR

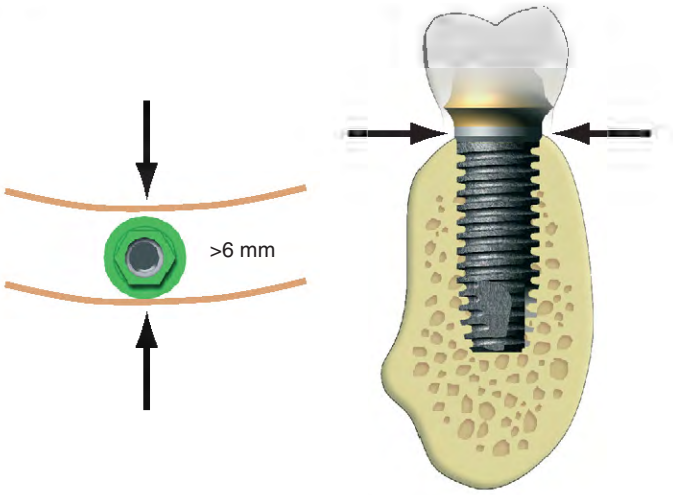

Figure 10-7 Minimum bone width for a 4-mm-diameter root form is 6 mm in the midfacial and lingual regions, because the round implant design results in more bone in all other dimensions (width and height).

of the implant, provided this cortical layer has not been removed by osteoplasty.

The initial width of available bone is related to the initial crestal bone loss after implant loading. Edentulous ridges that are greater than 6 mm in width have demonstrated less crestal bone loss than when minimum bone dimensions are available. Extraction sockets having more width at the crest also lose less bone during initial healing than sites with minimum width of cortical plates on the facial or lingual of the extraction site.

Available Bone Length

The mesiodistal length of available bone in an edentulous area is often limited by adjacent teeth or implants. As a general rule, the implant should be at least 1.5 mm from an adjacent tooth and 3 mm from an adjacent implant. This dimension not only allows surgical error, but also compensates for the width of an implant or tooth crestal defect, which is usually less than 1.4 mm. As a result, if bone loss occurs at the crest module of an implant or from periodontal disease with a tooth, the vertical bone defect will not spread to a horizontal defect and cause bone loss on the adjacent structure.[56] Therefore, in the case of a single-tooth replacement, the minimum length of available bone necessary for an endosteal implant depends on the width of the implant. For example, a 5-mm-diameter implant should have at least 8 mm of mesiodistal bone, so 1.5 mm is present on each side of the implant. A minimum mesiodistal length of 7 mm is usually sufficient for a 4-mm-diameter implant. Of course, the diameter of the implant is also related to the width of available bone and, in multiple adjacent sites, is primarily limited in this dimension. For example, a width of bone of 4.5 mm without augmentation requires a 3.5-mm or smaller implant, with inherent compromises (such as minimal surface area and greater crestal stress concentration under occlusal loads). Therefore in the narrower ridge, it is often indicated to place two or more narrow-diameter implants when possible to obtain sufficient implant-bone surface area to compensate for the deficiency in width of the implant. Because the implants should be 3 mm apart and 1.5 mm from each tooth, 13 mm or more in available bone mesiodistal length may be required when the narrower implant dimensions are used to replace a posterior tooth.

The ideal implant width for single-tooth replacement or multiple adjacent implants is often related to the natural tooth being replaced in the site. The tooth has its greatest width at the interproximal contacts, is narrower at the cement-enamel junction (CEJ), and is even narrower at the initial crestal bone contact, which is 2 mm below the CEJ.[57] The ideal implant diameter corresponds to the width of the natural tooth 2 mm below the CEJ, if it also is 1.5 mm from the adjacent tooth. In this way, the implant crown emergence through the soft tissue may be similar to a natural tooth. For example, a maxillary first premolar is approximately 8 mm at the interproximal contact, 5 mm at the CEJ, and 4 mm at a point 2 mm below the CEJ. Therefore a 4-mm-diameter implant (at the crest module) would be the ideal implant diameter, if it also is at least 1.5 mm from the adjacent roots (2 mm below the CEJ).

Available Bone Angulation

Bone angulation is the fourth determinant for available bone. The initial alveolar bone angulation represents the natural tooth root trajectory in relation to the occlusal plane. Ideally, it is perpendicular to the plane of occlusion, which is aligned with the forces of occlusion and is parallel to the long axis of the prosthodontic restoration. The incisal and occlusal surfaces of the teeth follow the curve of Wilson and curve of Spee. As such, the roots of the maxillary teeth are angled toward a common point approximately 4 inches away. The mandibular roots flare, so the anatomical crowns are more lingually inclined in the posterior regions and labially inclined in the anterior area compared with the underlying roots. The first premolar cusp tip is usually vertical to its root apex.

The maxillary anterior teeth are the only segment in either arch that does not receive a long axis load to the tooth roots, but instead are usually loaded at a 12-degree angle. As such, their root diameter is greater than the mandibular anterior teeth. In all other regions, the teeth are loaded perpendicular to the curves of Wilson or Spee.

Rarely does the bone angulation remain ideal after the loss of teeth, especially in the anterior edentulous arch (Figure 10-8). In this region, labial undercuts

WWW.HIGHDENT.IR

Figure 10-8 The angulation of bone may not be in the long axis of the missing tooth, especially in the anterior regions of the mouth. The computed tomography scan was obtained with a barium sulfate radiopaque template over the edentulous site of a lower anterior tooth. The available bone trajectory diverges 30 degrees from the tooth's angulation.

and resorption after tooth loss,[12,15,16] often mandate greater angulation of the implants or correction of the site before insertion. In the posterior mandible, the submandibular fossa mandates implant placement with increasing angulation as it progresses distally. Therefore, in the second premolar region, the angulation may be 10 degrees to a horizontal plane; in the first molar areas, 15 degrees; and in the second molar region, 20 to 25 degrees.

The limiting factor of angulation of force between the body and the abutment of an implant is correlated to the width of bone. In edentulous areas with a wide ridge, wider root form implants may be selected. Such implants may allow up to 25 degrees of divergence with the adjacent implants, natural teeth, or axial forces of occlusion with moderate compromise. The angled load to an implant body increases the crestal stresses, but the greater diameter implant decreases the amount of stress transmitted to the crestal bone. In addition, the greater width of bone offers some latitude in angulation at implant placement. The implant body may often be inserted so as to reduce the divergence of the abutments without compromising the permucosal site. Therefore an acceptable bone angulation in the wider ridge may be as much as 25 degrees.

The narrow yet adequate width ridge often requires a narrower design root form implant. Compared with larger diameters, smaller diameter designs cause greater crestal stress and may not offer the same range of custom abutments. In addition, the narrower width of bone does not permit as much latitude in placement regarding angulation within the bone. This limits the acceptable angulation of bone in the narrow ridge to 20 degrees from the axis of the adjacent clinical crowns or a line perpendicular to the occlusal plane.

Crown Height Space

The crown height space (CHS) is defined as the vertical distance from the crest of the ridge to the occlusal plane. It affects the appearance of the final prosthesis and the amount of moment force on the implant and surrounding crestal bone during occlusal loading. The CHS may be considered a vertical cantilever. Any direction of load that is not in the long axis of the implant will magnify the crestal stresses to the implant-bone interface and also to the abutment screws in the restoration. The greater the CHS, the greater the moment force or lever arm with any lateral force or cantilever. Esthetically, the prosthesis is less likely to replace the sole anatomical crowns of natural teeth when a greater CHS is present. The absence of a peri-implant ligament means that the bone-implant stresses cannot be managed by increasing the implant height. Therefore, as the CHS increases, a greater number of implants or wider implants should be inserted to counteract the increase in stress. For an ideal treatment plan, the CHS should be equal to or less than 15 mm for ideal conditions (see Chapter 6).

DIVISIONS OF AVAILABLE BONE

Division A (Abundant Bone)

Division A abundant bone often forms soon after the tooth is extracted. The abundant bone volume remains for a few years, although the interseptal bone height is reduced and the original crestal width is usually reduced by more than 30% within 2 years.[12] Division A bone corresponds to abundant available bone in all dimensions (Box 10-1 and Figures 10-9 to 10-11). It should be emphasized that the available bone height may be 20 mm for Division A, but this does not mean the implant length must be equal to the bone height. Because the stresses to the implant interface in good-density bone are captured at the crest of the ridge, an implant of 12 mm or more has been shown to

Box 10-1 Division A Dimensions

Figure 10-10 Both Division A arches were restored with fixed maxillary and mandibular implant restorations crown with heights inferior to 15 mm. In the FP-3 restoration, pink porcelain was used to replace the soft tissue drape.

be without compromise for long-term success, even though the implant does not engage the opposing cortical plate.

The Division A width of more than 6 mm is predicated on an implant diameter of at least 4 mm at the crest module, because abundant long-term data have been published regarding this implant size.[37,45] In abundant bone width (A+ bone) of greater than 7 mm, a wider (5-mm diameter) implant may be inserted, provided that 1 mm of bone remains around the buccal and lingual aspects of the implant. Osteoplasty may often be performed to obtain additional bone width.

The implant choice in Division A bone is a root form of 4 mm or greater in diameter. A larger diameter implant is suggested in the molar regions (5 to 6 mm in diameter). The length of the implant is 12 mm or greater. Longer implants are suggested in immediate-loading treatment options.

Division A bone should not be treated with smaller diameter implants for the final prosthesis. There are several advantages to the use of implants equal to or

Figure 10-11 A panoramic radiograph of the fixed maxillary and mandibular implant–supported restorations in Division A bone. The number of implants is related to the force conditions and bone quality of the patient.

greater than 4 mm in diameter, compared with smaller diameter implants (Box 10-2).

A patient with Division A bone should be notified that this is the most ideal time to restore their edentulous condition with implants. All too often, the doctor fails to educate the patient about the rapid decrease in bone volume width and the consequences of delaying treatment. When the bone volume is Division A, there is a decrease in treatment costs, with a reduction in the number and complexity of surgeries to the edentulous area with significant benefits to the patient. Unfortunately, these patients may not have significant problems with their existing restoration and therefore may not be motivated to address the situation. As the bone resorbs and the problems arise, a greater appreciation for the benefits of implant-supported restorations are realized. Just as the restoring dentist explains the need to replace a single tooth before tipping and extrusion of adjacent teeth and the risk of additional tooth loss, the patient should be educated as to the benefit of implant treatment while the area presents abundant bone.

The prosthetic options for Division A span the full gamut. An FP-1 restoration requires a Division A ridge. However, an FP-2 prosthesis most often also requires a Division A bone. An FP-2 restoration is the most common posterior restoration supported by multiple adjacent implants in partially edentulous patients, because of either bone loss or osteoplasty before implant placement. An FP-3 prosthesis is most often the option selected in the anterior Division A bone when the maxillary smiling lip position is high or a mandibular low lip line during speech exposes regions beyond the natural anatomical crown position.

For removable implant overdentures in Division A bone, the final position of the tooth and superstructure bar must be evaluated before surgery. A limited CHS is more common in Division A bone, and a final RP-4 or RP-5 result may require osteoplasty before implant placement. Division A bone may represent a contraindication for high profile O-ring attachments or

WWW.HIGHDENT.IR

Box 10-2 Division A Root Form Implant Advantages

- The larger the diameter of an implant, the greater the surface area and the less stress distributed through the crestal bone region.
- The larger diameter implants are closer to the lateral cortical plates of bone, which have greater density and therefore increased strength, modulus of elasticity, and bone-implant contact percentages.
- The larger diameter implants are less likely to fracture, because the strength of the material is increased by a power of four related to the radius of the implant. (A 4-mm-diameter implant is 16 times stronger than a 2-mm-diameter implant.)
- The smaller diameter implants are often one-piece to decrease the risk of fracture. The one-piece implants require an immediate restoration, rather than a submerged or one-stage approach. As such, likely loading and micromovement may occur at the bone-implant interface, with an increased risk of crestal bone loss and/or implant failure.
- The emergence profile angle of the crown is related to the implant diameter. The larger diameter teeth can be most esthetically restored with a wider diameter implant.
- The larger the implant diameter, the less stress applied to the abutment screw, and therefore complications such as screw loosening or fracture are less likely.
- The larger diameter abutment provides greater cement retention for the final restoration crown.
- Oral hygiene procedures are more compromised around smaller diameter implants restored with greater emergence profile angles and over contoured restorations.
- The crest module and crestal portion of many two-piece, small-diameter implants are smooth metal to increase the inter body wall thickness, thus creating shear loads to the crestal bone and an increased risk of bone loss.
- Implant costs to the patient are related to implant number, not diameter. Therefore increases in implant numbers for smaller diameter implants increase the cost to the patient (and the doctor).
- Division A root form implants are designed for variable bone density and can provide the greatest range of prosthetic options.

superstructures placed several millimeters above the tissue for hygiene considerations, because of a compromised CHS to accommodate prosthetic components (Figures 10-12 to 10-14).

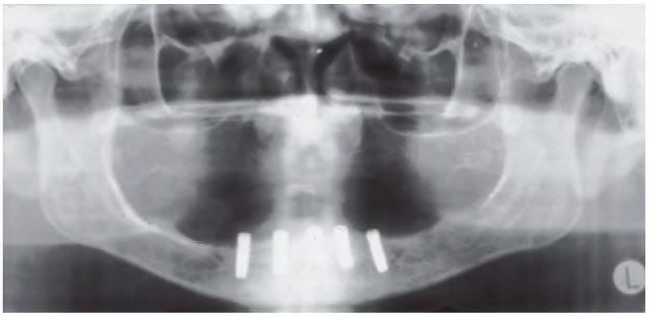

Figure 10-12 When planning implants in the anterior mandible for an overdenture, the following factors must be considered: crown height space for the denture teeth, acrylic, bar, and attachments. In Division A bone, the crestal bone may require osteoplasty to increase the crown height.

Division B (Barely Sufficient Bone)

As the bone resorbs, the width of available bone first decreases at the expense of the facial cortical plate, because the cortical bone is thicker on the lingual aspect of the alveolar bone, especially in the anterior regions of the jaws. There is a 25% decrease in bone width the first year and a 40% decrease in bone width within the first 1 to 3 years after tooth extraction.[12,15,16] The resulting narrower ridge is often inadequate for many 4-mm-diameter root form implants. Slight to mild atrophy is often used to describe this clinical condition. After this Division B bone volume is reached, it may remain for more than 15 years in the anterior mandible.[5] However, the posterior mandibular height resorbs four times faster than the anterior region. The posterior maxillary regions exhibit less available bone height (as a consequence of sinus expansion) and have the fastest decrease

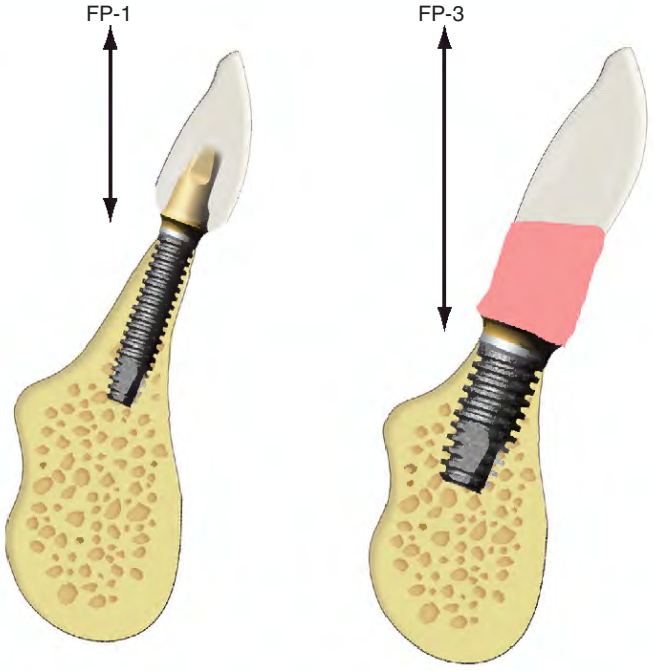

Figure 10-16 Options to treat a Division B ridge in the anterior mandible include a narrow implant with a final prosthesis closer to anatomical dimensions (FP-1) *(left)* or osteoplasty with Division A root forms and extended crown heights (FP-2 or FP-3) *(right)*.

of bone height of any intraoral region. As a result, the posterior regions of the jaws may become inadequate in height (C–h) earlier than the anterior regions.

Division B bone offers sufficient available bone height (Box 10-3). The Division B available bone width may be further classified into ridges 4 to 6 mm wide and B minus width (B–w) 2.5 to 4 mm wide, where bone grafting techniques are indicated (see Figure 10-4). Because the minimum mesiodistal length of a Division B ridge is less than that of Division A, a smaller diameter implant (i.e., 3 mm) may be used. Because the ridge width and implant diameter are narrower and forces increase as the angle of load increases, the angulation of occlusal load is also less. A CHS of 15 mm or less (similar to Division A) is necessary in Division B to decrease the moment of forces with lateral or offset loads, especially because of the smaller width dimension.

Three treatment options are available for the Division B edentulous ridge:

1. Modify the existing Division B ridge to another division by osteoplasty to permit the placement of root form implants 4 mm or greater in width (Figure 10-15). When more than 12 mm of bone height results, the bone converts to Division A. When less than 12 mm of bone height results, the bone converts to Division C–h.
2. Insert a narrow Division B root form implant.
3. Modify the existing Division B bone into Division A by augmentation.

To select the proper approach to this bone category, the final prosthesis must first be considered. When a Division B ridge is changed to a Division A by osteoplasty procedures, the final prosthesis design has to compensate for the increased CHS. For example, before surgery the available bone height may be compatible with an FP-1 prosthetic design. If, at the time of surgery, the ridge is found deficient in width for implant placement, it is not unusual to remove 3 mm of crestal bone before reaching a Division A width. This means the final restoration will require an additional 3 mm in height. Therefore it may result in an extended tooth (FP-2, FP-3) restoration (Figure 10-16). The osteoplasty option is less likely the treatment of choice for an FP-1 prosthesis with a B–w ridge, because even greater bone height reduction is required. The most common approach is to modify the narrower Division B ridge into another bone division by osteoplasty when the final restoration is an implant overdenture (Figures 10-17 to 10-19). The edentulous ridge crest may be reduced, thereby increasing the width of the ridge. If the CHS is less than 15 mm, the ridge division becomes Division A with a greater width than 6 mm. If the ridge height is reduced so that the crown height space is greater than 15 mm, the bone division is

WWW.HIGHDENT.IR

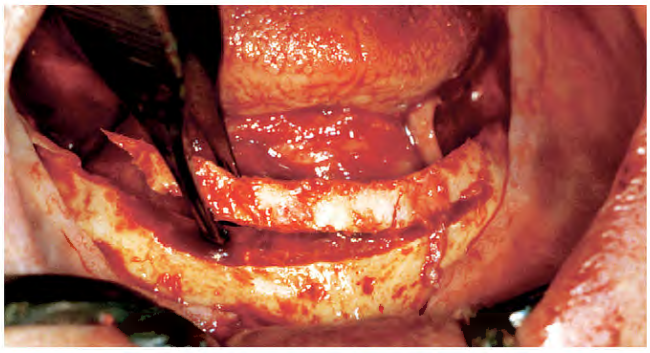

Figure 10-17 A Division B bone ridge may be modified by osteoplasty to increase the width of bone. The osteoplasty increases the crown height space for the prosthesis.

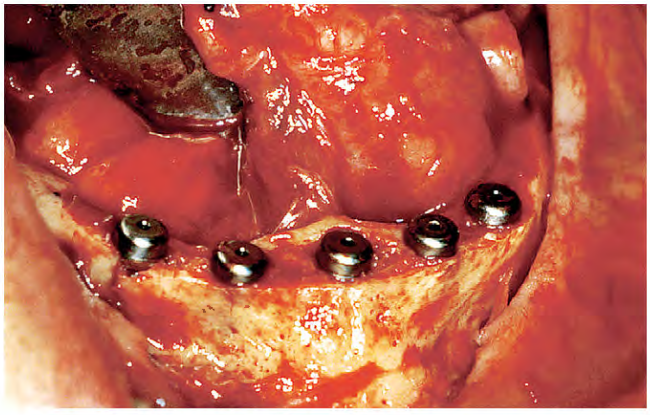

Figure 10-18 Five 4-mm-diameter anterior implants were placed after the osteoplasty in Figure 10-17. These implants were positioned with regard to the final restoration.

Box 10-4 Disadvantages of Division B Root Forms

1. Almost twice the stress is concentrated at the top crestal region around the implant.
2. Less overall surface areas means that lateral loads on the implant result in almost three times greater stress than Division A root forms.
3. Fatigue fractures of the abutment post are increased, especially under lateral loads.
4. The crown emergence profile is less esthetic (except for maxillary lateral or mandibular incisors).
5. Conditions for daily care are compromised around the cervical aspect of the crown.
6. The implant design is often poor in the crestal region. To increase implant body wall thickness to reduce fracture, no threads or compressive force design are present, but this further increases stress and the amount of shear loads to bone.
7. The angle of load must be reduced to less than 20 degrees to compensate for the small diameter.
8. Two implants are often required for proper prosthetic support, unless anterior single tooth replacement for maxillary laterals or mandibular incisors, so surface area ends up being greater because of implant number, *not* size.
9. Implant costs are not related to diameter, so an increase in implant number results in greater cost to the doctor and patient.

not changed to a Division A. Instead, it has been altered to a Division C–h bone volume and, when cantilevers or lateral forces are present on the prothesis, is not as predictable for endosteal implant placement as Division A. An RP-4 or RP-5 restoration most often requires option 1—osteoplasty—where adequate CHS is created to permit the fabrication of the overdenture and superstructure bar with attachments without prosthetic compromise.

The second main treatment option for the narrow available bone Division B is the small-diameter root form implant. Smaller diameter root form implants (3.0 to 3.5 mm) are designed primarily for Division B available bone. The Division B bone is narrower, so the implant body of the implant must bisect the bone and implant angulation is less flexible. The Division B root form implants present several inherent disadvantages when compared with the larger diameter implants (Box 10-4).[56-61] As a result of these concerns for the Division B root form, this option is mostly used for single tooth replacement of a maxillary lateral incisor or mandibular incisors where the restricted available bone is in mesiodistal width.[62,63]

The third alternative treatment for Division B bone is to change the Division B ridge into a Division A by grafting the edentulous ridge with autogenous or a combination of allograft and alloplast with or without guided bone regeneration techniques (Figure 10-20). If this graft is intended for implant placement, a healing period of at least 4 to 6 months is needed for maturation of the graft and before endosteal implants should be placed. An FP-1 restoration most often mandates option 3: augmentation. The emergence profile angle of the final crown, which does not compromise hygiene, requires

WWW.HIGHDENT.IR

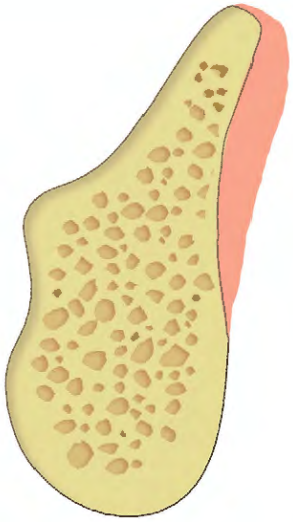

Figure 10-20 A Division B ridge anatomy may be modified to Division A by augmentation procedures.

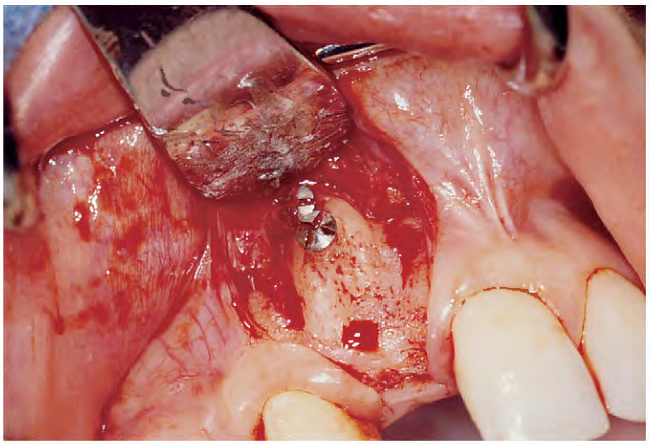

Figure 10-21 A reentry of an onlay ramus bone graft to a Divison B–w ridge. The ridge is now converted to Division A.

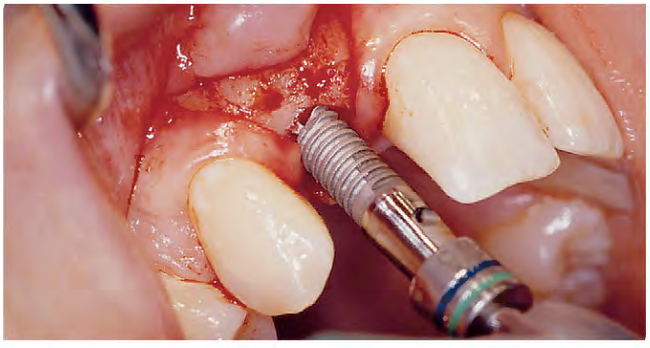

Figure 10-22 A root form implant may now be inserted without compromise to implant position or existing width of bone.

a Division A root form implant with the exception of maxillary lateral incisors or mandibular incisors. Stress factors may also dictate the surgical approach to Division B bone. In the presence of unfavorable stress factors, the number and width of abutments should be increased without increasing the CHS to provide a greater surface area of resistance to the magnified forces. To accomplish this goal, augmentation is indicated in Division B bone.

The success of alloplastic materials for augmentation correlates with the number of osseous walls in contact with the graft material.[64] Therefore a five-wall bony defect as a tooth socket forms bone more predictable with an alloplast than a one-wall defect as an onlay graft (see Chapter 37).

The distinction between B and B–w is especially important when augmentation is the method of choice. Bone augmentation is more predictable when the volume to augment is minimal and is for width, and least predictable when height is desired. For example, a width increase of 1 to 2 mm may be obtained with an alloplast and a guided bone regeneration, whereas more than 2 mm of width is more predictable with a autologous block graft. Some regions of the mouth are better suited than others for height augmentation (e.g., the floor of the maxillary sinus versus the posterior mandible).

An alternative for the augmentation approach for Division B bone is bone spreading. A narrow ostotomy may be made between the bony plates and bone spreaders are tapped into the edentulous site. The Division B ridge may be expanded to a Division A with this technique and allow a Division A implant or an alloplast to be inserted.[65]

The Division B–w ridge requires more than 2 mm of width increase, and therefore autologous bone is beneficial to predictably grow bone width. If the Division B–w ridge contour should be altered for improved prosthodontic relationships, an onlay particulate or block graft of autogenous bone is indicated. The autograft may be harvested from an intraoral region (such as the symphysis or ramus) and placed along the lateral aspect of the ridge that corresponds to ideal arch form (Figures 10-21 and 10-22). The implant placement should be delayed until after the augmentation process to permit ideal implant placement and to ensure complete bone formation before placing the implant. Division A root form implants may be placed 4 to 6 months after the autologous bone graft.[64-66]

The patient delaying treatment with a Division B bone situation should be notified of the future bone volume resorption. The augmentation of bone in height is much less predictable and requires more advanced techniques than the augmentation of width alone. For example, the patient may not be experiencing problems with a maxillary denture, but the Division B bone will resorb in height and decrease the stability and retention of the removable soft tissue–supported prosthesis. When

WWW.HIGHDENT.IR

treatment is delayed until patient problems begin, the overall result may be more difficult to achieve and more costly to the patient.

The final prosthesis type for Division B ridges is dependent on the surgical option selected. Grafted ridges will more often be used when a fixed prosthesis is desired, whereas ridges treated with osteoplasty before implant placement are likely to be supporting removable prostheses. The treatment option may be influenced by the region to be restored. For example, in the partially edentulous anterior maxilla, augmentation is most often selected because of esthetics. In the edentulous anterior mandible, osteoplasty is common. In the premolar region of the posterior mandible, Division B root form implants are often used because the bone density is adequate, available bone height is limited, and esthetics are not a major factor.

Division C (Compromised Bone)

The Division C ridge is deficient in one or more dimensions (width, length, height, or angulation) (Box 10-5) regardless of the position of the implant body into the edentulous site.

The resorption pattern occurs first in width and then in height. As a result, the Division B ridge continues to resorb in width, although height of bone is still present, until it becomes inadequate for any design of endosteal implant. This bone category is called Division C minus width (C–w) (Figure 10-23). The resorption process continues, and the available bone is then reduced in height (C–h). Moderate to advanced atrophy may be used to describe the clinical conditions of Division C. The posterior maxilla or mandible result with Division C–h more rapidly than the anterior regions because the maxillary sinus or mandibular canal limit vertical height sooner than the opposing cortical plates in the anterior regions. When the anterior mandible is C–h, the floor of the mouth is often level with the residual mandibular crest of the ridge. During swallowing, it may prolapse over the residual crest and implant sites, causing constant irritation of the permucosal implant posts and impairing proper design of the prosthetic superstructures.

The doctor must appreciate that the C–w bone will resorb to a C–h ridge as fast as the A resorbs to B and faster than B resorbs to C–w. In addition, without implant or bone graft intervention, the C–h available bone will eventually evolve into Division D (severe atrophy). Many completely edentulous patients are treated with implants in the mandible and conventional dentures in the maxilla, primarily because the mandibular C–h arch is more often the cause of patient complaint (Figure 10-24). However, the patient should be educated about the future maxillary bone loss that will render maxillary implant treatment almost impossible without advanced bone graft procedures before placement.

The Division C edentulous ridge does not offer as many elements for predictable endosteal implant survival or prosthodontic management compared with Divisions A or B. Anatomical landmarks to determine implant angulations or positions in relation to the incisal edge are usually not present; therefore greater surgical skill is required. The doctor and patient should realize that Division C ridge implant-supported prostheses are more complex and have slightly more complications in healing, prosthetic design, or long-term maintenance. On the other hand, the patients usually have greater need for increased prosthodontic support. In spite of the reduced bone volume, altered treatment plans that decrease stress can provide predictable, long-term treatment.

Box 10-5 Division C Bone

- Width (C–w bone): 0 to 2.5 mm
- Height (C–h bone) < 12 mm
- Angulation of occlusal load (C–a bone) > 30 degrees
- Crown height space (CHS) > 15 mm

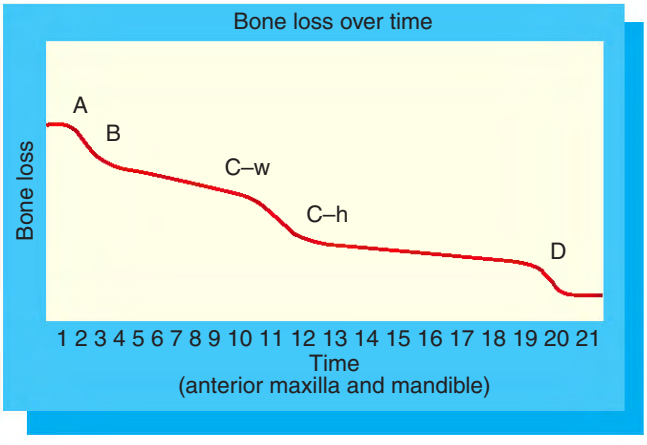

Figure 10-23 Bone resorbs from Division A to Division B and from Division C–w to C–h rapidly. Long plateaus are found for Division B and Division C–h.

Figure 10-24 Panoramic radiograph of a Division C–h anterior mandible with five root forms opposing a maxillary denture. The patient should be informed of the continued maxillary and posterior mandibular bone loss over time.

WWW.HIGHDENT.IR

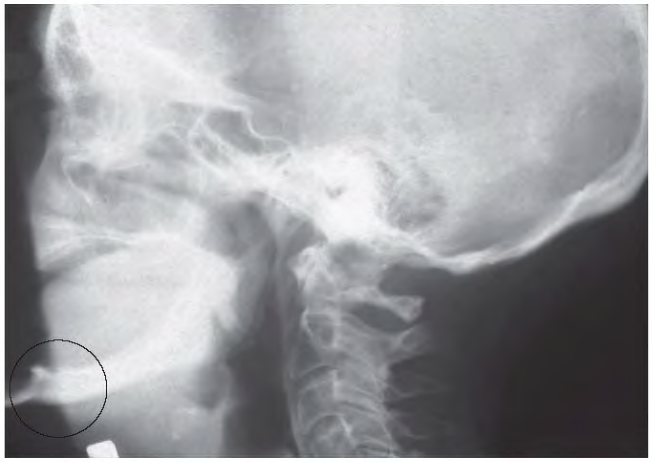

Figure 10-25 Lateral cephalogram of an anterior mandible with a 45-degree trajectory to the occlusal plane.

Figure 10-26 A C–a anterior mandible with four root form implants. The implants encroach on the floor of the mouth, complicate prosthesis fabrication, and impair speech and comfort during function.

There is one uncommon subcategory of Division C, namely C–a. In this category, available bone is adequate in height and width, but angulation is greater than 30 degrees regardless of implant placement (Figure 10-25). When present, this condition is most often found in the anterior mandible; other less-observed regions include the maxilla with severe facial undercut regions or the mandibular second molar with a severe lingual undercut. Root form implants placed in this bone category may be positioned within the floor of the mouth and compromise prosthetic reconstruction, speech, and comfort (Figure 10-26).

Implant treatment planning for the completely edentulous C–h arch is more complex than in Division A or B. There are seven implant treatment options for Division C bone (Box 10-6); all these options require greater skill than similar treatment modalities in Division A or B.

A C–w ridge may be treated by osteoplasty. An osteoplasty converts the ridge to C–h and, in the anterior mandibular region, most often to a width suitable for root form implants. The most common available bone division after osteoplasty of C–w is C–h available bone, not Division A, because the CHS is larger than 15 mm. On occasion, the C–w osteoplasty may convert the ridge to Division D, especially in the posterior mandible or maxilla. Care should be taken not to let this occur, because bone grafting procedures will be more challenging after the height has been reduced.

Another treatment option is to alter the Division C by grafting. After the ridge is augmented, it is treated with the options available in the acquired bone division. The patient who desires a fixed prosthesis often requires an autogenous graft prior to implant placement to acquire proper lip support and ideal crown height.

Augmentation of C–w is most often used when prosthetic guidelines require a fixed restoration or excess force factors require greater surface area implants and improved biomechanics for the prosthesis. The

Box 10-6 Division C Treatment Options

- Osteoplasty (C–w)
- Root form implants (C–h)
- Subperiosteal implant (C–h, C–a partial, or completely edentulous mandible)
- Augmentation procedures before implant insertion
- Disk design implants (posterior mandible, anterior maxilla)
- Ramus frame implant (C–h completely edentulous mandible)
- Transosteal implant (C–h anterior mandible)

C–w augmentation is more difficult than for Division B bone, because the need for bone volume is greater, yet the recipient bed is more deficient. Therefore block bone grafts are usually indicated.[66-68] Soft tissue complications, such as incision line opening, are also more common in C–w augmentations compared with Division B.

The C–h posterior maxilla is a common and unique edentulous condition. The residual ridge resorbs in width and height after tooth loss, similar to other regions. However, because of the initial ridge width dimension, a decrease of 60% in dimension still is adequate for 4-mm-diameter implants. In addition to the residual alveolar bone resorption, the maxillary sinus expands after tooth loss. As a result, the available bone height is decreased from both the crestal and apical regions. Sinus grafts, which elevate the maxillary sinus floor membrane and then graft the previous sinus floor region, were developed by Tatum in the mid-1970s.[65] This area is the most predictable intraoral region to augment in excess of 10 mm of vertical bone. Even alloplasts may be used for this technique. Therefore sinus grafting is often prescribed before placing endosteal implants in the C–h posterior maxilla (Figures 10-27 to 10-32).

Various implant approaches are used in the Division C–h available bone. Shorter endosteal implants are the

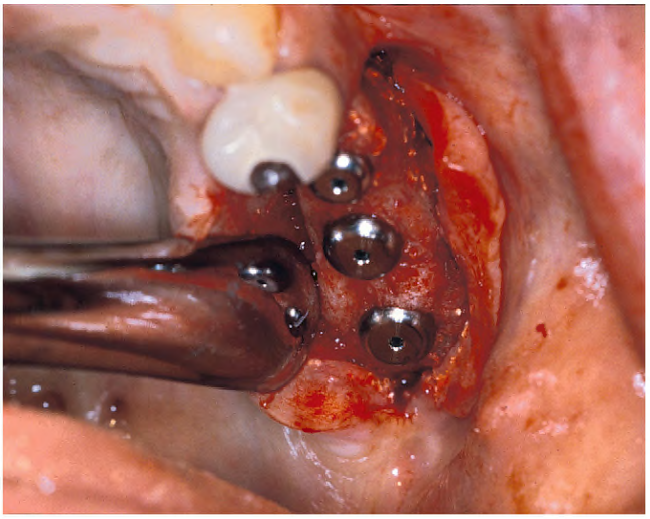

Figure 10-30 After the modification shown in Figure 10-29, three implants are inserted at reentry into the posterior maxilla. The second premolar implant is 4 mm in width; the molar sites are 5-mm-wide implants.

Figure 10-31 The three-unit fixed final restoration (FP-1) is cemented into position over the three implants.

most common options.[54,55] A C–h root form implant is usually 4 mm or greater in width at the crest module and 10 mm or less in height. Several studies indicate implant survival is decreased once an implant is 10 mm or less in height.[37,69,70] For example, a large multicenter study of 31 different sites and 6 different implant designs observed 13% failure with 10-mm implants, 18% failure with 8-mm implants, and 25% failure with 7-mm-long implants.[37] The implant failure does not occur after surgery, but rather after prosthetic delivery. This loading failure is a result of inadequate implant support combined with a magnification of force resulting from excessive CHS.

When endosteal root form implants are used in Division C–h bone with greater crown heights, additional implants should be placed to increase the overall

Figure 10-34 The five root forms and disc implant support a bar for a mandibular RP-4 overdenture opposing a conventional maxillary denture.

implant-bone surface area, and the prosthesis should load the implants in an axial direction. Because the CHS is greater than 15 mm, the design of a removable prosthesis should often reduce cantilever length and incorporate a stress relief mechanism. Reduced long-term predictability is usually expected if additional implants or less stressful prostheses are not used, because a greater moment force is transmitted to the implants.

Alternative designs to endosteal implants in the posterior mandibular edentulous Division C–h arch are subperiosteal and disk design implants (Figures 10-33 and 10-34).[71-73] Subperiosteal implants are more predictable in the mandibular arch than in the maxilla. The limitations of anatomy for root form implants may be bone angulation, a square arch form, or inadequate bone height. When the anterior bone angulation is unfavorable, root form implants may be positioned too far lingually for prosthodontic support, speech, or hygiene. The superstructure and abutment posts for the subperiosteal implant are designed and cast before implant placement. The permucosal posts may be designed with greater latitude than endosteal implants. When anterior root forms are placed in an edentulous mandible with a square arch form, the superstructure may not be cantilevered distally because of the poor anteroposterior distance. As a result, a fixed restoration or RP-4 overdenture prosthesis is contraindicated with anterior root forms in a square arch form. A subperiosteal implant may provide anterior and posterior bone support, and the square arch form does not contraindicate an RP-4 prosthesis. Autogenous grafts or nerve repositioning may be necessary to place endosteal implants in the posterior Division C–h mandible. The increase in treatment time, surgical risks and postoperative complications (such as paresthesia) are to be thoroughly discussed with the patient. Circumferential or unilateral subperiosteal implants permit the placement of posterior prosthodontic units without risks of paresthesia from nerve repositioning or lengthened treatment time associated with autogenous bone grafts and endosteal implants.[73]

Another alternative for the posterior mandible or premaxilla with Division C–h bone is a disk design implant that engages the lateral aspect of the cortical bone and may be used in available bone height of 3 mm or more. As a general rule, these implants are used in addition to other root form implants. Their inclusion in the treatment plan for C–h posterior sections of edentulous mandibles eliminate cantilevers in full-arch restorations.[71,74]

The prosthetic options for Division C ridges more often consist of removable prosthesis in the completely edentulous maxillary arch. A maxillary overdenture in a Division C ridge supports the upper lip without hygiene compromise. In the Division C mandible, the greater CHS often mandate an overdenture design with some soft tissue support (RP-5). A fixed restoration in the Division C mandible often requires both anterior and posterior implant support. The fixed prosthesis in Division C bone with greater than 15-mm CHS is most often a hybrid device, with denture teeth attached to a precious metal substructure with acrylic resin. In this way, the complications and costs of a porcelain-metal fixed restoration may be reduced.

WWW.HIGHDENT.IR

In general, Division C–h presents less favorable biomechanical factors to the implant support. Therefore, additional implants or teeth, cross-arch stabilization, soft tissue support, or an opposing removable prosthesis often need to be considered in the prosthetic design to improve the long-term prognosis. Treating the Division C ridge requires greater experience, caution, and training than does the previous two bone divisions; however, excellent results may be achieved.

The completely edentulous patient who does not have implant treatment should be well-educated that the bone resorption process will continue, with significant increased risks for the convention removable restoration. Waiting to treat the patient until irreparable problems develop is a poor treatment alternative that results in the need for more advanced procedures such as iliac crest grafts and significant risks of associated complications.

An alternative method of treatment for the maxilla is to fabricate a traditional denture in Division C arches after changing the division with nonresorbable hydroxyapatite. This treatment option is often indicated for a conventional maxillary denture on a C–w anterior maxilla. The patient and doctor should realize the augmented ridge is only a delay tactic for bone resorption, because it does not stimulate or maintain bone mass. Its primary intent is to provide additional retention and stability and delay the problems of the resorption leading to a Division C–h ridge. Bone augmentation for Division C–h bone to support complete dentures is rarely beneficial. Even more rarely should nonresorbable augmentation materials be used for additional support for a mandibular denture or for endosteal implant support.

In conclusion, as in all other bone divisions, the final prosthesis determines the treatment option. For mandibular RP-4 restorations, five root forms in the anterior mandible may be used (if the other dental criteria permit). However, the greater CHS or a square arch form may mandate an RP-5 prosthesis with anterior root form implants. The combination of anterior root forms and posterior subperiosteal implants (or disk implants) is a common treatment option for RP-4 or fixed prosthesis in the mandibular arch. Augmentation is often required for a fixed prosthesis in either of the Division C complete edentulous arches if stress factors are high and cannot be reduced.

Division D (Deficient Bone)

Long-term bone resorption may result in the complete loss of the residual ridge, accompanied by basal bone atrophy (Figure 10-35). Severe atrophy describes the clinical condition of the Division D ridge. At one time, it was believed only the alveolar process would resorb after tooth loss and the basal bone would remain. However, bone loss may continue beyond the previous roots of teeth and even include the bone over the inferior mandibular nerve or the nasal spine of the maxilla. Basal bone loss eventually results in a completely flat maxilla. In the mandible, the superior genial tubercles become the most superior aspect of the ridge. The mentalis muscle has lost much of its attachment, even though the superior portion of the muscle attaches near the crest of the resorbed ridge. The buccinator muscle may approach the mylohyoid muscle and form an aponeurosis above the body of the mandible. The mandibular arch also presents with mental foraminae and portions of the mandibular canal dehiscent. Therefore it is not infrequent that these patients complain of paresthesia of the lower lip, especially during mastication. The CHS is greater than 20 mm, which is a significant force multiplier and can rarely be reduced enough to render long-term success (Figure 10-36; Box 10-7).

The prosthetic result for Division D without augmentation is the poorest treatment outcome of all the divisions of bone. Fixed restorations are nearly always contraindicated, because the CHS is so significant.

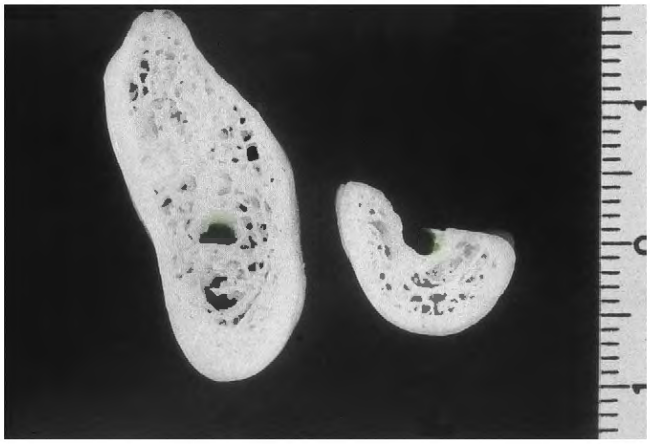

Figure 10-35 The left posterior mandible is Division A, with abundant bone in height and width *(left)*. The residual ridge on the right is a Division D with a dehiscent mandibular canal.

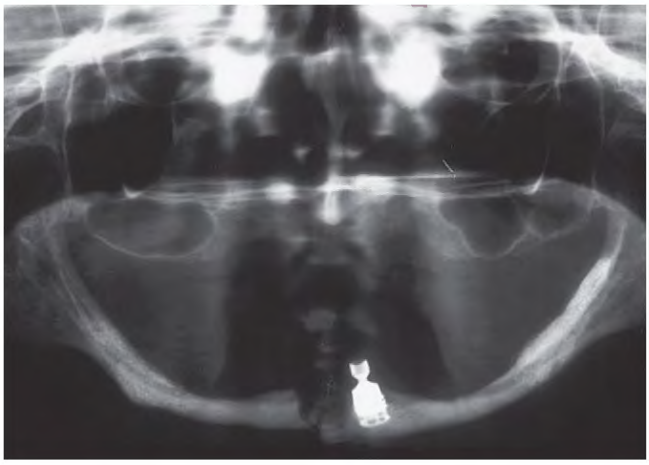

Figure 10-37 Anterior root form implants were placed in a Division D mandible. As a result of the failure of one implant, the mandible has fractured and has a continuity defect.

Completely implant-supported overdentures are indicated whenever possible to decrease the soft tissue and nerve complications, but require anterior and posterior implant support, which almost always require bone augmentation before implant placement. Bone augmentation for Division D is difficult to improve the CHS enough to warrant a fixed restoration. An RP-5 restoration is not suggested, because bone loss will continue in the soft tissue–supported region of the overdenture.

The completely edentulous Division D patient is the most difficult to treat in implant dentistry. Benefits must be carefully weighed against the risks. Although the practitioner and patient often regard this condition as the most desperate, these patients do not usually have oral antral fistulae or deviated facial features before treatment. If implant failure occurs, the patient may become a dental cripple—unable to wear any prosthesis (Figure 10-37).

Autogenous iliac crest bone grafts to improve the Division D are strongly recommended before any implant treatment is attempted.[74] After autogenous grafts are in place and allowed to heal for 5 or more months, the bone division is usually Division C–h or A and endosteal implants may be inserted (Figures 10-38 to 10-46).

The autogenous bone grafts are not intended for improved denture support. If soft tissue–borne prostheses are fabricated on autogenous grafts, 90% of the grafted bone resorbs within 5 years as a result of accelerated

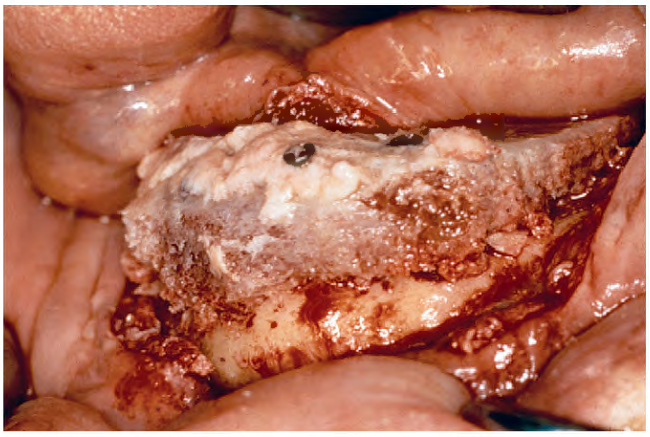

Figure 10-38 An autologous iliac crest bone graft in situ. The block graft is fixated with screws between the foramina and projects over the posterior canals.

Figure 10-39 Lateral cephalogram of the block graft in Figure 10-38. The residual anterior mandible was angled more than 30 degrees lingually, so the bone graft is contoured facially toward the incisal edge of the final restoration.

resorption.[75] Additional augmentation to compensate for this resorption is not indicated. Repeated relines, highly mobile tissue, sore spots, and patient frustration are all consequences. On the other hand, autogenous bone grafts are maintained long term in conjunction with implant placement. The completely flat Division D maxilla should not be augmented with only hydroxyapatite to improve denture support. Inadequate ridge form exists to guide the placement of the material. As a result, migration of the graft at the time of surgery or in the future after soft tissue loading is a frequent sequel.

The partially or completely edentulous patient with a posterior Division D maxilla and healthy anterior teeth or implants may undergo sinus graft procedures

Figure 10-45 A fixed maxillary and mandibular implant prosthesis are fabricated after healing.

with a combination of local autogenous bone, demineralized freeze-dried bone, and calcium phosphate bone substitutes.[65] The CHS may be insufficient for onlay grafts in the posterior maxilla, despite a lack of available bone height, because the sinus expands faster than the crest of the ridge resorbs. Endosteal implants of adequate height can rarely be positioned without a sinus graft. After 6 to 8 months after sinus graft, the Division D posterior maxilla is restored to Division A or C–h, and root form implants may be inserted for posterior prosthodontic support.

Past beliefs regarding subperiosteal implants indicated their use on atrophied bone over any other type of implant support, and the less bone available, the more ideal the indication for a subperiosteal implant. On the contrary, adequate bone should also be present

WWW.HIGHDENT.IR

Figure 10-46 Panoramic radiograph of the final restoration and implants.

for this implant modality. The maxilla rarely provides sufficient support in the Division D ridge for implants of any design. If adequate mandibular anterior bone is present with Division D posterior bone, root form implants, tripodal subperiosteal implants, mandibular staple implants, or ramus frame implants may be used cautiously in the anterior edentulous mandible. However, idiopathic fracture during surgery or from implant failure or removal is a more likely complication than in other bone division. Therefore practitioners treating Division D mandibles should be able to manage future complications, which may be extensive.

Endosteal root form implants without autogenous grafts may be used on rare occasions in the anterior Division D mandible when the remaining bone is dense and the opposing arch is edentulous. Care must be taken during placement, because mandibular fracture at insertion or during postoperative healing is a possible complication.[76,77] Under these conditions, the crown height space is very great and the number of implants often four or fewer. Implant failure after loading is a greater risk. Implant failure results with circumferential bone loss, which may be associated with mandibular fracture through the implant site. An RP-5 removable restoration is usually indicated for Division D with only anterior implants. However, the RP-5 restoration allows continued bone resorption and atrophy to continue in the posterior regions. Therefore the prudent therapy is to educate the patient as to the risks of the situation and offer an autologous bone graft and implants to support an RP-4 restoration. The choice to render treatment is the doctor's, not the patient's. The implant support should not be compromised when implant failure may result in significantly greater risks.

The Division D arch requires greater doctor training and results in more frequent complications related to grafting, early implant failure, and soft tissue management; therefore treatment options include a more guarded prognosis. It should be the goal of every dentist to educate and treat the patient before a Division D bone condition develops. The profession treats periodontal diseases before pain in the region occurs, and carious lesions are removed before abscess formation. The profession monitors bone loss around teeth in fractions of a millimeter and offers continued care to reduce the risks of future tooth and bone loss. Likewise, the prudent practitioner monitors bone loss in edentulous sites and offers education and treatment before deleterious effects.

SUMMARY

In implant dentistry, the prosthesis is designed at the onset of treatment to satisfy the patient's needs and desires and obtain optimal results. This may range from a completely fixed prosthesis to one with primarily soft tissue support. After the final prosthesis type has been established, the key implant positions, patient force factors, bone density in the implant sites, and implant number, size, and design are determined. The primary criterion for proper implant support is the amount of available bone. Four divisions of available bone, based on the width, height, length, angulation, and crown height space in the edentulous site, have been presented. Consistent implant treatment plan procedures elaborated for each category of bone may be followed.

The Division A edentulous ridge offers abundant bone in all dimensions. Division A root form implants are optimally used and most often as independent support for the prosthesis. Division B bone may provide adequate width for narrower, small-diameter root from endosteal implants. The decreased width and surface area usually require additional implants to be included in the final prosthesis design. Division B may be changed in condition to a Division A by augmentation or osteoplasty. The treatment options may be selected in light of the area to be treated. For example, in the anterior maxilla, augmentation is most often selected because of esthetics. In the anterior mandible, osteoplasty is common because of the available bone height and low esthetic concerns. In the posterior mandible, multiple Division B implants may be used, because the bone density is good, the available bone height is limited, and esthetics are not a primary factor. When stress factors are greater, bone augmentation precedes Division A root form implants, regardless of the anatomical location.

The Division C edentulous ridge exhibits moderate resorption and presents more limiting factors for predictable endosteal implants. The decision to restore with endosteal implants or to upgrade the bone division by augmentation before implant placement is influenced by the prosthesis, patient force factors, and patient's desires.

The Division D edentulous ridge corresponds to basal bone loss and severe atrophy, resulting in dehiscent mandibular canals or a completely flat maxilla. The patient often requires augmentation with

WWW.HIGHDENT.IR

autogenous bone before implant and prosthodontic reconstruction.

If the existing conditions do not qualify for a predictable end result, the patient's mind or mouth must be modified. For example, the expectations of the patient must be reduced so the prosthesis may be changed from FP-1 to RP-4, or the bone must be augmented to improve the height and width and change the division so that long-term implant support and prosthetic design will be compatible.

Chapter 11

Scientific Rationale for Dental Implant Design

Carl E. Misch, J. Todd Strong, Martha Warren Bidez

The treatment planning sequence for implant dentistry begins with the design of the final restoration.[1] After the position and number of teeth replaced and type of prosthesis are determined,[2] the patient force factors are evaluated.[3] The greater the force factors, the greater the implant support required. The bone density in the region of the implant abutments is then considered, with poorer bone densities requiring a greater amount of implant support.[4] The key implant positions and additional implant number are then determined, followed by the ideal implant size.[5] The available bone in the edentulous sites is then evaluated.[6] When the bone available is present for the size, number, and position of the implants for the planned prosthesis, the treatment proceeds with little compromise. When the bone is not present, a modification of the treatment is necessary. These modifications include: (1) bone augmentation to fulfill the ideal treatment plan; (2) consideration of optional implant locations, usually with additional implants, or an increase in implant size; or (3) optimization of implant design. A favorable implant design may compensate for risk for occlusal loads in excess of normal, poor bone densities, less than ideal implant position or number, or less than an ideal implant size.[7]

There are many different implant body designs available in implant dentistry. They may be categorized as a cylinder type, screw type, press fit, or a combination of features. Dental implants are often designed to answer a primary focus or belief that implant failure may stem from (1) implant surgery, (2) bacterial plaque complications, or (3) loading conditions. For example, in the past, implant body design was driven by the surgical ease of placement. A surgically driven implant design will tend to have a tapered, short implant body or a press-fit insertion. These features permit the implant site and implant to be surgically placed most easily.

A cylinder or press-fit implant has a friction-fit insertion and may have less risk of pressure necrosis from too tight an insertion pressure, has no need to bone tap (even in dense bone), and may have the cover screw already in place because no rotational force is required to insert the implant. As a result, cylinder or press-fit implants are the easiest to insert, were very popular in the 1980s, and were reported to have high initial success rates.[8,9] However, after 5 years of loading, reports of the cylinder implant include loss of crestal bone and implant failure more often observed (Figure 11-1).[10] Most likely, this was related to a fatigue overload condition and harmful shear loads on the bone causing large bone turnover rates, and ultimately less bone-implant contact percent and higher risk of overload failure.

The most predictable aspect of implant dentistry appears to be the surgical success. After many years of clinical studies and evaluations, the surgical success rate from implant insertion to uncovery of the implant is usually higher than 98%, regardless of the implant design or size.[11-14] As such, designing an implant for surgical ease does not appear to be the most important aspect of the overall implant-prosthetic–related process to reduce the incidence of complications.

Another focus of several implant designs is to reduce the plaque-related complications of treatment. With this concept in mind, one consistent implant body design features smooth metal surfaces at the crestal portion of the implant. A smooth crest module (the area between the implant body and prosthetic platform) of the implant is easier to clean related to oral hygiene methods and collects less plaque than rougher surfaces.[15] Therefore the rationale is that if bone loss occurs at the marginal regions of the implant, the smooth implant surface will harbor less plaque and be easier to clean.

The problem with this philosophy is the smooth crest module is initially placed below the crest of the bone and is a design that encourages marginal bone loss from the extension of a biological width after implant uncovery and from shear forces after occlusal loading.[16,17] As a result, this plaque-reducing design feature increases the peri-implant sulcus depth. Paradoxically, the feature designed to decrease bacteria complications actually increases the risks. Therefore an implant body designed for ease of surgery or to reduce peri-implantitis complications most often does not address the most common complications observed in implant prostheses.

WWW.HIGHDENT.IR

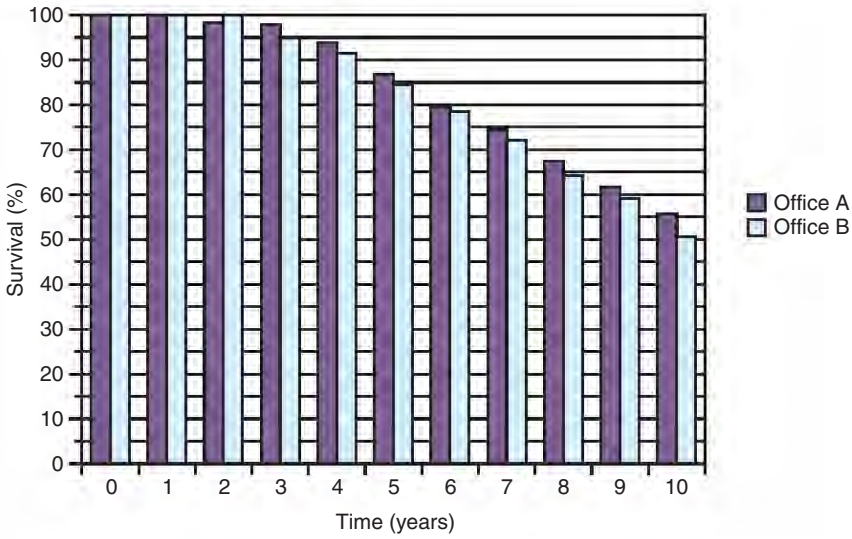

Figure 11-1 The hydroxylapatite-coated cylinder implant has almost 100% success in two offices for the first 3 years. After 5 years, 20% failure rates are observed, and at 10 years almost 50% failure rates are reported.

Table 11-1 Success Rates Using 5 mm as Borderline Compared to Clinical Survival

IMPLANT TYPE	NUMBER OF IMPLANTS PLACED	SUCCESS	CLINICAL SUCCESS*
Hollow screw	112	83 (74%)	101 (90.2%†)
Hollow cylinder	49	31 (63%)	37 (76%)
Angulated hollow cylinder‡	18	11 (61%)	16 (89%)
All implants	179	125 (69.8%)	154 (86%)

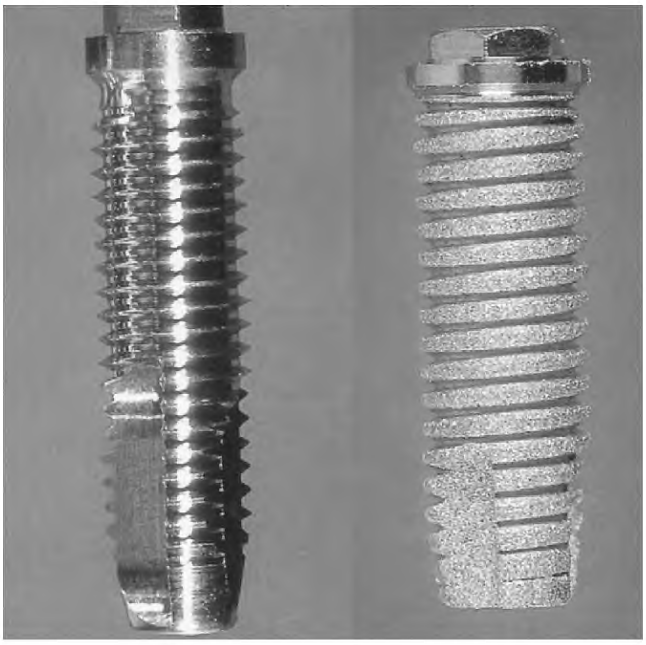
Data from Karoussis IK, Bragger U, Salvi GE et al: Effect of implant design on survival and success rates of titanium oral implants: a 10-year prospective cohort study of the ITI Dental Implant System, *Clin Oral Implants Res* 15:8-17, 2004.
* Clinical success meaning that the implant fulfilled the clinical criteria.
† Represents statistically significant difference compared with HC (Fisher's exact test, $P < 0.025$).
‡ ITI dental implant system.

Most implant body complications in the literature are related to early implant failure after loading, marginal bone loss before loading but after exposure of the implant, and marginal bone loss after the loading of the implant-bone interface.[18] Implant failures are most often observed as early loading failures in softer bone types or shorter implant lengths. A review of the literature by Goodacre et al. between 1981 and 2003 found that, after the implant was loaded, failure rates increased to an average of 16% in soft bone.[18] Misch reviewed the literature between 1981 and 2004 and found an overall 18% failure rate in implants shorter than 10 mm.[19] For example, Weng et al. reported in a multicenter study of 6 years, implant initial healing survival higher than 98%, but 7-mm implants failed 25% of the time within 18 months of loading and short implants in the posterior maxilla had the highest early loading failure of any intraoral region.[20] Therefore implant body designs should attempt to primarily address the primary causes of complications (i.e., the factors that address the loading conditions of the implant after the implants are placed in function).

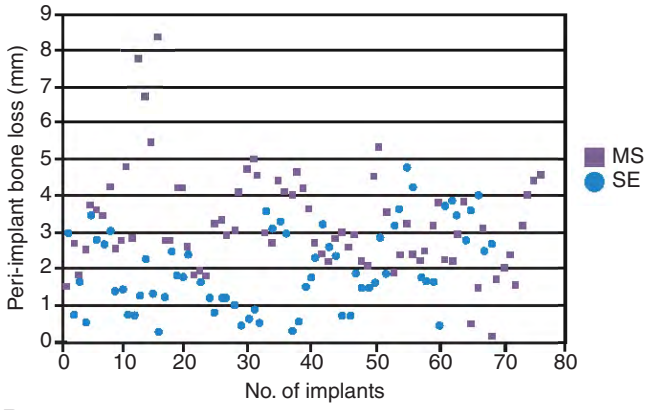
Different implant survival rates and different marginal bone loss after loading have been reported for different implant body designs. A report by Zechner et al. evaluated the peri-implant bone over a 3- to 7-year period around functionally loaded, screw-type implants with a machined surfaced V-thread and sandblasted, acid-etched, square-thread design.[21] Both these implants had a similar crest module and external hex connection. The range of bone loss in the study was 0.1 to 8.5 mm for the machined V-thread and 0.2 to 4.8 mm for the rough surface, square-threaded implant. There were 22 V-threaded implants that lost more than 4 mm of bone compared with three square-threaded implants. Bone loss of less than 1 mm was reported for 16 rough surface implants compared with only two machined surface implants (Figure 11-2). The range of bone loss and the incidence of bone loss both indicate implant design or surface condition made a difference in this report.

A prospective report by Karoussis et al. also indicated that different implant designs yield different incidences of crestal bone loss.[22] Three different implant designs from the same manufacturer (Straumann ITI Dental Implant Systems, Basel, Switzerland) were evaluated with a prospective study over 10 years (Table 11-1). The survival rate of each design over this time was 95.4% versus 85.7% versus 91.2%. The implant with the

WWW.HIGHDENT.IR



A



B

Figure 11-2 **A,** Two different implant designs were evaluated over a 3- to 7-year period in the anterior mandible. The crest module and microgap position were similar. The implant on the left was a machined, V-shaped thread. The implant on the right was a roughened, square-threaded design. **B,** A 22–V-thread design implant (MS) lost more than 4 mm of bone over a 3- to 7-year period. In the square-threaded implant (SE) design group, 16 implants lost less than 1 mm of bone during this time frame.

highest survival rate (hollow screw design) lost more than 5 mm of bone in 26% of the implants, whereas the two other designs reported 37% and 39% incidence of greater than 5-mm bone loss. More than 6 mm of marginal bone loss occurred in 22% of implants with the first design and in 35% and 33% for the other two designs. Therefore implant survival and marginal bone loss was related to implant design.

In a 3-year clinical study, a different amount of marginal bone loss was reported between the Nobel Biocare Brånemark implant and the Straumann ITI implant, with ITI having a greater range of bone loss after loading (Figure 11-3).[23] The microgap and machined surface of

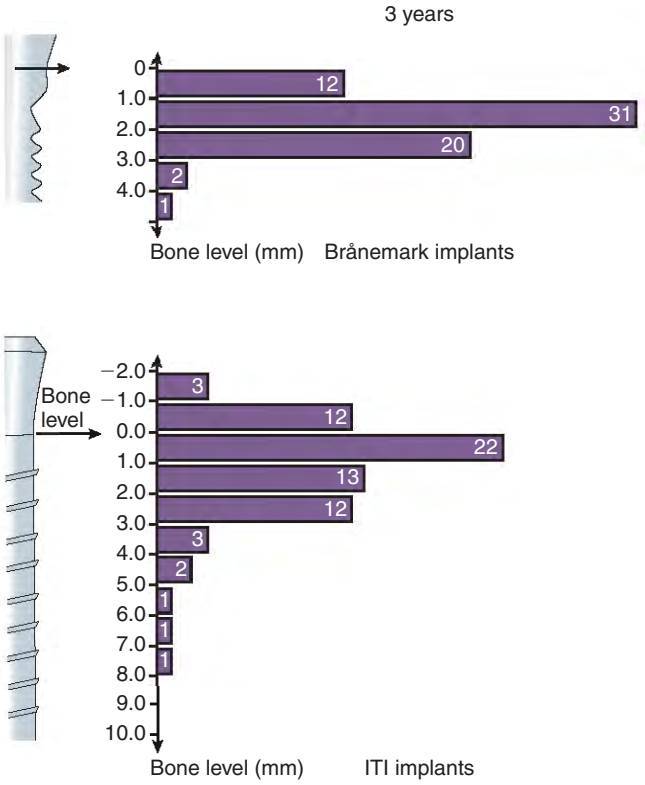


Figure 11-3 Brånemark implants and ITI implants were compared in the partially edentulous maxilla. The ITI implant *(bottom)* has a wider range of marginal bone loss.

the Nobel implant caused less bone loss than the rough cylinder shape at the crest after loading with ITI. In other words, several clinical reports found different implant designs influence not only the implant survival, but also the amount of early crestal bone loss after loading. This chapter will build on and apply basic biomechanics and demonstrate how these principles are related to implant design in order to decrease the more common complications observed in implant dentistry.

IMPLANT DESIGN RELATED TO OCCLUSAL FORCES

Dental implants function to transfer loads to surrounding biological tissues. Thus the primary functional design objective is to manage (dissipate and distribute) biomechanical loads to optimize the implant-supported prosthesis function. Biomechanical load management is dependent on two factors: the character of the applied force and the functional surface area over which the load is dissipated. There are more than 90 dental implant body designs available. A biomechanical rationale of dental implant design may evaluate these designs as to their efficacy to manage biomechanical loads. Fundamental scientific principles related to force and surface area may then be combined with engineering principles to pursue the desired clinical goals.

WWW.HIGHDENT.IR

Force Type and Influence on Implant Body Design

Three types of forces may be imposed on dental implants within the oral environment: compression, tension, and shear. Bone is strongest when loaded in compression, 30% weaker when subjected to tensile forces, and 65% weaker when loaded in shear.[24] An attempt should be made to limit shear forces on bone, because it is least resistant to fracture under these loading conditions. This is most important in regions of decreased bone density, because the strength of bone is also directly related to its density.[25]

An implant has a macroscopic body design and a microscopic component to implant design. Both design features (although independent) are relevant for the clinical behavior. The microscopic features are most important during initial implant healing and the initial loading period. The macroscopic implant body design is most important during early loading and mature loading periods. This chapter will focus on the macroscopic aspect of implant body design.

Smooth-sided, cylindrical implants provide ease in surgical placement; however, the bone-implant interface is subject to significantly larger shear conditions. In contrast, a smooth-sided, cylindrical, tapered implant provides for a component of compressive load to be delivered to the bone-implant interface, depending on the degree of taper.[26] The greater the taper, the greater the component of compressive load delivered to the interface. Unfortunately, the amount of taper cannot be greater than 30 degrees or the implant body length is significantly reduced, along with the immediate fixation required for the initial healing. As a negative feature, the greater the taper of a smooth-sided implant, the less the overall surface area of the implant body under load and the less initial stability provided by that implant at an immediate extraction and implant insertion.

Unlike a cylinder implant, a tapered threaded implant serves no functional surface area advantage, because the threads of a screw bear the compressive loads to the bone. The tapered, threaded implant provides some surgical advantage during initial insertion, because it inserts down within the osteotomy halfway before engaging bone. However, the lesser surface area of a tapered implant increases the amount of stress at the crestal portion, as demonstrated in three-dimensional finite element studies.[27] In addition, in a tapered threaded implant, threads at the apical half are often less deep, because the outer diameter continues to decrease. This limits the initial fixation of the implant.

A smooth-cylinder implant body results in essentially a shear load at the implant-bone interface. Bone grows to a cylinder-shape implant during initial healing. However, this type of body geometry must rely on a microscopic retention system such as roughening or coating (acid etch, mechanical etch, or coatings such as titanium plasma spray or hydroxylapatite [HA]) for the initial loading period.[28] The integrity of the implant interface during initial loading is therefore dependent on the shear strength of the implant surface-to-bone bond. The quality of the coating (e.g., HA) is absolutely paramount in such applications.[29] If the HA is altered from friction during implant surgical insertion, infection, mechanically removed during treatment of peri-implantitis or from bone remodeling over years of function, the remaining smooth-sided cylinder is severely compromised for healthy load transfer to the surrounding tissues (Figure 11-4).[30]

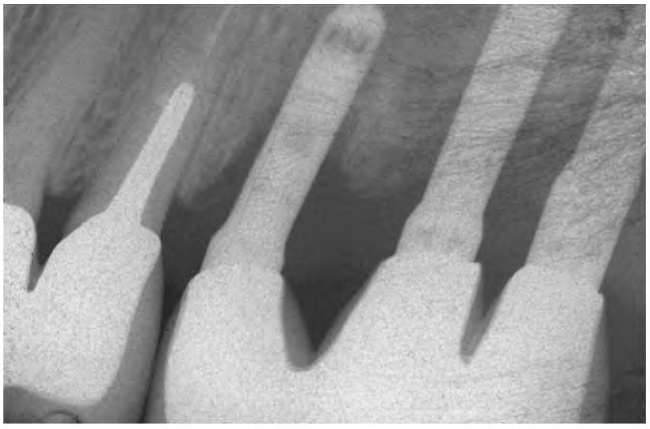

Figure 11-4 The microdesign of a cylinder implant places shear loads to the bone interface. As such, the surface conditions must be rough to compensate for the implant body design. In situations that compromise the integrity of the surface coating, the load bearing capabilities of this design are greatly compromised.

The surface conditions of an implant may enhance bone-implant contact (BIC) and adhesion qualities to the bone-implant interface at initial healing. However, the surface coatings on cylinders do not permit compressive forces to be effectively transmitted to the bone cells, because the microfeatures of the coating are too small for the cells to be loaded in compression.[31] Therefore the surface area–bone contact percentage is greater during initial healing, but the functional surface area over which loads are effectively dissipated during long-term loading to the surrounding bone is most dependent on the macroscopic design of the implant body. For example, Watzek et al. evaluated screw shape and cylinder implants with histologic and histomorphometric analysis after 18 months of occlusal loading in baboons.[32] There was a significant difference in BIC, with screw-type implants having higher values in both the maxilla and mandible (Figure 11-5).[32] In addition, the trabecular bone pattern was irregular around the cylinder implants, but the bone was organized perpendicular to the threads around the screw implants (Figure 11-6).[32] Therefore the bone trabeculae pattern and the higher BIC resulted in a superior support system for threaded implants.

An implant retrieval clinical report by Bolind et al. evaluated cylinder implants compared with threaded

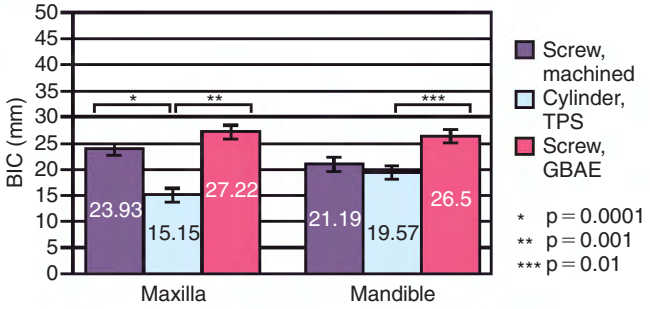

Figure 11-5 Comparison of a cylinder and two screw-type implant designs used in baboons. The bone-implant contact (BIC) is greater in the maxilla and mandible for screw-type designs.

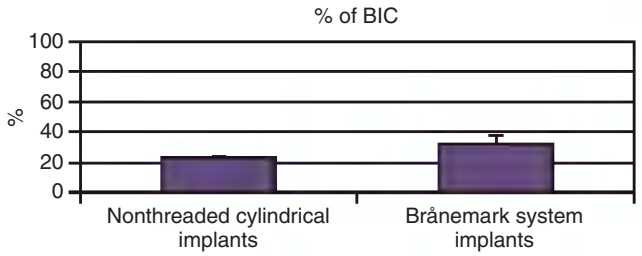

Figure 11-7 Evaluation of human retrievals of 85 cylinder implants and 85 threaded (machined) implants. The bone-implant contact (BIC) is greater in threaded implants, and greater marginal bone loss is observed in the cylinder implant group.

implants from functioning prostheses.[33] Consecutively retrieved oral implants from 117 patients, with 85 cylinder implants and 85 threaded implant designs, were evaluated. Greater BIC was found around threaded implants, and greater marginal bone loss was observed around cylinder implants (Figure 11-7).[33] It should be noted the cylinder implants in this report had a roughened surface condition, whereas the threaded implants had a machined surface. Numerous reports demonstrate roughened surfaces have higher BIC compared with machined surfaces. In this human retrieval report, therefore, implant body design was more important than the surface condition of the implant for crestal bone loss and overall BIC after loading. In Figure 11-8, an HA-coated cylinder is splinted to two HA-coated threaded implants. More crestal bone loss is observed on the cylinder implants.

Any smooth shear surface on an implant body increases the risk of bone loss because of inadequate load transfer.[34] Figure 11-9 depicts one such example characterized by extensive crestal resorption adjacent to a long, smooth shear surface on the two implant bodies (Core-Vent/Paragon implant). The crestal bone loss contributed to an increase in crown height (which further magnifies stress from bending moments) and the fracture of two abutments. The implant body next to these cylinder-type implants was loaded in the same prosthesis, yet the plateau implant body design (which is a compressive load design) maintained bone height over the years of loading.

Force Direction and Influence on Implant Body Design

Bone is weaker when loaded under an angled force.[35] The greater the angle of load, the greater the stresses to the implant-bone interface. The noxious effect of angled loads to bone is further exacerbated because of the anisotropy of bone.[36] Anisotropy refers to how the character of bone's mechanical properties, including

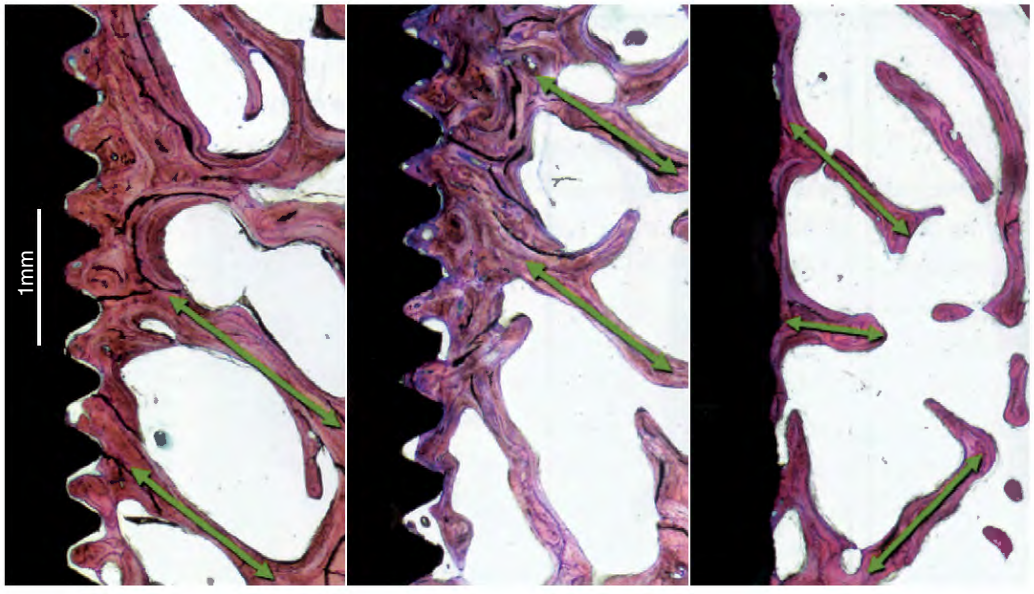

Figure 11-6 Trabecular bone has a more organized form to resist occlusal stresses for screw-type implants compared with cylinder implants. *(From Watzek G, Zechner W, Ulm C et al: Histologic and histomorphometric analysis of three types of dental implants following 18 months of occlusal loading: a preliminary study in baboons,* Clin Oral Implants Res *16:408-416, 2005.)*

WWW.HIGHDENT.IR

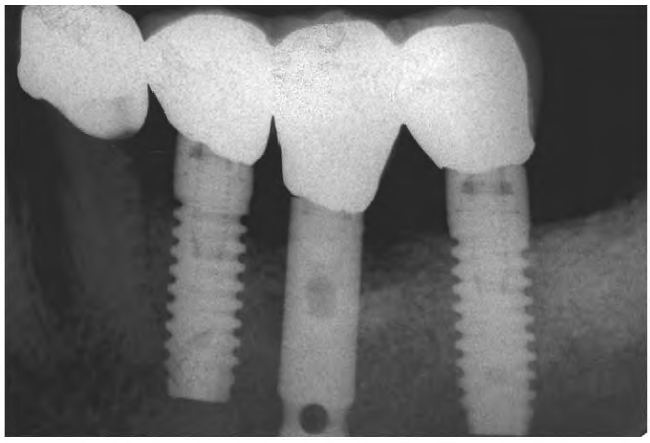

Figure 11-8 A hydroxylapatite (HA)-coated cylinder implant is splinted to two HA-coated screw type implants. Greater crestal bone loss is observed around the cylinder implant.

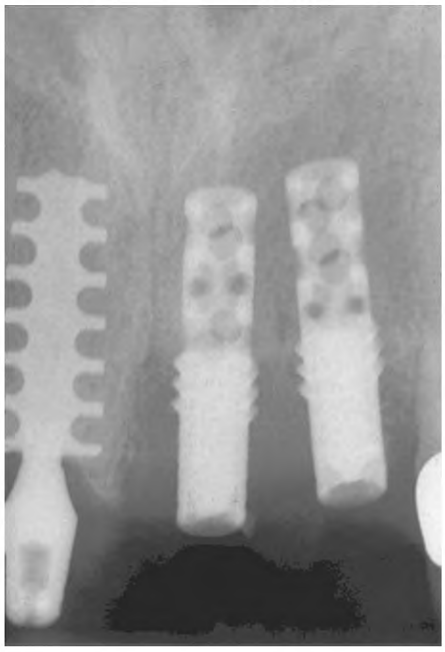

Figure 11-9 Two cylinder-neck design implants were splinted to a plateau implant design. After several years of loading, the crestal bone loss on the cylinder-neck design led to implant abutment fracture.

ultimate strength, depends on the direction in which the bone is loaded. A 30-degree angled load will increase the overall stress by 50% compared with a long axis load, especially around the crestal portion of the implant.[37] Therefore, under ideal conditions, the implant body long axis should be perpendicular to the curve of Wilson and curve of Spee to apply a long axis load to the implant during occlusal load in centric occlusion (where the occlusal forces are usually the greatest). As the angle of load to the implant-bone interface increases, the stresses around the implant increase. As a result, virtually all implants are designed for placement perpendicular to the occlusal plane. Additionally, axial alignment places less shear stress on the overall implant system (i.e., porcelain, cement, abutment and abutment screw components, crestal bone, implant body, and implant-bone interface) and decreases the risk of complications, as screw loosening and fatigue fractures.

Implant body designs with threaded features have the ability to convert occlusal loads into more favorable compressive loads at the bone interface; therefore thread shape is particularly important when considering long-term load transfer to the surrounding bone interface (Figure 11-10). Under axial loads to an implant-bone interface, a buttress or square-shaped thread (typical of BioHorizons, BioLok, and Ankylosis) would transmit compressive forces to the bone. Under axial loads to a dental implant, a V-thread face angle (typical of implants from Zimmer, LifeCore, 3i, and some Nobel Biocare designs) is comparable to the reverse buttress thread (typical of some Noble BioCare designs) because of the similarity in the inferior portion of the thread face angle.

A reduction in shear load and subsequent shear stresses at the thread-bone interface reduces the risk of bone failure and possible reduced bone-implant contact percent of the implant if all the other factors are equal, which is particularly important in compromised

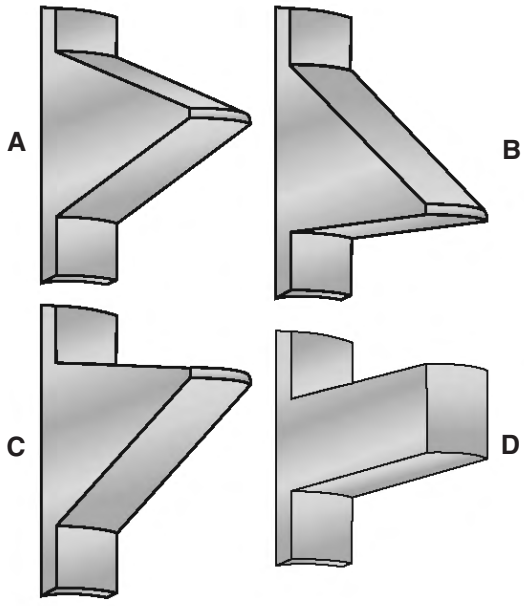

Figure 11-10 The four basic thread shapes for implant design include: **(A)** V-thread, **(B)** buttress thread, **(C)** reverse buttress thread, and **(D)** square thread.

bone densities or shorter implant lengths.[38] The thread shape (macroscopic design) is independent from the surface coating (microscopic design). For example, any threaded implant surface may also be textured with HA coating or other roughened surface conditions to enhance osteointegration and increase the bone-implant contact percent during initial healing.

WWW.HIGHDENT.IR

IMPLANT BODY: FUNCTIONAL VERSUS THEORETICAL SURFACE AREA

Forces applied to the implant may be evaluated in magnitude, duration, type, and direction. The surface area over which the forces are applied is also relevant and is inversely proportional to the stress observed within the implant system *(stress = force ÷ surface area)*. It can be clearly seen from this basic engineering equation that, to reduce stress, the force must decrease or the surface area must increase.

For a given bone volume, implant surface area should be optimized for functional loads. Thus an important distinction is made between theoretical total surface area and functional surface area of an implant. Because bone is 65% weaker to shear forces and 35% weaker to tensile forces, functional surface area is defined as the area that actively serves to dissipate compressive loads to the implant-bone interface.[38] Functional thread surface area, therefore, is that portion of the thread that participates in compressive load transmission under the action of an axial (or near-axial) occlusal load.

In contrast to functional surface area is total theoretical surface area, which may include a "passive" area on the implant that does not participate in load transfer, or has a feature so small bone cannot adapt to load transfer. For example, plasma spray coatings are often reported to provide up to 600% more total surface area for the potential bone-implant contact.[26] However, the size of each plasma spray particle is less than 8 µm, and the 120-µm bone cell does not receive a transfer of mechanical stress from this feature. The amount of actual BIC that can be used for compressive loading may be less than 30% of the total theoretical surface area (Figure 11-11).

An improved functional surface area per *unit length of the implant* (in contrast to *total* surface area) is beneficial to reduce the mechanical stress to bone. Most stress to the implant-bone interface in D1 to D3 bone is in the crestal 5 to 9 mm of the implant; therefore the design of the implant body in the coronal 9 mm is most important to appropriately distribute occlusal stresses to the bone.[27,39,40] For example, a conventional 20-mm V-shaped or reverse buttress-threaded implant of a constant thread depth may have more *total* surface area compared with a 13-mm square threaded or plateau design implant. The *functional* area, however, that is available to resist compressive biomechanical loads in the zones of greatest stress to the BIC may be significantly higher in the 13-mm implant because of the thread geometry.

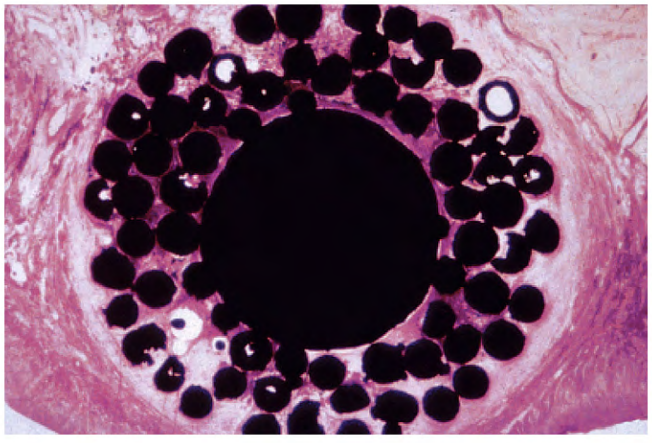

Figure 11-11 Functional surface area of an implant design does not include spaces too small for bone to grow into and act as a stress transfer medium. *(From Steflik D, Corpe RS, Young TR et al: Light microscopic and scanning electron microscopy retrieval analysis of implants biomaterials retrieved from humans and experimental animals,* J Oral Implantol *27:5-15, 2001.).*

Functional surface area also plays a major role in addressing the variable initial BIC zones related to bone density upon initial loading. D1 bone, the densest bone found in the jaws, is also the strongest, has the stiffest modulus of elasticity, and has the highest initial BIC percent, which approximates 80%. D2, D3, and D4 bone have progressively decreasing percentages of bone at the initial implant interface, with D4 bone ranging around 25% interface contact at the initial healing and uncovery of a machined titanium implant.[4,41] As a result, the implant geometric body design, length, and bone density are related to the functional surface area. For example, in more compromised bone sites (i.e., D4 bone), longer implants are required to resist off-axis and moment loads because of cantilevers, improper occlusion, or parafunction.[42] Recall that mechanical stress is equivalent to the applied load divided by the surface area over which the load is dissipated. D4 bone has the weakest biomechanical strength and the lowest BIC area to dissipate the load at the implant-bone interface. The functional surface area requirements would increase from a minimum for an implant in D1 bone to a maximum for implants in the D4 bone (Figure 11-12).[42]

The diameter of an implant may influence the length requirements of the implant body, because the functional surface area is increased. However, the higher bite forces and lower bone density of the posterior regions of the mouth may not always be able to be addressed adequately by only implant diameter. For example, Ivanoff et al. in 1999 found 6-mm-long implants with a 5-mm diameter had a failure rate of 33% in the mandible and 10% in the maxilla.[44] The 8-mm-long, 5-mm-diameter implant yielded 33% and 25% failure rates in the mandible and the maxilla, respectively. On the other hand, the longer 10-mm and 12-mm implants that were 5 mm in diameter yielded no mandibular failures and a 10% failure rate in the maxilla. Therefore the 5-mm implant diameter was not enough to compensate for the shorter implants in this report.

An ideal treatment plan would include implant length of 12 mm or greater with 4-mm diameter for most anterior implant sites and 5 mm or greater in the

WWW.HIGHDENT.IR

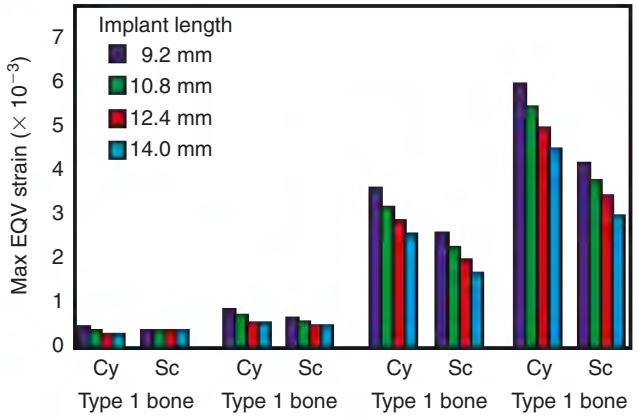

Figure 11-12 The required functional surface area is less for implants in D1 bone *(far left)* and greatest for implants in D4 bone *(far right)*. Screw-type implants have more functional surface area, which is an advantage, especially in softer bone types. *(From Tada S, Stegiaroiu R, Kitamura E et al: Influence of Implant design and bone quality on stress/strain distribution in bone around implants: a 3-dimensional finite element analysis,* Int J Oral Maxillofac Implants *18:357-368, 2003.)*

molar regions.[5] When the ideal implant size cannot be inserted because of inadequate bone, an alternative to bone augmentation may be to increase the surface area of the implant by modifying the implant body design.

IMPLANT BODY GEOMETRY VERSUS OCCLUSAL LOAD

Different implant survival rates and amounts of marginal bone loss may be directly related to different implant body designs. The macrodesign of an implant has an important bearing on the overall surface area to the load of the bone. Protruding elements of the implant surface, such as ridges, crests, teeth, ribs, or the edge of threads may act as stress transfers to the bone when load is applied. Hoshaw et al. tensile loaded titanium V-threaded implants (Nobel Biocare Brånemark) in the cortical bone of canine tibiae (Figure 11-13).[45] The osteons in the tibia are usually oriented parallel to the long axis of the bone. However, around the implants with axial tensile loads, osteons were oriented encircling the implants and secondary osteons appeared oriented around the depth of the implant threads. Therefore the cortical bone remodeling observed around endosteal implants may be an attempt to improve strain orientation of the bone in relation to the functional loads.

In an animal study using a square thread, microscopic observation noted that when the bone did not fully occupy the threads, greater bone volume was observed on the lower aspect compared with the upper aspect of the square threads (Figure 11-14).[46] In addition, a bone bridge was found from one square thread to another. The square thread shape of the tested implants was designed to enhance compression loads and reduce shear loads

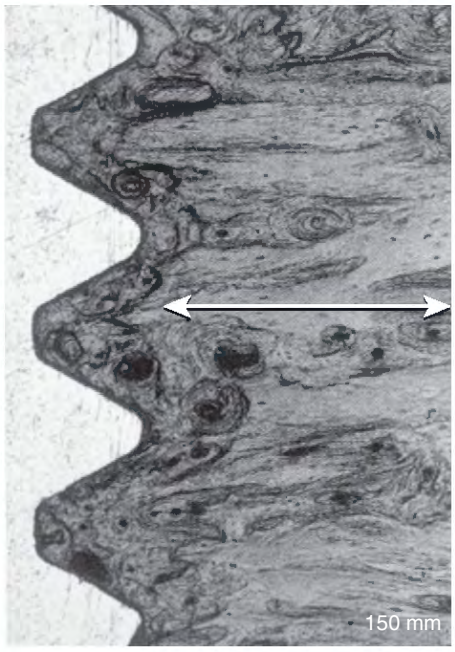

Figure 11-13 Hoshaw tensile loaded implants in dog tibiae. The osteons in the tibia of the dog run parallel to the long axis to resist the weight and axial forces of the animal. When the implants were inserted perpendicular to the long axis and tensile loaded for 5 days, the osteons 4 to 5 mm around the implants reoriented to encircle the implant rather than remain parallel to the long axis of the tibiae to resist the tensile loads. *(From Hoshaw SJ, Brunski JB, Cochran GVB: Mechanical loading of Brånemark fixtures affects interfacial bone modeling and remodeling,* Int J Oral Maxillofac Implants *14:173-180, 1999.)*

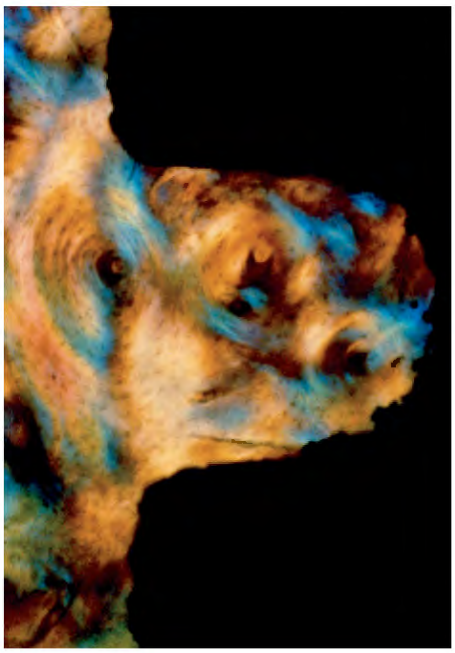

Figure 11-14 Bone bridges forming from one square thread to another and a higher bone contact percent on the bottom of a square thread, which could load the bone in compression. *(From Baumgardner JD, Boring G, Cooper RC et al: Preliminary evaluation of a new dental implant design in canine models,* Implant Dent *9:252-260, 2000.)*

WWW.HIGHDENT.IR

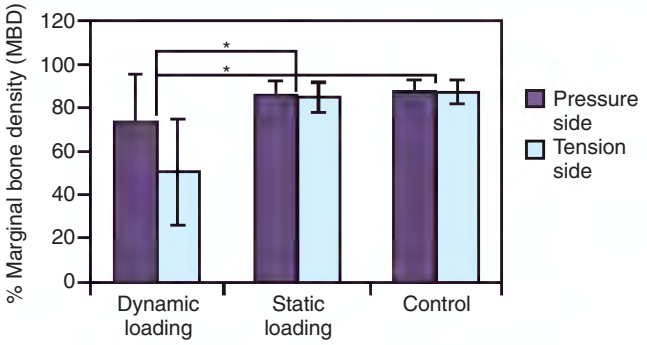

Figure 11-15 There is more bone on the bottom of a V-threaded implant (pressure side) compared with the thread (tensile side) for dynamic-loaded implants. The static loaded and unloaded implants have a similar bone density on the top and bottom of the thread.

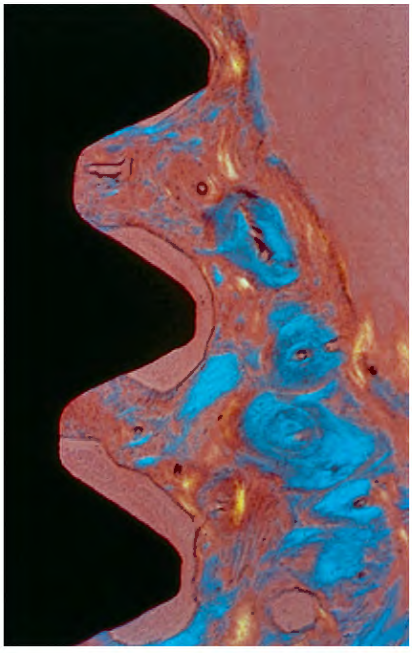

Figure 11-16 Lateral loads are placed to V-shaped implants, and bone bridging is found from the depth of one thread to another. Because the strain would be highest at the peak of a thread and lowest at the depth, the bone contact point is related to lower strain positions. *(From Kohn DH: Overview of factors important in implant design,* J Oral Implantol *18:204-219, 1992.)*

delivered to the implant interface. Duyck et al. also found in an animal model that the bone density was equally distributed above and below a threaded implant after initial bone healing. However, after dynamic loading, the bone implant density was greater on the bottom of the thread face angle and less on top of the thread (Figure 11-15).[47] Kohn and Hollister demonstrated that when the Nobel Biocare Brånemark implant was loaded laterally, a bone bridge formed from the depth of one thread to another (Figure 11-16).[48] The local strain field within the bone-implant interface under this condition is inhomogeneous. During a lateral load, the strain was more concentrated at the tip of the thread and the strain was decreased from the exterior to the interior regions of the thread. Kohn and Hollister speculated that because the strains were highest at the tip of each thread, bone was resorbed, and where strains were reduced at the depth of the thread, bone was maintained.

A retrieval report by Bolind et al. confirmed a consistent pattern of BIC location in humans.[33] The bone contact was least at the tip of each thread (where the highest strain occurs) and was the greatest under the thread face angle (where the bone is loaded more in compression). Therefore the design of the implant not only governs the initial stability of the implant, but as important determines the BIC percent and location of contact available for effective load transfer to the bone after occlusal loading.

SCIENTIFIC RATIONALE FOR IMPLANT DESIGN

Cortical and trabecular bone are modified by modeling or remodeling.[49] Modeling is the result of independent sites of formation and resorption that change the shape or size of bone. Remodeling is a process of resorption and formation at the same site that replaces previously existingbone and is primarily responsible for the change in bone quality. Bone modeling and remodeling are primarily controlled by the mechanical environment of strain.

The histologic description of bone includes lamellar bone, woven bone, composite bone, and bundle bone.[50] The first two of these bone types are often found next to an osteointegrated dental implant. Lamellar bone is the most organized, highly mineralized, and strongest of the bone types. It has been called *load-bearing bone* and is most desired next to an implant. Woven bone also is called *immature bone* because it is unorganized, less mineralized, and has less strength than the other types. These histologic terms may be used to describe the macroscopic bone types of cortical and trabecular bone.

Nicolella et al. found that a 0.15% deformation in a bone specimen may have microstructural level strain values as large as 3.5% at various regions within the cellular microstructure.[51,52] Microstrain levels 100 times less than the ultimate strength of bone may be responsible for remodeling rates within the structure, because the bone cell membranes are able to act as a mechanosensory system in bone.[53] In other words, the cellular behavior of bone cells is largely determined by the mechanical environment of strain or deformation of the bone cells.[54-56] It is speculated that the source of energy to open the ion membrane channels in the bone cell membrane is the microstrain in the cells as a result of the load applied to the bone.[57,58]

Frost described four microstrain zones for compact bone and related each of these categories to the mechanical adaptation to strain.[59] These four zones include the pathologic overload zone, the mild overload

WWW.HIGHDENT.IR

zone, the adapted window, and the acute disuse window. Briefly stated, the pathologic overload zone and the acute disuse window are the two extremes of bone reaction to strain conditions. Each of these conditions, however, may result in a similar condition of less bone. Pathologic overload could lead to microfractures, which require repair and may result in net bone resorption. The disuse zone also increases remodeling, which decreases bone mass (see Figure 7-7).

The remodeling rate, or bone turnover, is the time needed for new bone to replace the existing bone and allows for the adaptation of bone to its environment (e.g., next to a dental implant).[60] The bone remodeling rate (BRR) also has been expressed as a percentage or volume of new bone within a specific time period. Lamellar bone forms at a rate of 1 to 5 µm each day, whereas woven bone can form at rates of more than 60 µm each day.[61,62] Therefore a higher BRR is directly related to an increase in the amount of woven bone formation. The mild overload zone is more likely to have a higher BRR than the adapted window zone and more reactive woven bone formation (less organized, less mineralized, and weaker) to create and maintain bone mass in response to the mechanical challenge.[63] The adapted window zone is most likely to be organized, highly mineralized, lamellar bone. Misch et al. stated the adapted window would be the ideal strain condition next to a dental implant, providing bone that is more mature and more resistant to periodic changes in strain conditions.[64] Therefore the BRR may be directly related to the strength of the implant interface and the degree of risk for the implant-bone interface. The higher risk is related to higher turnover rates, because the bone is less mineralized, less organized, and less strong at the interface.

Interface remodeling allows a viable bone interface to form between the dental implant and the original bone after the implant has been surgically inserted.[62] Before implant insertion, the bone is usually mature, lamellar bone. The surgical trauma causes the bone to repair, with primarily woven bone formation. By the end of 4 months of a maturation phase next to an implant interface, osteoblasts have deposited about 70% of the mineral found in mature vital bone and have reformed lamellar bone. The remaining 30% of mineral deposition occurs during secondary mineralization over the next 8-month period.[50]

After the bone has healed and the implant is then loaded, the interface again remodels, as influenced by its local strain environment.[49] If woven bone forms as a result of mechanical loading, it is called *reactive woven bone* and is very similar in structure and properties to the "repair" woven bone from surgical trauma. The long-term maintenance of the implant involves a continuous remodeling of the interface. In part, this allows new bone to replace bone, which may have sustained microfractures or fatigue as a result of cyclical loading. In vivo microdamage in bone and an elevated remodeling activity to repair those regions have been identified by Frost.[65] To date, the BRR of the bone in the jaws for humans is not well documented; however, it appears to reach 40% each year.[66]

Microdamage in cortical bone surrounding screw-type implants has been reported during both insertion and with pullout forces, and the amount of microdamage was related to the thread design of the implants.[67] Microdamage acts as a key step in signaling increases in remodeling and replacement of skeletal tissue and is similar to the local tissue remodeling response to physical injury in other tissues.[68] Mori and Burr provided evidence of an increased BRR in regions of microfracture from fatigue damage.[69] Verborgt et al. found that in the ulnae of rats, fatigue loading produced a large number of terminal dUTP nick-end labeling to detect apoptotic cells (TUNEL)-positive osteocytes in bone surrounding microcracks.[70] The intracortical resorption was almost 300% greater than the controls. The authors noted a strong association between microdamage, osteocyte apoptosis, and subsequent bone remodeling. Therefore, in addition to the increased BRR at the interface that is related to the trauma induced during the implant surgery, there may be heightened remodeling of bone some distance beyond the surgical interface after loading. Hoshaw et al. found an increase in bone remodeling next to threaded dental implants in dog tibiae when loaded for 5 consecutive days after a 12-month initial healing period.[45] Hoshaw et al. also found titanium threaded implants with axial tensile loading have higher remodeling rates and less mineralized bone than control implants that did not receive a load after healing.[71] The increase in the BRR found in the overload zone of Frost and the increase in BRR from the microfracture are directly related.

Barbier and Schaper investigated implant-supported prostheses under nonaxial and axial loads.[72] A higher cellular response, including osteoblasts and inflammatory cells, was observed next to implants under nonaxial shear loading conditions compared with axial loads (Figure 11-17). These authors stated nonaxially loaded implants exhibited a greater BRR compared with axially loaded implants in animals with the same implant design. It appears the implant design, direction of load, or surface condition may all affect the bone at the implant interface, which affects the bone turnover rate at the interface. Because bone in the jaws usually remodels at 40% per year, this most likely represents the adapted window zone. The higher the BRR, the more likely the bone is in an overload condition.

Thread Geometry

Threads are designed to maximize initial contact, enhance surface area, and facilitate dissipation of loads at the bone-implant interface.[38] Functional surface area per unit length of the implant may be modified by varying

WWW.HIGHDENT.IR

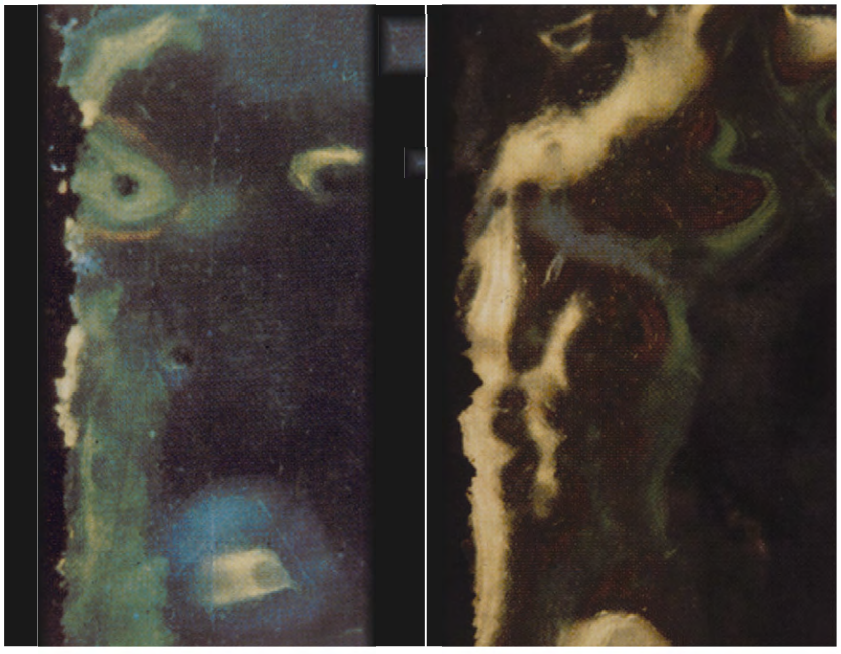

Figure 11-17 **A,** In this study of loaded implants in an animal (dog), axially loaded implants have lamellar bone more often at the interface. **B,** Implants with non-axial loading have primarily woven bone at the interface, a higher bone remodeling rate, and osteoclasts and inflammatory cells. *(From Barbier L, Schepers E: Adaptive bone remodeling around oral implants under axial and nonaxial loading conditions in the dog mandible,* Int J Oral Maxillofac Implants *12:215-223, 1997.)*

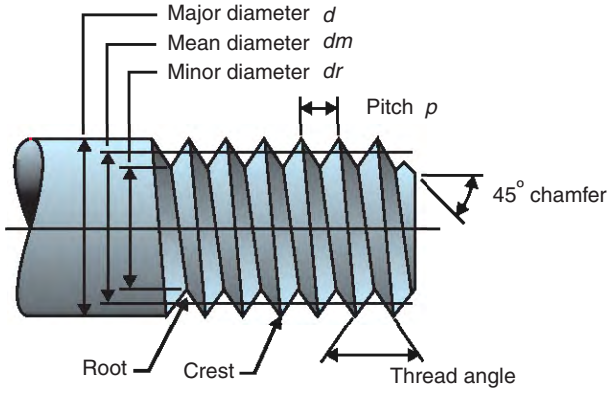

Figure 11-18 There are several parameters of an implant that may alter the functional surface area. Three of these include: thread pitch, thread shape, and thread depth.

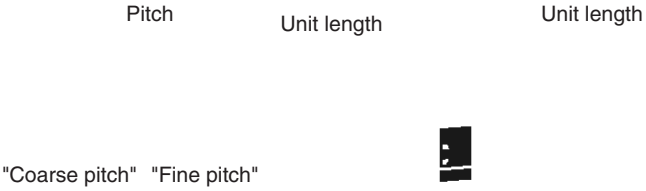

Figure 11-19 The thread pitch describes the number of threads per unit length of an implant. The implant on the right has a smaller thread pitch and greater surface area, whereas the implant on the left has the largest thread pitch and the least overall surface area.

three geometric thread parameters: thread pitch, thread shape, and thread depth (Figure 11-18).[43]

Thread Pitch

Thread pitch is the distance measured parallel between adjacent thread form features of an implant.[38] The height of the threaded portion of the implant body divided by the pitch equals the threads per unit length. The smaller (or finer) the pitch, the more threads on the implant body for a given unit length, and thus the greater surface area per unit length of the implant body if all other factors are equal. Restated, a decrease in the distance between threads will increase the number of threads per unit length. The greater number of threads, the greater the surface area, if all other factors are the same (Figure 11-19). Because stress is directly related to the magnitude of the force and indirectly related to the area over which the force is applied, the implant pitch may be made smaller when the magnitude of the force is greater than usual.[38]

Roberts observed in an animal model that the thread number may affect the bone implant contact percentage.[62] When two different implant designs were placed in the same animal, a higher BIC was observed with the implants with the greater thread number (Figure 11-20).

It is interesting to note that of all the design variables, pitch has the most significant effect on changing the surface area on a threaded implant. This is a major point to consider when looking at the anatomical dimensional limitations presented in the oral environment. For example, when an ideal implant length cannot be planned without advanced bone augmentation, an implant with greater thread numbers may improve the functional surface area for the height dimension compromise.[73]

WWW.HIGHDENT.IR

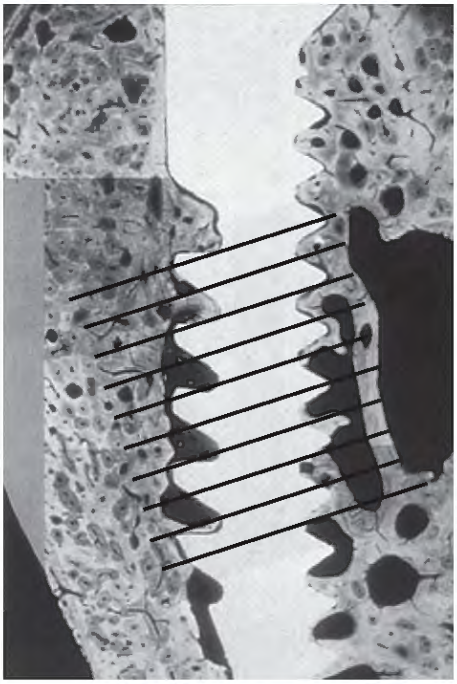

Figure 11-20 There is a higher bone-implant contact (BIC) with implants of greater thread number compared with implants with fewer threads. A composite of a typical result demonstrates a higher BIC on the right side compared with the left side of the implant. *(From Roberts WE, Smith RK, Zilerman Y et al: Osseons adaptation to continuous loading of rigid endosseous implants,* Am J Orthod *86:95-111, 1984.)*

The thread pitch may be used to help resist the forces to bone with poorer quality.[36] Because the softest bone types are 58% weaker than ideal bone quality, the implant thread number may be increased to increase the overall surface area and reduce the amount of stress to the weaker bone trabeculae. Therefore if force magnitude is increased, implant length is decreased, or bone density decreased, the thread pitch may be decreased to increase the thread number and increase the functional surface area.

Most manufacturers provide implant systems with a fixed pitch and fixed surface area per unit length, regardless of the character of forces or the bone density of the anatomical site. However, different popular implant designs often have different thread pitches. For example, the distance between the threads for one implant design is 1.5 mm (Straumann ITI), whereas a thread pitch of 0.6 mm exists for others (Zimmer Screw-Vent, Biomet 3I). Each implant pitch has a different number of threads per unit length and a different amount of functional surface area.

The thread number is most significant for the shorter length implants. For example, the Straumann ITI 6- and 8-mm-long implants may only have three threads to carry the compressive load (Figure 11-21). On the other hand, the thread pitch of other implant designs may feature 7 to 10 threads for a similar length (Figure 11-22). The greater the thread number, the greater the initial fixation and the greater the overall surface area after loading.

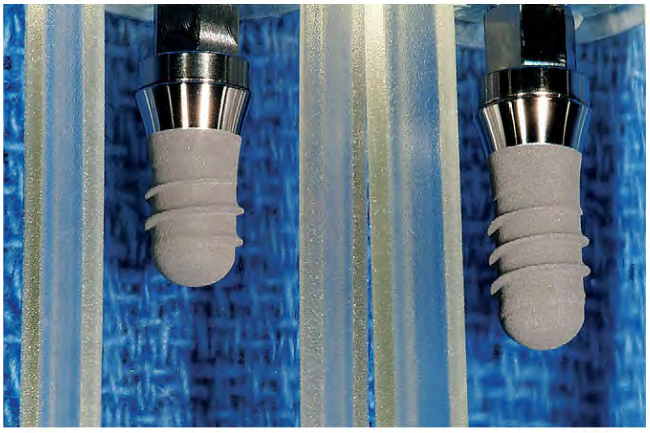

Figure 11-21 The Strauman ITI implant length on the left is 6 mm, and the one on the right is 8 mm. Each implant only has three threads for surgical fixation and load bearing after healing.

Figure 11-22 The BioHorizons Maestro implant on the left (7 mm long) has 7 threads. The implant on the right (9 mm) has 10 threads because of variable thread pitch designs.

The thread number may be affected by the implant crest module design. When the implant body has an extended smooth crest module, the number of the thread to support the occlusal load is reduced. For example, some implant designs have a smooth crest module of 3 mm or more, whereas other designs have only a 0.7-mm area above the first thread. When the thread pitch is 0.5 mm, there are four fewer threads for every 2 mm of smooth crest module. Therefore a 7-mm-long implant may have 28% fewer threads with an extended smooth crest module (Figure 11-23).

Several manufacturers advertise implant bodies with double or triple thread leads (e.g., Zimmer, Nobel Biocare). These terms relate to the manufacturing process and do not increase functional surface area. Rather than machining one thread at a time with one cutting instrument, a double thread uses two cutting blades and a triple thread uses three blades to manufacture the threads. As a result, when a one thread lead implant rotates 1 rpm, the implant inserts a distance of one thread. A double-thread implant at 1 rpm inserts two

WWW.HIGHDENT.IR

Figure 11-23 The internal hex implant design on the left (Zimmer ScrewVent) features an internal hex. The implant on the right (BioHorizons Maestro) has an external hex crest module. The implant on the left is 1 mm longer, but has fewer threads than the implant on the right. The implant on the left is manufactured with triple thread lead; the one on the right has a single thread lead. However, the overall surface area is not affected by the thread lead.

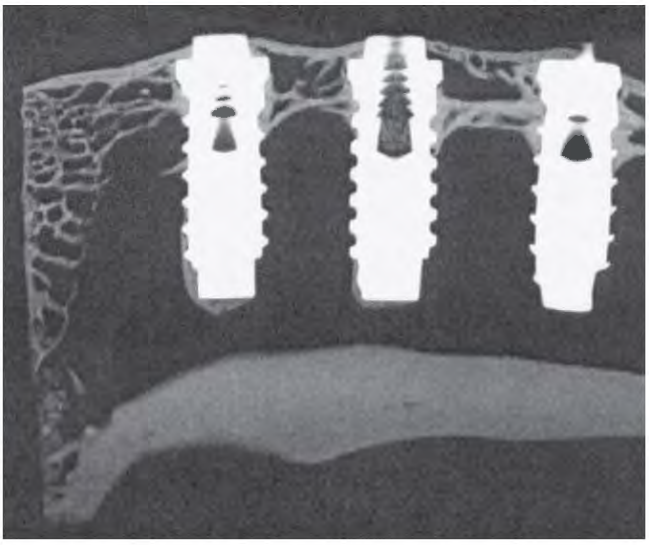

Figure 11-24 In this animal study, three different thread designs were evaluated for initial bone healing. The thread number, depth and surface condition (resorbable blast medium [RBM]) were kept identical. The implant length and diameter were also the same. The crest module designs of the implants were also similar.

threads into the bone. If the revolutions per minute on a single thread lead is doubled (e.g., 30 rpm versus 15 rpm), both implants thread into the bone at the same rate. In any case, no functional surface area change is found between a single- double-, or triple-thread lead.

The surgical ease of implant placement is related to thread number. The fewer the threads, the easier to insert the implant. If fewer threads are used in denser bone, the ease of placement is improved, because hard bone is more difficult to tap and insert a threaded implant.

Thread Shape

The thread shape is another important characteristic of overall thread geometry.[38] As described previously, thread shapes in dental implant designs include: square, V-shape, buttress, and reverse buttress (see Figure 11-10). In conventional engineering applications, the V-thread design is called a *fixture* and is primarily used for fixating metal parts together.[74] The reverse buttress thread shape was initially designed for pullout loads by Krupp.[74] This screw design was used to secure cannons to concrete bunkers so that the discharge forces during firing of the cannon would not pull the screws out of the foundation. The force transfer for occlusal loads to the bone is similar to that of the V-thread design. Dental implant applications dictate the need for a thread shape optimized for long-term function (load transmission) under occlusal, intrusive (the opposite of pullout) load directions. The square or power thread provides an optimized surface area for intrusive, compressive load transmission. Most automobile jacks or engineering designs built to bear a load use some form of a square design. Yet very few implant designs have incorporated a square thread design (BioHorizons, Ankylosis). A buttress thread shape may also load the bone with primarily a compressive load transfer (e.g., BioLok).

The thread shape has primarily design applications for loading conditions, but may also contribute to the initial healing stage for the direct bone interface. An animal study by Steigenga et al. compared three thread shapes with identical implant width, length, thread number, thread depth, and surface condition[75-77] (Figure 11-24).

Table 11-2 Percentage of Bone to Implant Comparing V-Shaped, Reverse Buttress, and Square-Threaded Implant Designs

N = 12 *n* = 69	V-SHAPED THREAD	REVERSE BUTTRESS	SQUARE THREAD	SIGNIFICANCE
Percent bone implant contact	65.46*	63.05†	74.37†	*$P < 0.01$ †$P < 0.001$

N, Number of rabbits; *n*, number of implants evaluated; *P*, significance value.
* V-shaped thread.
† Reverse buttress or square thread.
Comparisons were made using one-way analysis of variance with Bonferroni multiple comparisons test.

WWW.HIGHDENT.IR

Table 11-3 Reverse Torque Removal Values (N-cm) Comparing V-Shaped, Reverse Buttress, and Square-Threaded Implant Designs

N = 12 *n* = 36	V-SHAPED THREAD	REVERSE BUTTRESS	SQUARE THREAD	SIGNIFICANCE
Reverse torque value (N-cm)	15.58*	15.46†	23.17†	*†P < 0.05

N, Number of rabbits; *n*, number of implants evaluated; *P*, significance value.
* V-shaped thread.
† Reverse or square thread.
Comparisons were made using repeated measures analysis of variance with Bonferroni multiple comparisons test. F = 2.6723, P = 0.02 for overall model.

The V-shaped and reverse buttress thread shapes had similar BIC percent and similar reverse torque values to remove the implant after initial healing (Table 11-2). The square thread design had a higher BIC percent and a greater reverse torque test value (Table 11-3). Therefore it appears thread shape may also be a parameter in an implant design for the initial healing phase of osteointegration.

A consistent loading profile approach is warranted in implant dentistry. In general, materials are strongest under compressive loads and weakest to shear loads. This is true for porcelain, dental cements, implant materials, fixation screws, and bone.[36] Therefore a compressive force should be applied to all these components and shear force should be reduced wherever possible.

The face angle of the thread or plateau in an implant body can modify the direction of the occlusal load imposed on the prosthesis and abutment connection to a different direction at the bone interface. The face angle of a V-shaped thread is 30 degrees off the long axis, whereas a square thread may be perpendicular to the long axis. As a result, occlusal loads in the axial direction of an implant body may be compressive at the bone interface when the implant body incorporates square or plateau designs, but can be converted to higher shear loads at the bone interface when the implant body incorporates V-shaped threads (Figure 11-25).[38]

The shear force on a V-thread face that is 30 degrees (typical of Zimmer Screw-Vent and Biomet 3I) is approximately 10 times greater than the shear force on a square thread.[43] The shear component per unit length of a reverse buttress thread design is similar to a V-thread when subjected to an occlusal load. The shear component of a 15-degree face angle (Straumann ITI implant) is five times greater than the shear force on a square thread. The reduction in shear loading at the thread-bone interface provides for more compressive load transfer, which is particularly important in compromised bone density, short implant lengths, or higher force magnitudes.

A 30-degree load to an implant increases the force to the bone-implant interface by 50% compared with a long axis load, and the shear component of force is increased.[24] A 30-degree load to the implant-bone interface loads the bone interface at a 30-degree angle and also decreases the compression and tensile strength of the interface. The 30-degree load to bone decreases the bone strength in compression by 11% and decreases the tensile strength of bone by 26%.[24] Therefore, when a long axis load is delivered to the implant crown, the face angle of the implant body thread can modify the occlusal axial load to an angle bone-implant load. A power thread (square) may load the bone interface in compression when an axial load is delivered to the implant crown.

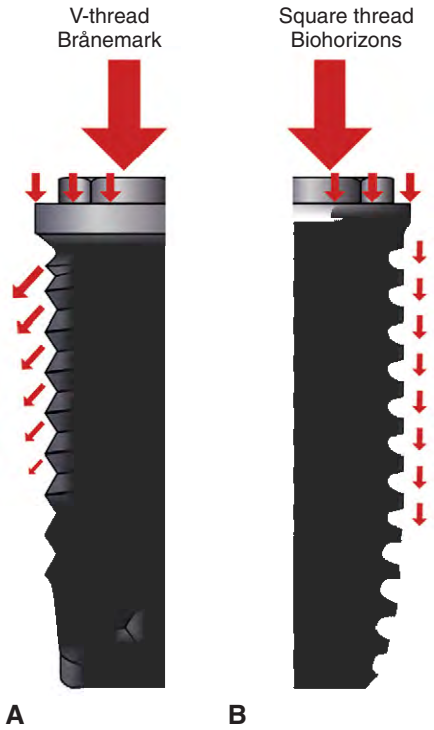

Figure 11-25 **A,** A long axis load to an implant body with V-thread with a 30-degree thread face converts the load direction to a 30-degree angle at the implant interface. An axial load on the prosthesis may result in an axial load to the implant platform. However, the implant body design may convert the primary compressive forces to the prosthesis and results in a 30-degree angled force with more tensile and shear loads to the implant-bone interface. **B,** A plateau or square-thread design can deliver a compressive force to the bone when the implant is loaded in the long axis. The implant body design determines the type of force transmitted to the implant-bone interface.

Figure 11-26 Evaluation of three thread type implants of similar diameter and length, thread number, and depth with a three-dimensional finite element analysis. The overall stresses and shear stresses are compared. The square-thread implant has less overall stress and less shear stress. The V-shape thread and reverse buttress thread shape are similar. *(From Kim WT, Cha YF, Oh SJ et al: The three dimensional finite element analysis of stress according to implant thread design under the axial load,* Korean J Oral Surg *27:3-8, 2001.)*

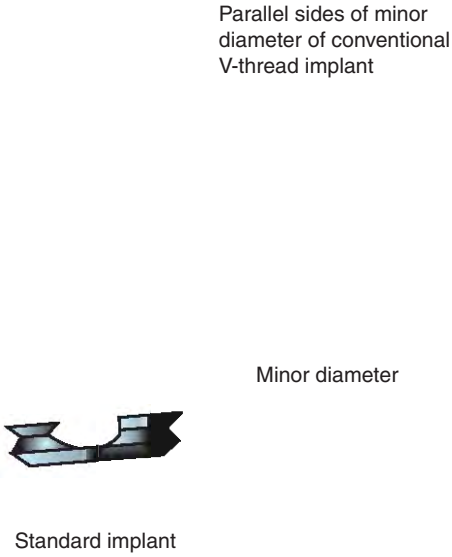

Figure 11-27 The thread depth of an implant refers to the distance between the outer (or major) diameter and the inner (or minor) diameter of the thread. The deeper the thread depth, the greater the functional surface area.

A finite element, three-dimensional study of a thread shape was evaluated by Kim et al.[78] An implant with the same number and depth of threads with different thread shapes (V-shaped, reverse buttress and square) were evaluated (Figure 11-26). The V-shape and reverse buttress had similar values. The square thread had less stress in both compressive and, more important, shear forces. Chun et al. also used finite element analysis to evaluate design parameters of osteointegrated dental implants.[79] They also concluded the square-thread design has a beneficial shape for occlusal loading compared with other thread designs.[14,80,81] Therefore thread shape may alter the functional load conditions and influence the type of force transmitted to bone. A review of the literature suggests that the square thread implant design may provide similar success rates in the maxilla and mandible in a wide range of differences in bone density.[14,71-73]

Thread Depth

The thread depth is the distance between the major and minor diameter of the thread (Figure 11-27).[38] Conventional implants provide a uniform thread depth throughout the length of the implant. A straight minor diameter, which is used in almost every screw-type dental implant, results in uniform cross-sectional area throughout a parallel-walled implant length. A tapered implant often has a similar minor diameter, but the outer diameter decreases in relationship to the taper, so the thread depth decreases toward the apical region. As a result, this implant design has overall less surface area, which is more critical in shorter implant lengths. The tapered, threaded implant may have less ability to fixate the bone in the apical region at initial insertion and has less functional surface area. The implant body taper may result in higher stresses, especially in shorter implant lengths.[27]

The greater the thread depth, the greater the surface area of the implant, if all other factors are equal. Different manufacturers use different thread depths. Some threaded implants have a 0.24-mm thread depth (Nobel Replace), the thread depth of Straumann ITI is 0.3 mm, and the thread depth of many V-shape threads is 0.375 mm (Biomet 3i and Zimmer Screw-Vent). The square thread of the 4-mm-diameter BioHorizons implant body has a 0.42-mm thread depth. Therefore, if all other factors were equal, each type of implant in these examples would have a different functional surface area directly related to the depth of the thread, with BioHorizons having the most surface area and Nobel Replace the least (Table 11-4).

WWW.HIGHDENT.IR

Figure 11-28 The BioHorizons implant on the left is 4 mm in diameter and has a thread depth of 0.42 mm. The center and right implants are 5 and 6 mm in diameter, respectively, and have a thread depth of 0.78 mm. As a result, the surface area of the two implants on the right increase by implant diameter and thread depth and have more than 200% more surface area than the implant on the left.

The more shallow the thread depths, the easier it is to thread the implant in dense bone, and the less likely bone tapping is required prior to implant insertion. Because implant surgeons often decide what implant they will insert based on ease of surgical insertion, it is not unusual that an implant with fewer threads and less deep threads are selected, because both conditions facilitate insertion. However, after the implant is placed into the bone, the conditions that make implant surgical insertion easier create less functional surface area, and increase the risk of occlusal overload to the bone-implant interface.

In the conventional implant design, the implant body design remains identical, regardless of the implant diameter. As a consequence, the implant increases in surface area by 15% to 25% for every 1-mm increase in diameter.[6] However, as the implant becomes wider, the depth of the thread may be deeper without decreasing the body wall thickness between the inner diameter and the abutment screw space within the implant. Therefore the thread depth may be modified relative to the diameter of the implant, and thereby the overall surface area may be increased by 150% for every 1-mm-diameter increase (Figure 11-28). For example, the Biomet 3I 4.0-mm-diameter implant body has 200-mm^2 surface area, and the 5.5-mm implant has 245-mm^2 surface area (when the implant is 12 mm long). The 4.0-mm-diameter BioHorizons implant has a 215-mm^2 surface area and the 5-mm implant has a 356-mm^2 surface area.[27,31]

The overall functional surface area of an implant body is therefore related to the thread pitch, thread shape, and thread depth. Tables 11-4 and 11-5 illustrate the difference in several popular implant designs when the implant body is 12 mm long. Note the difference between the 4- and 5-mm-diameter implants. It is interesting to note the molars of natural teeth have 200% more surface area than the premolars. Natural teeth not only increase their diameters, they also modify their design to cope with the higher bite forces in the posterior regions of the mouth. Yet most implant designs only increase surface area by 10% to 30% with a larger-diameter implant body.

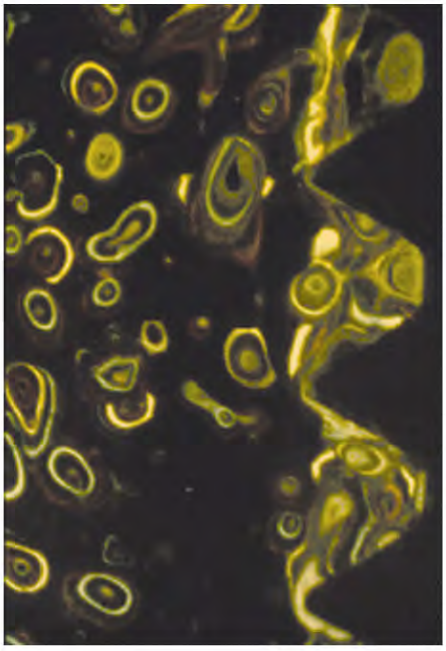

Figure 11-29 In an animal model (dog) the remodeling rate of bone away from the implant was 40% per year (physiologic or adapted window). The bone remodeling rate next to the Brånemark implant (Nobel Biocare) was 500% per year (mild overload zone). *(From Garetto LP, Chen J, Parr JA et al: Remodeling dynamics of bone supporting rigidly fixed titanium implants: a histomorphometric comparison in four species including humans,* Implant Dent *4:235-243, 1995).*

Bioengineering of an Implant Design

Recent studies have shown that when implants act as functionary unit for a prosthesis, an elevated BRR is an ongoing response adjacent to many dental implants.[82] A BRR higher than 500% per year in the bone immediately

WWW.HIGHDENT.IR

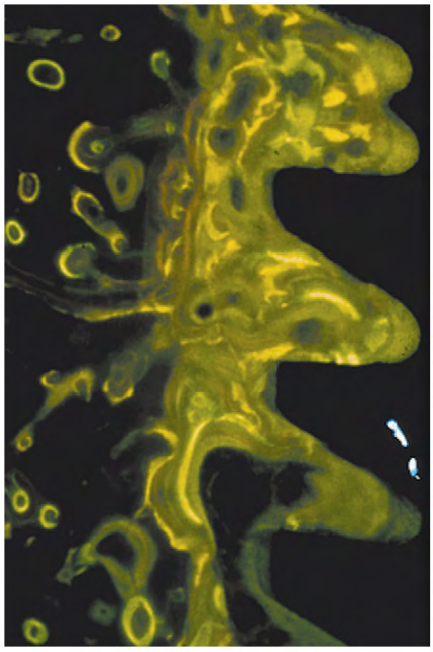

Figure 11-30 Garetto et al. evaluated in an animal model (dog) the bone remodeling rate (BRR) next to a SteriOss dental implant (Nobel Biocare). The bone several millimeters away from the implant had a BRR of 40% per year. The region around the implant had a BRR of 680% per year (mild to pathologic overload). As a result, the SteriOss dental implant had a smaller percentage of bone-implant contact compared with the Brånemark implant design. The higher the BRR, the less lamellar bone and the closer to the pathologic overload zone, which may cause formation of fibrous tissue. *(From Garetto LP, Chen J, Parr JA et al: Remodeling dynamics of bone supporting rigidly fixed titanium implants: a histomorphometric comparison in four species including humans,* Implant Dent *4:235-243, 1995.)*

adjacent (within 5 mm) to a V-shape threaded implant, but approximately 50% in the regions distant from the interface has been observed. These findings suggest the bone at the interface of the implants in their report is likely in the mild overload zone (Figure 11-29). Cooper presented a histologic report of Roberts, in 1999, which evaluated the turnover rate of bone next to a macrosphere surface design (Sybron Corp., Endopore) implant retrieved from a human maxilla in the premolar region.[83] This implant had a BRR that ranged between 400% and 908% per year. It is interesting to note the developers of this implant design report that bone loss is often a consequence of stress shielding as in orthopedic hip prostheses as determined by finite element analysis, rather than overload conditions. Therefore they believe more stress should be applied to the implant interface. The BRR, at least in this one reported patient, appears to indicate a greater strain condition does exist with this design, compared with other implants or conditions that have been reported.

Roberts et al. observed a difference in interface contact percentage between an asymmetrical implant thread design (Nobel Biocare, SteriOss, Yorba Linda, Calif.) and a symmetrical threaded surface (Nobel BioCare, Brånemark, Gothenburg, Sweden).[84] The V-shaped thread of Brånemark had a higher bone contact and reduced bone turnover rate (500%) compared with the reverse buttress thread shape with a reduced thread number (Steri-Oss implant with 680% BRR) (Figure 11-30). Therefore the BRR reported is different in each of these three different designed implants.

If an implant design is bioengineered so that loading will produce a microstrain within the adapted window zone, it should maintain lamellar bone at the interface during loading, as represented by a similar BRR adjacent to and distal to the implant interface. Therefore a prospective goal of an implant design project involved modifying the parameters that affect the response of the surrounding bone tissue next to the implant at the cellular level.[85]

The magnitude of load may also affect the BRR at the implant interface. Roberts evaluated successful implants in humans, used for orthodontic anchorage for 3 years or more.[86] The bone-implant interface of these implants only remodeled at a rate in the range of 30% per year. The duration of an orthodontic force is constant, and the forces used for tooth movement (<5 N) is far inferior to the typical forces of function or parafunction (up to 250 N). As a result, the lower bone turnover rate may signify the small-magnitude tensile loads at the implant interface during orthodontic anchorage. Brunski et al.[87] used a dog model in which overloads were applied to a titanium V-shaped thread screw dental implant. Implants in the mandibles and radii were allowed to heal for 4 to 7 months and then loaded with cyclical axial compression in the mandibles and axial tension on the radii sites. There were no significant differences between the controls and loaded interfaces. Brunski et al. believe this was most likely a result of insufficient levels of loading to observe a difference. The similar result may also be related to the thread shape, which gives similar stress profiles in compression and tension. A follow-up study by Hoshaw et al.[71] using dog tibiae and larger axial tensile loads with a longer healing time before loading found more crestal bone loss around the loaded implants, an elevated BRR in the cortex, and resorptive modeling on the periosteal surface. There are several studies and reports that demonstrate prosthetic loading conditions on the implants can cause implant failure, crestal bone loss, or implant fracture.[88] It is therefore hypothesized the phenomenon of the elevated BRR at the implant interface, compared with that found several millimeters away, may be used as an indication of increased biomechanical risk for the supporting implant-bone interface, as related or created by specific clinical conditions.[64]

To reduce shear loading to bone, a square-thread design to axial loading may be used on the body of the dental implant.[77,78] The turnover rate of bone within the threads of the BioHorizons Maestro D2 and D3 implants in both a dog study and human case report has been reported to be 40% to 50% and was the same

WWW.HIGHDENT.IR

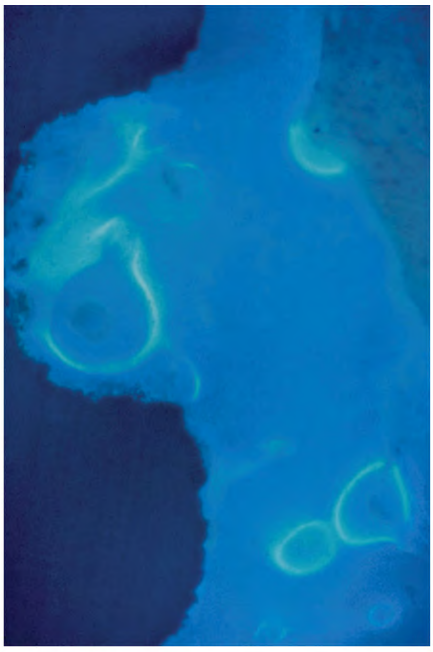

Figure 11-31 A square-threaded implant was loaded in an animal model. A bone remodeling rate of 50% per year was observed, which was similar to the remodeling rate several millimeters from the implant interface.

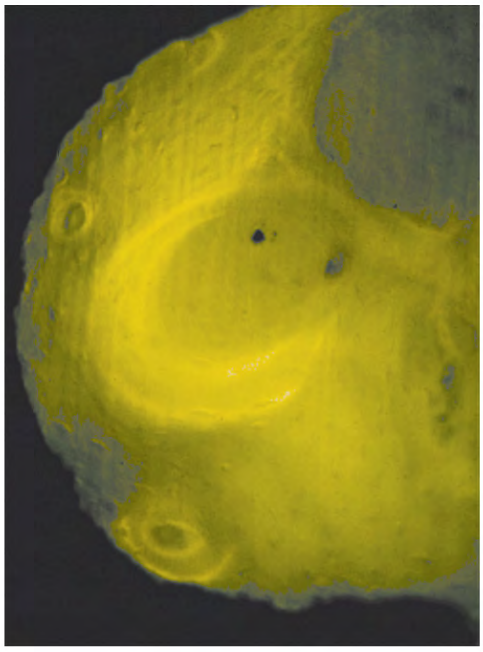

Figure 11-32 The bone remodeling rate of bilateral maxillary first premolar implants with a square thread design was evaluated after 1 year of occlusal loading in a human. The bone remodeling rate was 40% to 50% per year and similar to the bone away from the implant interface.

as observed in the bone away from the implant interface (Figures 11-31 and 11-32).[46,64] This rate corresponds to the rate of lamellar bone remodeling in the adapted window zone. This condition may place the interface at less biomechanical risk, because lamellar bone is more mineralized, more rigid, and stronger compared with the reactive woven bone found in the mild overload zone.

The concept presented in this chapter is not meant to suggest adequate strain levels may only be obtained with one implant design, or even that ideal strain levels are necessary for long-term maintenance of osteointegration. The strain environment around an endosteal implant is very complex, and variables such as bone density, bone volume, and bone shape are most likely influential, but not yet fully understood. Future experimental models should evaluate how the influence of implant design, surface condition, intensity of load, frequency of load, direction of force, and bone density interrelate to the long-term success of dental implants. It is suggested the bone turnover rate may be a method to evaluate these conditions.

Crest Module Considerations

The crest module of an implant body is the transosteal region, which extends from the implant body and often incorporates the antirotation components of the abutment implant connection. The crest module of the implant has a surgical influence, a biological width influence, a loading profile consideration (characterized as a region of highly concentrated mechanical stress), and a prosthetic influence. Therefore this area of the implant body is a determinant for the overall implant body design.

During the surgical phase the crest module design primarily benefits the crestal implant interface. The crest module of an implant should be slightly larger than the outer thread diameter of the implant body. In this way, the crest module seals completely the osteotomy, providing a barrier and deterrent for the ingress of bacteria or fibrous tissue during initial healing.[43] The seal created by the larger crest module also provides for greater initial stability of the implant following placement, especially in softer unprepared bone, because it compresses the crestal bone region.[43]

The larger crest module diameter also increases surface area, which can further decrease stress at the crestal region. A crest module height of 2 mm, which is 4.2 mm compared with 4.0 mm, has 5% greater surface area ($\pi \times$ diameter).[6] Because the stresses are highest in this region, the greater surface area decreases stress to the bone and increases the strength of the implant body.

The increase in crest module diameter increases the platform of the abutment connection with a stress reduction to the abutment screw during lateral loading. In fact, the platform dimension is more critical to reduce the stress applied to the abutment screw than is the height (or depth) of the antirotational hex of the abutment to implant body connection.[89]

The concept of designing an implant crest module with a smooth collar is for a reduction of plaque accumulation and improved hygiene (Figure 11-33). However, the crest module is initially placed below the bone in

WWW.HIGHDENT.IR

Figure 11-33 Many implants have a crest module with a smooth metal collar for reduction of plaque accumulation and improved oral hygiene conditions.

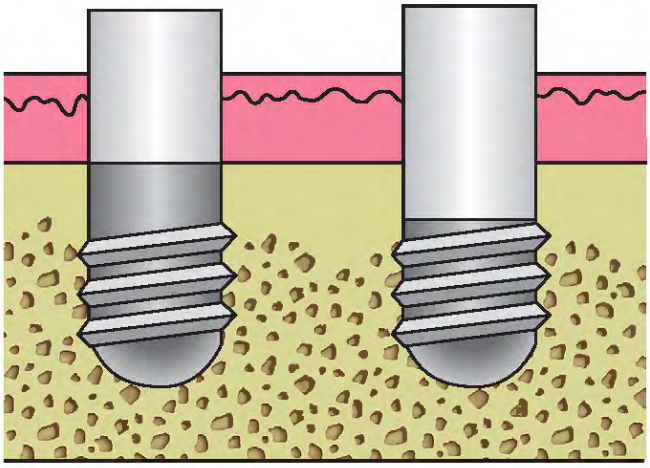

Figure 11-34 Herman evaluated the initial unloaded healing of 12 one-piece transgingival implant designs in dogs. The implant on the left had roughened metal placed at the crestal region. The implant on the right had a smooth metal collar of 1.5 mm placed below the crestal bone.

most two-piece implant designs. Therefore the need for daily hygiene and plaque control is not relevant, unless crestal bone loss occurs. The initial sulcular soft tissue thickness approximates 3 mm above the bone. A toothbrush bristle only extends 0.5 to 1 mm into the sulcus during oral hygiene procedures. Therefore unless the tissue recedes, even when bone loss occurs on the implant crest module, the gingival sulcus depth cannot be accessed by hygiene procedures after crestal bone loss, especially because the gingival sulcus increases in depth after marginal bone loss.

There are at least six causes of marginal bone loss at the crestal bone region of implants, including the formation of a "biological width" and occlusal overload after the implant is in function.[90,91] The biological width of an implant is related to marginal bone loss before, or separate from, occlusal loading influences. Both these entities have increased bone loss risk when smooth metal is placed below the bone. In an animal study, Herrman placed one-piece implants with a 1.5-mm smooth crest module below the bone and compared it with a roughened crest module of similar design at the bone crestal level in dogs (Figures 11-34 and 11-35).[92] The two implant designs were followed for 6 months, with no occlusal load. Within 1 month after the implant insertion and extension through the soft tissue, marginal bone loss occurred to the smooth region 1.5 mm below the crestal region. No bone loss occurred when the implant crest module was rough and placed at the level of the crestal bone. Hammerle et al. inserted similar implant designs in human patients and found a similar

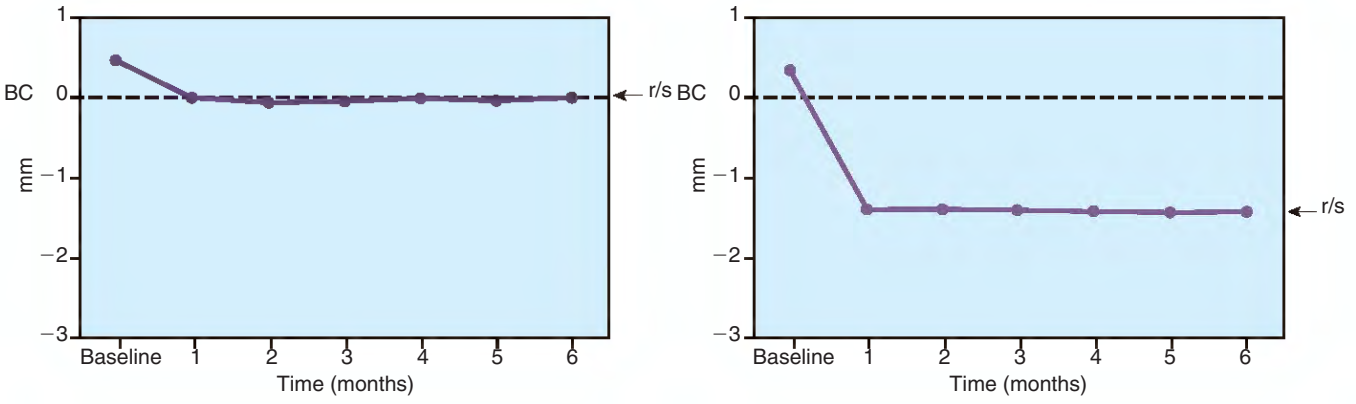

Figure 11-35 **A,** The implants with a 1.5-mm smooth metal collar below the bone lost 1.5 mm of bone to the first month during an unloaded 6 month period. **B,** The implants with a rough surface at the crestal bond lost no bone during an unloaded 6-month period.

WWW.HIGHDENT.IR

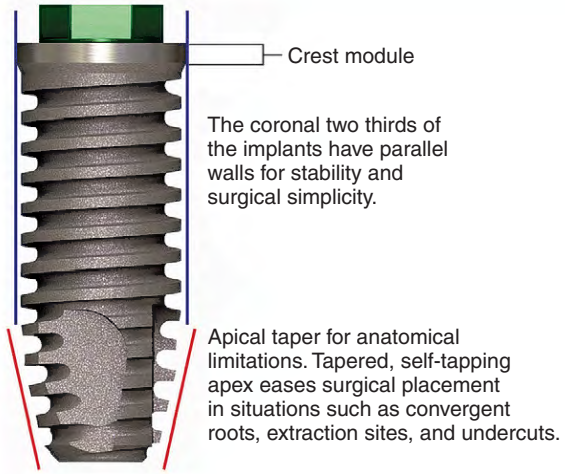

Figure 11-36 A 0.5-mm smooth metal collar may provide for a closer abutment-crest module connection compared with a rough surface connection. The apical end of an implant is often tapered to ease surgical placement, because it fits within the osteotomy prior to engaging the walls of the bone.

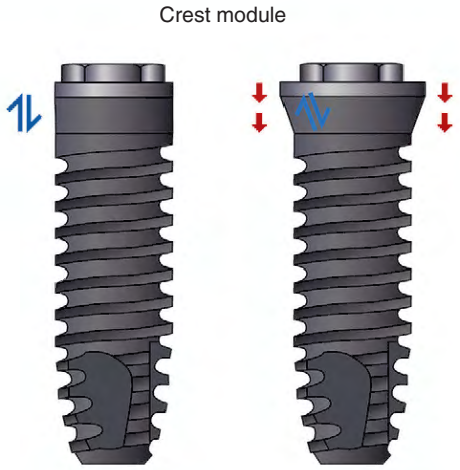

Figure 11-37 The crest module with a cylinder metal collar transfers primarily shear forces to the bone *(far left).*

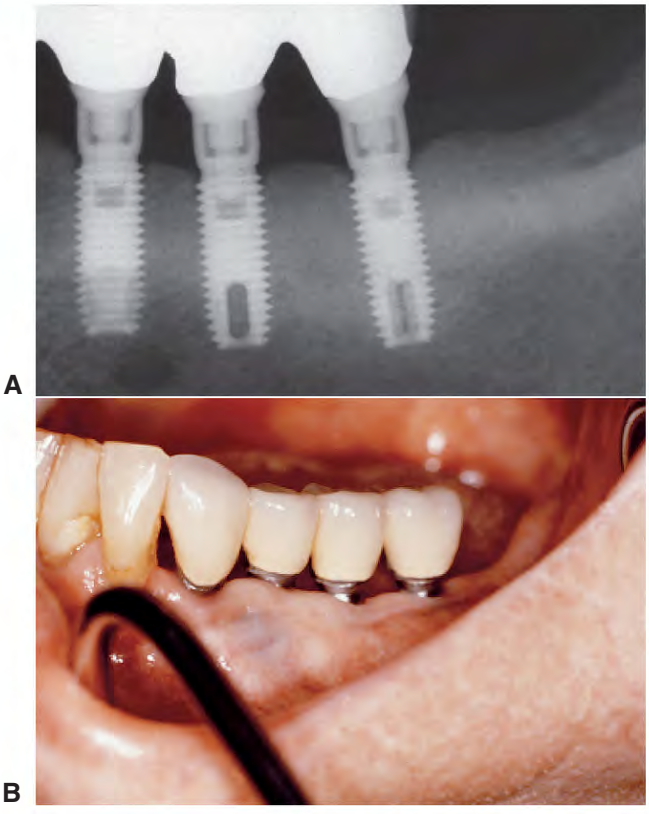

Figure 11-38 **A,** These three implants with an acid-etched collar were placed at the crest of the bone. After 2 years of occlusal loading, the bone has been lost to the first thread on all three implants. **B,** The clinical appearance of 3.5 mm of bone loss in this patient was tissue shrinkage and exposure of the implant crest modules.

crestal relationship to smooth metal below bone.[16] Hanggi et al. also compared two different crest module designs in patients and found the longer smooth metal collar had more crestal bone loss.[93] Therefore the crest module of the implant should not have an extended smooth area placed below the bone.

A biological width of at least 0.5 mm has been reported apical to the abutment-to-implant connection regardless of the implant crest module design. A 0.5-mm collar length may provide for a desirable smooth surface close to the perigingival area, while preserving the biomechanical performance of the remaining portion of the crest module (Figure 11-36). The microgap between the implant crest module and abutment may also be reduced when polished surfaces are approximated.

The next consideration of the crest module is related to occlusal loading.[17,34,91,94] Most of the occlusal stress occurs at the crestal region of an implant design.[91,94] A smooth, parallel-sided crest module will increase the risk of bone loss after loading (Figure 11-37). As previously discussed, smooth metal promotes shear stresses in the adjacent bone interface.[90] Because bone is 65% weaker to shear loads, attempts to limit shear are prudent. In addition, smooth metal does not encourage bone cell contact before loading.[15] When the surface condition of the implant is roughed, the BIC is increased during initial healing. Reverse torque tests observe consistent higher values when roughened surfaces are compared with machined or polished surface conditions.[95] Significant loss of crestal bone has been reported for implants with machined (smooth) coronal regions, and the amount of the bone loss is directly related to the length of the smooth crest module (Figure 11-38).[96] This bone loss is attributed to the biological width before loading and the lack of effective mechanical loading between the machined coronal region of the implant and the surrounding bone after occlusal loading. This clinical problem is reduced by using implants that incorporate a roughened surface and a crest module designed to reduce shear loading.

WWW.HIGHDENT.IR

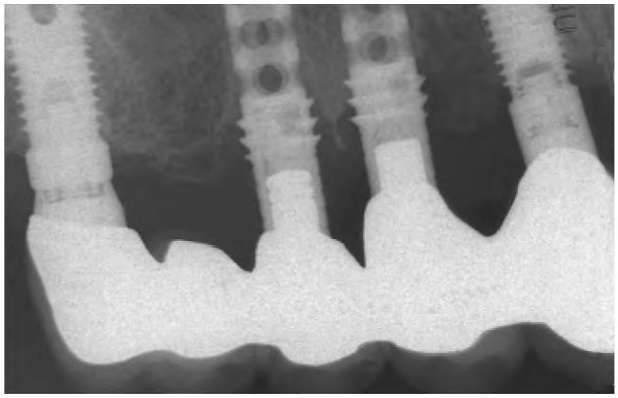

Figure 11-39 The amount of crestal bone loss is often related to the implant design. In this five-unit fixed partial denture, there are three different implant designs. The implant on the far left has a 2-mm smooth collar and a hydroxylapatite-coated thread. The two center implants have a sharp buttress threaded acid-etched cylinder smooth metal collar. The implant on the far right has a 4.5-mm smooth collar above the first thread.

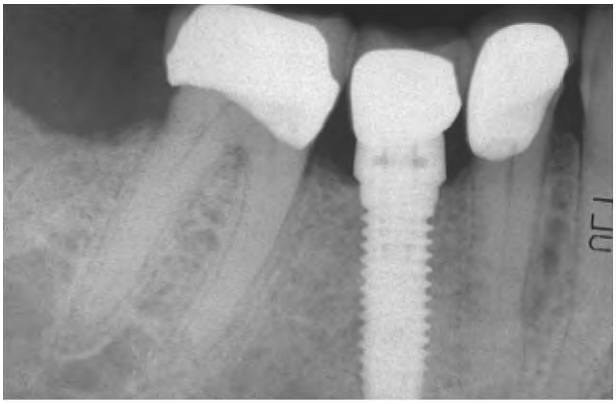

Figure 11-40 Implants with a biomechanical design to reduce crestal stresses often have less crestal bone loss in clinical reports (i.e., BioHorizons Maestro Dental Implant).

A roughened surface (but a shear load design crest module) maintains the bone through the biological width cycle, but may lose the marginal bone during the occlusal load conditions. For example Straumann ITI has a roughened crest module, which is a cylinder below the bone. The initial bone loss before loading is minimal. However, a clinical report on human patients demonstrated 26% of the implants[5] lost more than 5 mm of bone and 22% lost more than 6 mm during a 10-year prospective study[22] (see Table 1-1). Astrand et al. compared ITI and Brånemark implants in partially edentulous maxillae. The roughened surface ITI had more bone loss than the machined metal Brånemark implants (see Figure 11-3).[23] DeBruyn et al. followed clinical outcomes of screw-vent implants (with an internal hex and long rough cylinder crest module). Crestal bone loss was consistently found at least to the first thread, which accounted for more than 2 mm of bone loss.[97] In other words, a rough crest module may not be sufficient to stop crestal bone loss once the implant is loaded.

It has been a common clinical observation that bone is often lost to the first thread after loading, regardless of the manufacturer type or design. Bone often grows above the threads during healing, but after prosthesis loading, bone loss is often observed. For example, the first thread is 1.2 mm below the platform of the Nobel Biocare Mark IV implant, 2 mm below the platform on the Nobel Replace design, and 3.5 mm on internal hex Zimmer implant designs. The magnitude of the crestal bone loss is often directly related to the distance between the crest module and the first thread distance, with the most bone loss on the internal hex crest module design with an extended cylinder crest module (regardless of whether it is smooth or rough) (Figure 11-39). Therefore the bone loss cannot be related to a specific biological width, but may be in part caused by crest module design. The bone loss often stops at the first thread because the first thread changes the shear load created by the crest module to a component of compressive loading. Instead of designing the crest module for shear, an improved design can reduce the crestal bone loss risk.

Any crest module design that incorporates an angled geometry or grooves to the crest module, coupled with a surface texture that increases bone contact, will impose a beneficial compressive component to the contiguous bone and decrease the risk of bone loss. By way of example, implants designed with stress transfer features (i.e., Astra, BioHorizons) often exhibit less bone loss in clinical reports (Figure 11-40).[14,80] This is not a coincidence, but rather is a design feature that influences the end result.

The prosthetic features of the crest module may affect the implant design. For example, in an internal hex implant, the antirotational feature of the abutment is designed within the implant body. As a result, the implant body is lower in profile and easier to cover with soft tissue during surgery. In addition, the antirotational feature is often deeper within the body compared with external hex implants. However, because the internal antirotation feature is wider than an abutment screw, the wider body diameter at the crest module is reduced. As a result, the threads on the outside of the implant body can not be designed at or above the antirotational feature of the implants. Therefore greater smooth metal and shear forces are observed above the first implant body thread compared with an implant with an external hex (Figure 11-41). The threads may progress more crestally with the external hex, because the abutment screw diameter is narrower and the outer body wall is thicker; therefore the threads may approach the crestal region of the implant.

Apical Design Considerations

The apical portion of a root form implant is most often tapered to permit the implant to seat within the

WWW.HIGHDENT.IR

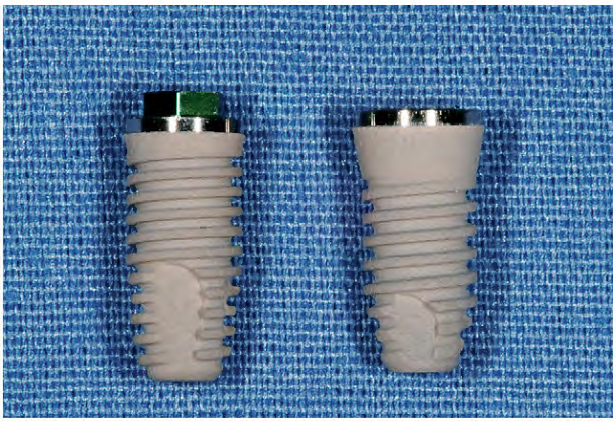

Figure 11-41 The implant on the left has an external hex; the implant on the right has an internal hex (BioHorizons Dental Implants). The external hex designs allow the fabrication of threads closer to the crestal region of the implant.

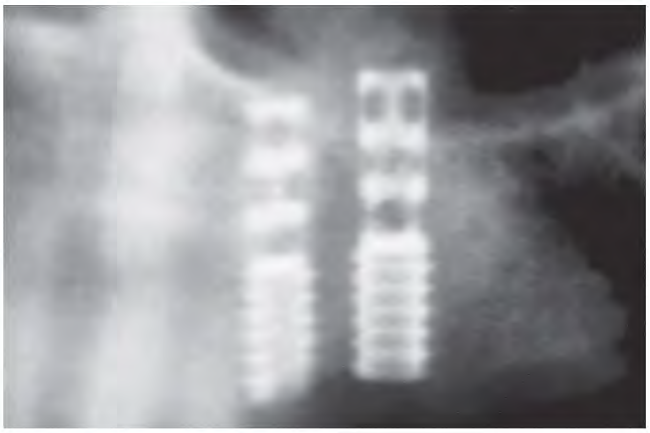

Figure 11-42 The apical hole or open cylinder may fill with mucus when placed within a sinus and result in a retrograde infection around the implant.

osteotomy before the implant body engages the crestal bone region (see Figure 11-36, *B*). As a result, the patient does not need to open the mouth as wide, which is especially of benefit in the posterior regions of dentate patients. This apical feature favors the initial step of implant insertion.

Most root form implants are circular in cross section. This permits a round drill to prepare a round hole, precisely corresponding to the implant body. Round cross sections, however, do not resist torsion/shear forces when abutment screws are tightened or when freestanding, single-tooth implants receive a rotational (torsional) force. As a result, an antirotational feature is incorporated into the implant body, usually in the apical region. The most common design is a hole or vent. In theory, bone can grow through the apical hole and resist torsional loads applied to the implant. The apical hole region may also increase the surface area available to transmit compressive loads to the bone.

A disadvantage of the apical hole occurs when the implant is placed through the sinus floor or becomes exposed through a cortical plate. The apical hole may fill with mucus and become a source of retrograde contamination (Figure 11-42) or will likely fill with fibrous tissue. If the apical hole is several millimeters in height, the region filled with fibrous tissue decreases bony contact in the apical region of the implant. This concern is greatest with an open basket body design, less with a vertical hole of 4 mm, and even less with a round 1-mm hole. The apical aspect of a solid implant (without apical hole) may slightly perforate any opposing cortical plate and act as a wedge to seal the opening.

Another antirotational feature of an implant body may be flat sides or grooves along the body or apical region of the implant body. Bone grows against the flat or grooved regions and helps resist torsional loading. In addition, the grooves or recessed areas of the apical portion of the implant help to enhance the "self-tapping" aspect of an implant design. This occurs in several ways. First, the recess areas of the apical portion allow bone fillings from the cutting threads to fill the area. Otherwise, these bone chips may fall to the apical floor and prevent the implant from completely seating or compress into the trabecular bone and contribute to a pressure or resistance to rotational insertion of the implant. Second, the recess area may be designed to decrease the angle of the cutting thread along the apical portion of the implant. As a result, less torque is required to thread the implant into the bone.

The apical end of each implant should be flat rather than pointed. Pointed geometry has less surface area, thereby raising the stress level in that region of bone. Additionally, if an opposing cortical plate is perforated, a sharp, V-shaped apex may irritate or inflame the soft tissues if any movement occurs (e.g., the inferior border of the mandible).

IMPLANT BODY BIOMATERIAL RELATED TO FRACTURE

Implant bodies and components have a risk of fracture, most often during the intermediate to long-term loading condition. According to Goodacre et al., the risk of implant body fracture in the early to intermediate period for implants 3.75 mm in diameter is 1%, the abutment screw fracture risk is 2%, and the prosthetic screw risk is 4%.[18] However, the incidence of fracture dramatically increases when force conditions are greater. Cantilevers, angled loads, and parafunction increase the risk of fracture. The risk of fracture also increases over time. Rangert reported that in the long-term loading condition, 80% of all failures may be related to implant body fracture.[98] The elements of the implant body that influence the fracture risk include the biomaterial, the size, and the design.

WWW.HIGHDENT.IR

Force Magnitude and Implant Body Design

Normal physiology imposes constraints on the magnitude of forces that must be withstood by engineering designs in the oral environment. The magnitude of bite force varies as a function of anatomical region and state of the dentition. Average bite forces can range from 10 to 350 lb.[99] The magnitude of force is greater in the molar region (200 lb), less in the canine area (100 lb), and least in the anterior incisor region (25 to 35 lb). These average bite forces increase with parafunction to magnitudes that may approach 1000 lb in the posterior regions.[100]

Many biocompatible materials are unable to withstand the type and magnitude of parafunctional loads that may be imposed on dental implants. As an example, ceramic, which has excellent biocompatibility, is very susceptible to tension and bending loads. Such loads are commonly applied to dental implants and render this material unsuitable in many implant body applications. In addition, materials such as HA are quite biocompatible with biological tissues, but lack the mechanical material properties to withstand the loads imparted on implants. In contemporary applications, many of these materials are considered for use as a coating when applied to a stronger substrate material.

Titanium and titanium alloys have a long history of successful use in dental and orthopedic applications. The excellent biocompatibility of titanium and its alloy has been well documented.[101] There are four grades of CP titanium used in dentistry (grades I to IV), and one grade of titanium alloy (grade V). Regardless of the grade of titanium or alloy, the surface condition to the bone is similar (i.e., titanium oxide). With its highly active titanium oxide layer, these materials are extremely well tolerated by local tissues. Titanium-aluminum-vanadium alloy (Ti-6Al-4V) has been shown to exhibit the most attractive combination of mechanical and physical properties, corrosion resistance, and general biocompatibility of all metallic biomaterials.[101,102] The primary advantage of titanium alloy as compared with other grades of titanium is its strength. As shown in Table 11-6, the mechanical properties of titanium alloy are superior to those of commercially pure titanium.[103-105] Titanium alloy is four times stronger than grade 1 CP-titanium and almost twice as strong as grade 4. Ultimate strength and fatigue strength is a primary consideration given the ramifications of the loading profiles to which dental implant bodies are subjected and the possible component fractures incurred due to inferior materials or designs.

The modulus of elasticity (stiffness or rigidity) of the four different grades of titanium is similar (103 GPa), and titanium alloy is only slightly higher (113 GPa). Although there is a significant difference in strength between grades of CP titanium and its alloy, the elastic modulus is similar for all of these materials. Titanium and its alloy represent the closest approximation to the stiffness of bone of any surgical grade metal used as an artificial replacement for skeletal tissue, even though it is almost 6 times stiffer than dense cortical bone. However, because of the geometry and functional requirements of dental implants, the elastic modulus is not nearly as important as the biocompatibility and strength offered by titanium alloy. Thus titanium alloy represents the best compromise (given current biomaterials technology) between biomechanical strength, biocompatibility, and the potential for relative motion (from modulus mismatch) at the bone-implant interface.

Implant Design Failures Related to Biomaterial and Force Magnitude

Two examples of implant body failures related to biomaterial choice have appeared in the historical implant literature. The vitreous carbon implants optimized the modulus of elasticity (stiffness) of the biomaterial (carbon) without appropriate attention to ultimate strength considerations. Conversely, Al_2O_3 ceramic implants optimized ultimate strength without adequate attention to modulus of elasticity or type of loading conditions placed on implants in parafunction.

The vitreous carbon implant design was composed of a smooth, tapered-step carbon body with an internal 316-L stainless steel post. The stiffness of the carbon was compatible with the surrounding bone; however, the carbon body was incapable of withstanding the physiologic loads within the oral environment.[106,107] The geometric design of the implant is equally, if not more important to resist occlusal loads. Microcracks in the body developed, and a pathway of biological fluids was thus introduced to the internal stainless steel post. The post was then subjected to dramatic corrosion with the subsequent release of metallic ions

Table 11-6 Mechanical Properties for Different Grades of Titanium

PROPERTY	GRADE 1	GRADE 2	GRADE 3	GRADE 4	TI-6A1-4V
Tensile strength, min (MPa)	240	345	450	550	930
Yield strength, 0.2% offset, min (MPa)	170	275	380	483	860
Modulus of elasticity (GPa)	103	103	103	103	113

Grades 1 to 4, CP titanium; *Ti-6Al-4V,* titanium-aluminum-vanadium alloy.

WWW.HIGHDENT.IR

into the interfacial tissues. Gross tissue inflammation with ultimate implant failure and removal resulted. A close match of biomaterial and bone material stiffness alone cannot, in isolation, provide clinical success.

The ceramic implants, as a class, were antithetical to the carbon implants. Ultimate compressive strength was optimized at the sacrifice of matching biomaterial and bone stiffness. In addition, the brittle nature of ceramic and susceptibility of failure in tension and shear require geometric designs of the implant that may not be compatible with the anatomical dimensional limitations (i.e., available bone width and height) of the jaw. The modulus of elasticity for ceramics is approximately 33 times stiffer than cortical bone.[108] The result was apparent stress shielding of the interfacial bone. Bone must receive greater than 50 microstrains to function in a physiologic load window.[109] The very stiff ceramic implants carried a disproportionate amount of the load, and the interfacial bone was moved into disuse atrophy.

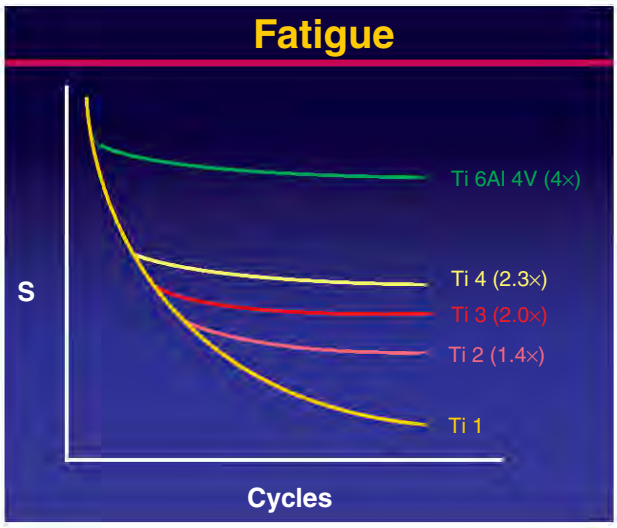

Figure 11-43 Implant bodies and components made of titanium alloy have a lower risk factor related to complication of fatigue fracture. The bone-implant contact percent is similar because all grades of titanium and titanium alloy form titanium oxide on the surface. Therefore the bone cannot distinguish between these materials. S, stress.

FORCE DURATION AND IMPLANT BODY DESIGN

The duration of bite forces on the dentition has a wide range. Under ideal conditions, the teeth come together during swallowing and eating for only brief contacts. The total time of those brief episodes is less than 30 minutes per day.[110] Patients who exhibit bruxism, clenching, or other parafunctional habits, however, may have their teeth in contact several hours each day. This force duration essentially is able to create a fatigue load on the implant.

Influence on Implant Body Design

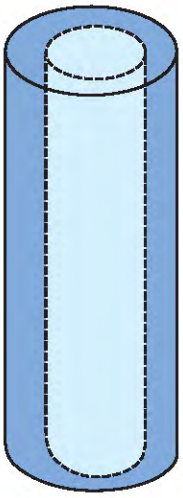
Implant bodies and components are prone to fatigue fractures, with incidence reported between 1% to 4% after 5 to 10 years of loading.[18,111] The most common cause of long-term failure occurred when a grade 1 titanium implant body was used, coupled with a less than ideal treatment plan that has higher stresses, as was demonstrated with 80% of failures from fracture of the Brånemark implant body.[98] An increase in fracture risk was also observed with parafunctional forces when a cantilever load was applied to the implant body.[35] Several factors influence the risk of fracture because of fatigue, including the material, force type, the direction of the applied load, and the overall geometric design.

Typical mechanical failures are due to either static loads or fatigue loads. Static load (i.e., one load cycle) failures cause the stress in the material to exceed its ultimate strength after one load application. Fatigue load failures happen if the material is subjected to lower loads but repeated cycles of that load. The endurance limit or fatigue strength is the level of highest stress a material may be repetitively cycled without failure. The endurance limit of a material is often less than one half its ultimate tensile strength. Therefore fatigue and ultimate strength values are related, but fatigue is a more critical factor, especially for patients with parafunction because they impose higher stress magnitude and greater cycles of load. Different materials have varying degrees of resistance to repeated loading and subsequent fatigue-related failures. The fatigue strength of titanium alloy (Ti-6Al-4V) is four times greater (and safer) than grade 1 titanium, and almost two times greater than grade 4 titanium (Figure 11-43).[105] Therefore long-term fracture of implant bodies and components may be dramatically reduced with the use of titanium alloy rather than any grade of commercially pure titanium. Therefore grades 1 to 4 titanium is at greater risk of implant body fracture under any condition when compared with the alloy (grade 5).

IMPLANT BODY SIZE AND DESIGN RELATED TO FRACTURE

Implant body designs used in the posterior areas of the mouth with higher forces should incorporate specific design features that make them less susceptible to the higher load profiles; therefore, further decreasing the risk of fracture. The ability of implants and components (e.g., abutment screws) to resist fracture from bending loads is directly related to the component's moment of inertia (or bending fracture resistance factor). This parameter is a function of the size of the cross-sectional

WWW.HIGHDENT.IR



$$I_{hollowcylinder} = \frac{1}{4} \times \pi \times (r_{outerdiameter}^4 - r_{innerdiameter}^4)$$

$$I_{hollowcylinder} = \frac{1}{4} \times \pi \times (1.475^4 - 1.25^4)$$

$$\text{or } I = 1.799 \text{ mm}^4$$

Figure 11-44 The equation for determining resistance to fatigue fracture is largely controlled by wall thickness in a dental implant.

geometry of the component. A solid cylinder fracture resistance is equal to the radius to the fourth power.

$$\text{I (moment of inertia)}_{\text{solid cylinder}} = \frac{1}{4} \times \pi \times \text{radius}^4$$

Therefore an implant or component 2 times as wide is 16 times more resistant to fracture. As a result, wider diameter implants may be used when offset loads (cantilevers) or greater stress conditions (i.e., parafunction, molar regions) exist.

The relationship of moment of inertia to overall fracture resistance can be demonstrated by this engineering mechanics equation:

$$\sigma = \frac{My}{I}$$

Where σ represents the stress, M is the moment load caused by eccentric loading and cantilevers, y is a point in the center of the part, and I is the moment of inertia. Therefore it can be shown that by increasing I, which is dependent on the part geometry, stress is decreased. Restated, by optimizing the implant body geometry within the anatomical dimensional limitation, it is possible to reduce the overall stress in the implant.

Considering the same equations, it can be shown that an abutment screw, which has a smaller cross-sectional area than an implant (typically about 2 mm), is more susceptible to fracture. This is particularly true when the abutment screw comes loose and bears a large, disproportionate component of a transverse load to the occlusal surface.

Some investigators have suggested the phenomenon of screw breakage to be a long-term advantage for the implant. Restated, it is better for the screw to break than the implant because the screw is easily retrievable—the implant body is not. Although this concept has some value, it is also a faulty safety factor. Most implant prostheses have more than one implant abutment. As soon as one screw loosens or breaks, the stresses are increased to the remaining implants, components, and bone interfaces. The additional off-axis loads resulting from the screw fracture increases the stresses in the overall system and may contribute to bone loss or implant component fracture of the remaining fixated units. Therefore, rather than depending upon a safety factor as a broken screw when the stresses are too great, transverse load contacts should be identified and corrected by designing reduced cantilevers or occlusal adjustments before screw breakage is imminent.

Implant body design may also increase the risk of long-term fatigue fracture. The abutment screw length is shorter than the receptor site within the implant. This permits the receptor site within the implant to be machined and allows the abutment screw to tighten the abutment, without the risk of "bottoming out" before the screw is completely tightened. The cross section of this portion of the implant body can be modeled as an annulus or hollow cylinder, similar to the cross section of a pipe. The wall thickness of the implant body in the region below the abutment screw controls the resistance to fatigue fracture (Figure 11-44).

Morgan et al. reported on fatigue failures of Brånemark implants subjected to bending loads.[111] Scanning electron micrographs of the fracture surfaces, coupled with the known position of the implants within the oral environment, enabled the authors to determine the load direction was buccolingual bending. Implant fracture occurred, as predicted, in the region of the implant that was characterized by a reduced annular cross section (Figure 11-45). When the abutment screw is only 6 mm long, and crestal bone loss of 6 mm occurs, the annulus (and weakest portion of the implant

WWW.HIGHDENT.IR

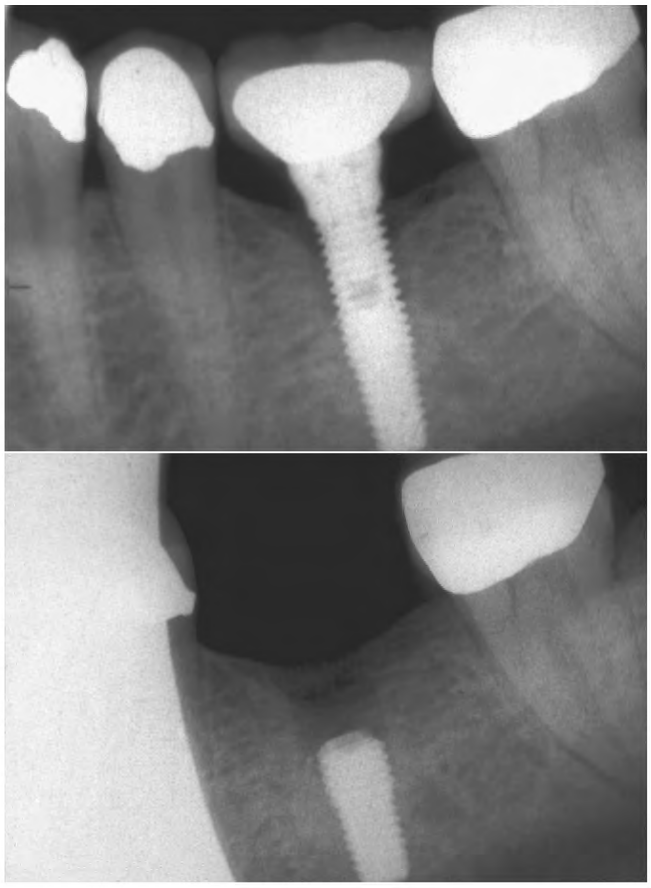


Figure 11-45 **A,** The annulus is the space within the implant body, below the abutment screw. **B,** When bone loss occurs to the annulus, the hollow cylinder implant design is susceptible to fracture.

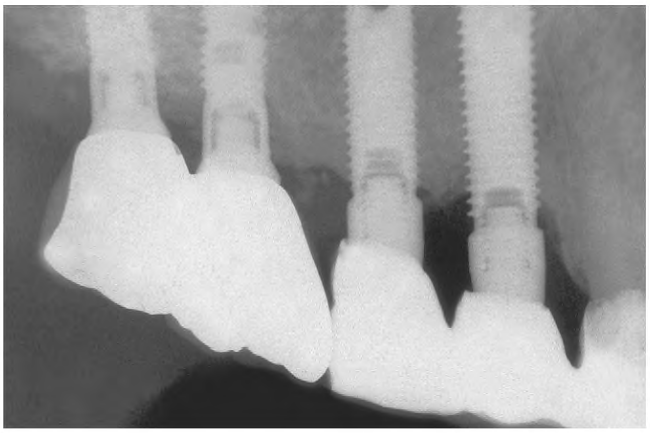

Figure 11-46 The anterior two implants are splinted together, and the abutment screw stops within the implant body near the crestal bone level. The annulus (open pipe design) of the implant body is weakest at this position.

body) is positioned in the highest stress locations from the increased bending moment at that location. As a result, implant body fracture is imminent. Therefore the abutment screw length is an important implant design issue and should be as long as possible.

The formula for the bending fracture resistance in an annulus condition is related to the outer diameter radius to the fourth power, minus the inner diameter radius to the fourth power. For example, if a 3.75-mm-diameter implant has a 0.4-mm thread depth, the outer diameter related to body fracture is actually 2.95 mm (3.75 to 0.4 mm on each side or 2.95 mm with a radius of 1.475 mm). If this implant has a 2.5-mm abutment screw hole (inner radius of 1.25 mm), its moment of inertia or bending fracture resistance at the end of the screw can by shown as:

$$I_{\text{hollow cylinder}} = \frac{1}{4} \times \pi \times (1.475^4 - 1.25^4)$$

Even a small dimensional change in wall thickness can result in a significant change in bending fracture resistance, because the dimension is multiplied to a power of four. When the outer diameter increases 0.1 mm and the inner diameter remains unchanged, the moment of inertia increases to 2.329 mm^4 or a 30% increase in strength. When the outer diameter remains unchanged and the inner diameter decreases 0.1 mm, the increase is 2.087 mm^4, or a 16% increase. Therefore an increase in outer diameter has a more significant effect on body wall strength, even though the metal thickness is similar in both scenarios. Therefore a 4-mm-diameter implant body has a significant increase in strength, compared with a 3.75-mm implant body, especially at the annulus position. The overall bending stress (and likelihood of fracture) decreases exponentially as the moment of inertia (bending fracture resistance factor) increases (Figures 11-46 and 11-47).

An interesting analysis compares a solid, one-piece implant to a two-piece, traditional root form implant. A solid implant with a 1.23-mm-diameter has the same resistance to bending fracture as the annulus region of a 3.75-mm traditional design. Moreover, a solid 3-mm implant has an approximately 340% increase in moment of inertia over the 3.75-mm traditional two-piece root form at the annulus position.

The crest module of an implant body may be designed to have a space around the abutment screw. This space increases the risk of fracture at this location. An external hex implant has the space above the implant body, whereas an internal hex system has the space within the implant body. Therefore the external hex has a slightly higher risk of fracture within the abutment, and an internal hex implant body has an increased risk of fracture at the crest module of the implant. The reduced strength of the implant body is not as great as the annulus at the end of the abutment screw. However, the lack of metal continuity is at the crest of the ridge, where the greatest forces occur. As a result, conditions as a decrease in implant diameter or angled forces increase the risk of fracture to the crest module at this site (Figure 11-48).

WWW.HIGHDENT.IR

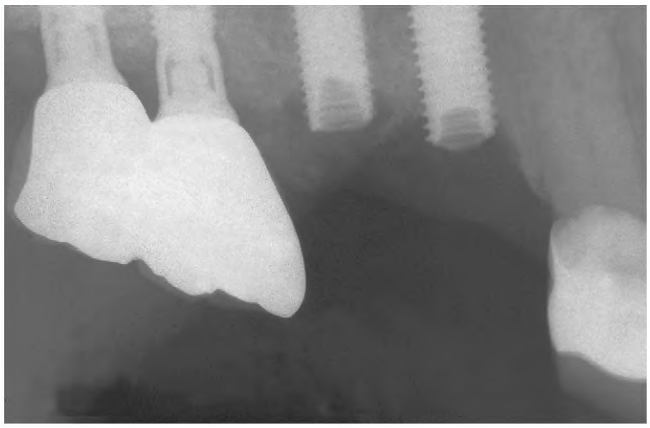

Figure 11-47 The two implants in Figure 11-46 fractured at the annulus position as a result of fatigue.

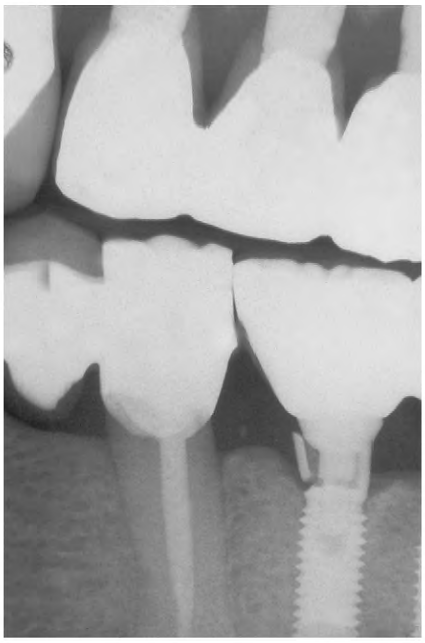

Figure 11-48 The internal hexagonal implant shown (Screw Vent, Zimmer, Encino, Calif.) has fractured at the crest module as a result of fatigue and implant design.

SUMMARY

The implant body design is responsible for transmitting the occlusal stress of the prosthesis to the supporting bone. The product used by the implant team may increase or decrease the risk of screw loosening, crestal bone loss, implant body bone loss, peri-implantitis, esthetics of the soft tissue drape, implant failure, and implant body fracture. Therefore it is prudent to make a selection based on a scientific approach, rather than on advertising or marketing opinion. This decision is even more important when force factors are greater than usual, bone density is poorer than usual, or implant body size is reduced.

Chapter 12

Preimplant Prosthodontics: Overall Evaluation, Specific Criteria, and Pretreatment Prostheses

Carl E. Misch, Francine Misch-Dietsh

Implants serve as a foundation for the prosthetic support of missing teeth. However, in the partially edentulous patient, the existing teeth may often require restorations or treatment. The existing conditions of the stomatognathic system should be evaluated and treated, when necessary. As such, preimplant prosthodontic considerations are a vital phase of the overall treatment before implant surgery. For example, the surgical decision to augment or perform osteoplasty before implant surgery is primarily dependent on the desired prosthetic result. Most all conventional forms of construction, from buildings to art form, require a clear vision of the end result before the project is begun.

OVERALL EVALUATION

The preimplant prosthodontic evaluation of the patient's overall condition closely resembles traditional dentistry. When a restoring dentist first evaluates the prosthetic needs of a patient, an orderly process is required, regardless of the current state of the dentition. In other words, regardless of whether the patient has all teeth or is missing all teeth, after the dentist accepts the responsibility of long-term professional guidance and treatment as necessary, a consistent approach to care is beneficial. There are five initial elements that should be assessed in sequence and treated when indicated. These elements include: maxillary anterior tooth position, the existing occlusal vertical dimension, the mandibular incisor edge position, the maxillary occlusal plane, and the mandibular occlusal plane (Box 12-1). These elements are evaluated in a partially edentulous patient during the initial clinical examination and on mounted diagnostic casts (which may also serve for diagnostic wax-up procedures).

MAXILLARY ANTERIOR TOOTH POSITION

The position of the existing maxillary anterior teeth is first assessed. Most often these natural teeth are adequate in location and incisal edge position. However, if their position is undesirable for any reason, orthodontics or restoration may be indicated. At this point, the evaluation is not for the cosmetic aspects of tooth color or shape,

Box 12-1 Sequence of Treatment

Overall evaluation

Maxillary anterior tooth position
Occlusal vertical dimension
Mandibular incisal edge
Maxillary posterior plane
Mandibular posterior plane

Specific criteria

Lip lines
Maxillomandibular arch relationship
Existing occlusion
Crown height space
Temporomandibular joint status
Extraction of hopeless or guarded-prognosis existing teeth
Existing prostheses
Arch form (ovoid, tapering, square)
Natural tooth adjacent to implant site
Soft tissue evaluation of edentulous sites

WWW.HIGHDENT.IR

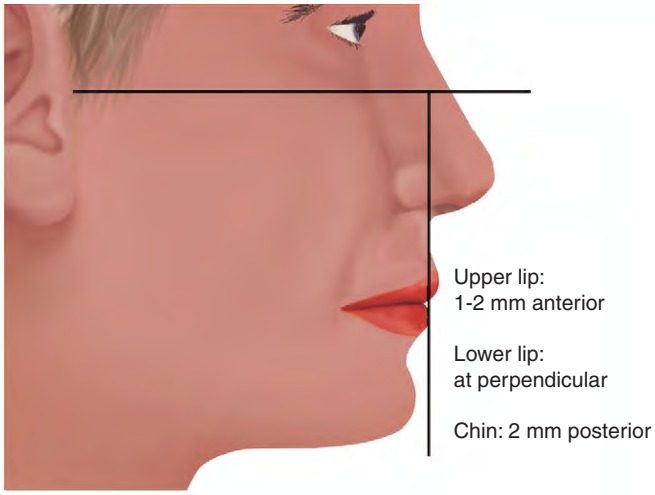

Figure 12-1 The labial position of the teeth is first evaluated relative to the support of the maxillary lip. A vertical line drawn through the subnasal point and perpendicular to the Frankfort plane is a baseline. The maxillary lip should be 1-2 mm anterior to this line, the lower lip even with the line, and the chin 2 mm behind the line.

but tooth position is scrutinized. If the maxillary incisor edge is modified in either the horizontal or vertical plane, all other four elements of the stomatognathic system may also need to be changed.

The labial position of the maxillary anterior teeth is first determined with the lip in repose. This is primarily evaluated by overall support of the maxillary lip and its relationship to the balance of the face, especially in relation to the nose and presence or absence of a philtrum in the midline (Figure 12-1).[1-7] When the teeth are positioned more labial, the vertical position of the lip is elevated. Likewise, a more palatal position of the maxillary anterior teeth results in a more inferior or extended position of the lip. If the labial or horizontal position is going to be altered, orthodontic therapy is the treatment of choice. On occasion, a prosthetic or surgical approach may be indicated with or without orthodontic treatment.

The next step in the evaluation process (when the labial position is acceptable) is the vertical position of the maxillary anterior teeth related to the lip in repose. The maxillary canine is the key for this position. Misch has suggested the canine tip be located approximately 1 mm level with the lip in repose, regardless of the age or sex of the patient (Figure 12-2).[8] A horizontal line drawn from one canine tip to the other should be level to the horizon. The central incisors are 1 to 2 mm longer in a horizontal plane to the canines.

If the patient is wearing a maxillary complete denture, the maxillary anterior tooth position is often incorrect. As a result of resorption of the premaxilla, the denture shifts apically and posteriorly after the bone loss pattern. No other region of the mouth should be restored until this position is corrected, because it negatively influences the proper position of every other segment (e.g., occlusal vertical dimension, mandibular anterior tooth position, posterior planes of occlusion).

Figure 12-2 The vertical position of the maxillary anterior teeth is assessed. The ideal position is determined by the canine to lip in repose position: a horizontal line is drawn from canine tip to canine tip, and the central incisors are 1 to 2 mm longer. This position is consistent (within 1 mm) regardless of the age or sex of the patient.

The maxillary anterior horizontal and vertical tooth positions are evaluated prior to any other segment of the arches, including the occlusal vertical dimension (OVD). If the maxillary anterior teeth are significantly malpositioned, the clinician should obtain further diagnostic studies, such as a cephalometric radiograph, to determine the relationship of the maxilla to the cranial base. The patient may have unfavorable skeletal relationships (vertical maxillary excess or deficiency). If the position of the natural maxillary anterior teeth is undesirable for any reason, orthodontics, orthognathic surgery, or restoration may be indicated. After the position of the maxillary anterior teeth is acceptable, the next prosthetic step is the evaluation of the OVD.

EXISTING OCCLUSAL VERTICAL DIMENSION

In order to determine the crown height space (CHS), the overall issue of OVD must be addressed. The patient's existing OVD should be evaluated early in an implant prosthetic treatment plan, because any modification

WWW.HIGHDENT.IR

will significantly modify the overall treatment. Not only will a change in OVD require at least one full arch to be reconstructed, it will also affect the CHS and therefore the potential number, size, position, and angulation requirements of the implants. The OVD is defined as the distance between two points (one in the maxilla and the other directly below in the mandible) when the occluding members are in contact.[9] This dimension requires clinical evaluation of the patient and cannot be evaluated solely on the diagnostic casts.

The determination of the OVD is not a precise process, because a range of dimensions is possible without clinical symptoms.[10-23] At one time, it was believed OVD was very specific and remained stable throughout a patient's life. However, this position is not necessarily stable when the teeth are present or after the teeth are lost. Long-term studies have shown this is not a constant dimension and often decreases over time without clinical consequence in the dentate or partially or completely edentulous patient. A completely edentulous patient often wears the same denture for more than 10 years, during which time the OVD is reduced 10 mm or more without symptoms or patient awareness.

The OVD may be altered permanently without the symptoms of pain or dysfunction. However, this is not to say that altering the OVD has no consequence. A change in OVD affects the CHS. As such, it may affect the biomechanics of the support system of a prosthesis. In addition, any change in the OVD will also modify the horizontal dimensional relationship of the maxilla to the mandible. Therefore a change in OVD will modify the anterior guidance, range of function, and esthetics.

The most important effect of OVD on tooth (implant) loading may be the effect on the biomechanics of anterior guidance. The more closed the OVD, the farther forward the mandible rotates and the more Class III the chin appears (Figures 12-3 and 12-4). In a Class II, division 2 patient, the more closed the OVD, the steeper the anterior guidance and the greater the vertical overlap of the anterior teeth. Anterior guidance is necessary to maintain incisal guidance during mandibular excursions to decrease the risk of posterior interferences. These conditions will increase the forces to the anterior teeth. Increasing the OVD has the opposite effect. In general, for the dentate patient it may be more precarious to close an OVD than to open it, because the resulting anterior rotation of the mandible will position mandibular incisor teeth facially in a closer relationship to the maxillary teeth in centric occlusion. In completely edentulous patients restored with fixed implant prosthodontics, a change in OVD in either direction affects biomechanics. Opening the OVD and decreasing the incisal guidance with a resulting bilaterally balanced occlusion may increase forces placed on posterior implants during mandibular excursion. Closing the OVD may increase the forces to anterior implants during any excursion. On occasion, a change in the OVD may also affect the sibilant sounds by altering the horizontal position of the mandible.

The OVD is almost never naturally too large and, unless some manufactured interference has been created, it is within clinical guidelines or collapsed. Therefore the restoring dentist most often should determine whether the OVD needs to be increased. In other words, the existing OVD is a position to start the evaluation, not one that necessarily must be maintained.

According to Kois and Phillips, three situations primarily mandate the modification of the OVD: (1) esthetics, (2) function, and (3) structural needs of the dentition.[12] Esthetics is related to OVD for incisal edge positions, facial measurements, and the occlusal plane. Function is related to the canine positions, incisal guidance, and angle of load to teeth or implants. Structural requirements are related to dimensions of teeth for restoration while maintaining a biological width.

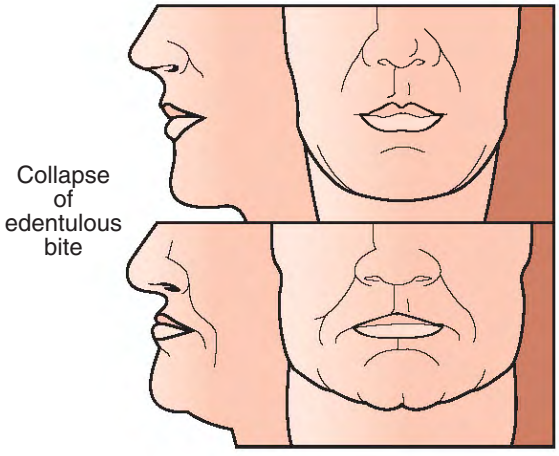

Figure 12-3 The closed occlusal vertical dimension (OVD) rotates the chin farther forward.

Figure 12-4 The more closed the occlusal vertical dimension, the farther forward the mandibular teeth occlude.

WWW.HIGHDENT.IR

Methods to Evaluate Occlusal Vertical Dimension

In traditional prosthodontics, a range of techniques has been described to establish the OVD. Objective methods use facial dimension measurements, whereas subjective methods rely on esthetics, resting arch position, and closest speaking space. There is no consensus on the ideal method to obtain the OVD. Therefore this dimension is part art form and part science. And yet it is critical enough that a final treatment plan should not be rendered until a determination has been made relative to this dimension.

The subjective methods to determine OVD include the use of resting interocclusal distance and speech-based techniques using sibilant sounds. Niswonger proposed the use of the interocclusal distance ("freeway space"), which assumes that the patient relaxes the mandible into the same constant physiologic rest position.[13] The practitioner then subtracts 3 mm from the measurement to determine the OVD. Two observations conflict with this approach. First, the amount of freeway space is highly variable in the same patient, depending on factors such as head posture, emotional state, presence or absence of teeth, parafunction, and time of recording (greater in the morning). Second, interocclusal distance at rest varies 3 to 10 mm from one patient to another. As a result, the distance to subtract from the freeway space is unknown for a specific patient. Therefore the physiologic rest position should not be the primary method to evaluate OVD. However, it should be evaluated once the OVD is established to ensure a freeway space exists when the mandible is at rest.

Silverman stated that approximately 1 mm should exist between the teeth when making an *S* sound.[14] Pound further developed this concept for the establishment of centric and vertical jaw relationship records for complete dentures.[15,16] Although this concept is acceptable, it does not correlate to the original OVD of the patient. Denture patients often wear the same prosthesis for more than 14 years and during this time lose 10 mm or more of their original OVD. Yet all of these patients are able to say "Mississippi" with their existing prosthesis. If speech were related to the original OVD, these patients would not be able to pronounce the *S* sound because their teeth would be more than 11 mm apart. Therefore the speaking space should not be used as the only method to establish OVD. After the OVD has been determined, the speaking space should be observed, and the teeth should not touch during sibilant sounds. On occasion, a short adjustment period of a few weeks may be required to establish this criterion. Therefore a transitional prosthesis should be used to evaluate this position in case it must be modified before the final restoration.

Kois[12] has noted the subjective method of esthetics to establish an OVD is the most difficult to teach inexperienced dental students and therefore is least likely to be initially addressed when teaching the concepts of determining OVD. However, experienced clinicians often value this method more than any other to assess OVD.

After the position of the maxillary incisor edge is determined, the OVD influences esthetics of the face in general. Facial dimensions are directly related to the ideal facial esthetics of an individual and can be easily assessed regardless of the clinician's experience.[17-25] This objective evaluation is usually the method of choice to evaluate the existing OVD or establish a different OVD during prosthetic reconstruction. In addition, it may be performed without the need of additional diagnostic tests.

Facial measurements can be traced back to antiquity, when sculptors and mathematicians followed the *golden ratio* for body and facial proportions as described by Pythagorus. The golden ratio relates to the length and width of a golden rectangle as 1 to 0.618. Many human body proportions follow the golden ratio because it is considered the most esthetically appealing to the human eye.[18-20,25] Leonardo da Vinci later contributed several observations and drawings on facial proportions, which he called *divine proportions*.[21] He observed the distance between the chin and the bottom of the nose (i.e., OVD) was a similar dimension as (1) the hairline to the eyebrows, (2) the height of the ear, and (3) the eyebrows to the bottom of the nose—and each of these dimensions equaled one third of the face.

Many professionals, including plastic surgeons, oral surgeons, artists, orthodontists, and morticians, use facial measurements to determine OVD. A review of the literature found that many different sources reveal many correlations of features that correspond to the OVD:

1. The horizontal distance between the pupils
2. The horizontal distance from the outer canthus of one eye to the inner canthus of the other eye
3. Twice the horizontal length of one eye
4. Twice the horizontal distance from the inner canthus of one eye to the inner canthus of the other eye
5. The horizontal distance from the outer canthus of the eye to the ear
6. The horizontal distance from one corner of the lip to the other, following the curvature of the mouth (cheilion to cheilion)
7. The vertical distance from the external corner of the eye (outer canthus) to the corner of the mouth
8. The vertical height of the eyebrow to the ala of the nose
9. The vertical length of the nose at the midline (from the nasal spine [subnasion] to the glabella point)
10. The vertical distance from the hair line to the eyebrow line
11. The vertical height of the ear
12. The distance between the tip of the thumb and the tip of the index finger when the hand lays flat, with the fingers next to each other (Figure 12-5)

WWW.HIGHDENT.IR

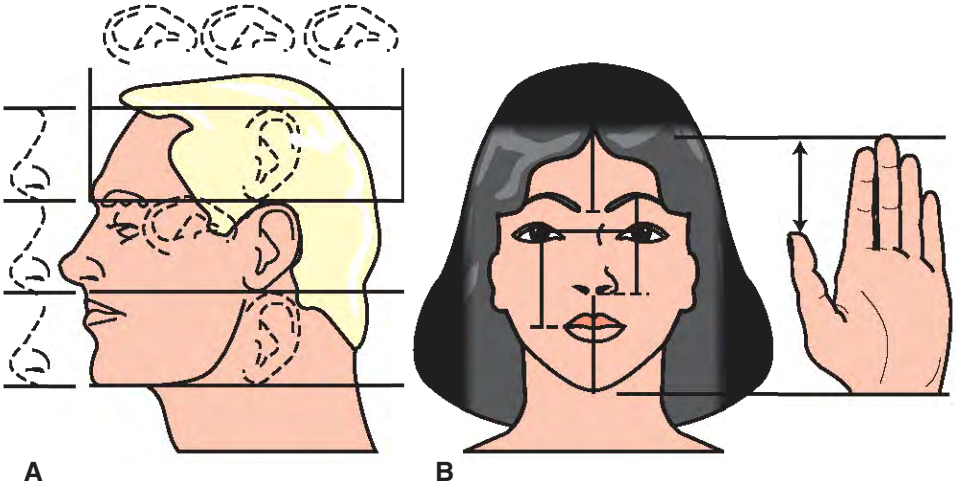

Figure 12-5 The occlusal vertical dimension (OVD) may initially be evaluated by objective measurements, comparing facial dimensions to the existing OVD. Leonardo da Vinci described divine proportions in the following way: **(A)** "The distance between the chin and the nose and the hairline and the eyebrows are equal to the height of the ear and a third of the face. From the outer canthus of the eye to the ear, the distance is equal to the height of the ear and to one-third of the face height." **B,** In addition, facial height (from chin to hairline) is equal to the height of the hand, and the nose is the same length as the distance between the tip of the thumb and the tip of the index finger.

All these measurements do not correspond exactly to each other, but usually do not vary by more than a few millimeters (with the exception of the vertical height of the ear) when facial features appear in balance. An average of several of these measurements may be used to assess the existing OVD. In a clinical study by Misch, the OVD was often slightly larger than the facial measurements listed (more in men than women), but was rarely a smaller dimension.[22] The subjective criteria of pleasing esthetics may then be considered after the facial dimensions are within balance to each other.

Radiographic methods to determine an objective OVD are also documented in the literature. Tracings on a cephalometric radiograph is suggested when gross jaw excess or deficiency is noted. Such conditions may stem from vertical maxillary excess, vertical maxillary deficiency, vertical mandibular excess (long chin), vertical mandibular deficiency (short chin), apertognathia or Class II, division 2 (deep bite) situations. Orthodontic treatment planning of a dentate patient often includes a lateral cephalogram and may be used to evaluate OVD (glabella-subnasale, subnasale-menton). The same measurements may be performed on the edentulous patient.[26,27]

Esthetics are influenced by OVD, because of the relationship to the maxillomandibular positions. The smaller the OVD, the more Class III the jaw relationship becomes; the greater the OVD, the more Class II the relationship becomes. The maxillary anterior tooth position is determined first and is most important for the esthetic criteria of the reconstruction. Alteration of the OVD for esthetics rarely includes the maxillary tooth position. For example, the OVD position may be influenced by the need to soften the chin for a patient with a large mental protuberance.

After the OVD satisfies the esthetic requirement of the prosthetic reconstruction, it may still be slightly refined. For example, the OVD may be modified to improve the direction of force on the anterior implants. In addition, anterior mandibular implants on occasion are too facial to the incisal edge position, and increasing the OVD makes them much easier to restore. Therefore, because the OVD is not an exact measurement, the ability to alter this dimension within limits may often be beneficial.

The evaluation of the pretreatment OVD is also very important for the patient wearing a complete maxillary denture opposing a partially edentulous mandible, especially in the case of edentulous posterior segments that are not compensated by a removable partial denture (Kennedy-Applegate Class I). Under these conditions, a combination (Kelly) syndrome may be present and is especially noteworthy if the OVD is within normal limits.[28] The clinical symptoms include: (1) maxillary incisor denture position up and rotated back from ideal, (2) lower natural anterior teeth overerupted and beyond the mandibular occlusal plane, (3) horizontal occlusal plane tilted apically in the anterior and occlusally in the posterior regions, (4) enlarged tuberosities encroaching on the mandibular interarch space, (5) maxillary palatal hyperplasia, and (6) highly mobile tissue in the premaxilla. In addition, because the mandibular posterior teeth have been missing many years to develop this syndrome, there is a lack of posterior bone in the mandible to place endosteal implants (Figure 12-6).

The proper maxillary incisal edge position and OVD are especially critical for these patients, because of the incidence of mandibular incisor extrusion beyond

WWW.HIGHDENT.IR

Figure 12-6 **A,** A combination syndrome describes the clinical conditions occurring when a maxillary denture opposes mandibular anterior teeth and no partial denture. The mandibular teeth overerupt as the maxillary denture seats up in the anterior and down in the posterior. **B,** The premaxillary bone is lost and the tuberosities enlarged.

the maxillary occlusal plane. The extrusion is usually accompanied by the alveolar process. To position the maxillary incisors properly, the mandibular anterior teeth must be repositioned at the proper incisal plane. Endodontic therapy and crown lengthening procedures usually precede the restorations on the lower arch to obtain a retentive and esthetic restoration.

On occasion, the remaining roots of the mandibular anterior teeth are too short to consider for long-term prognosis after the crown lengthening is performed. Under these conditions, extraction of the mandibular anterior teeth, alveoloplasty, and implant placement may be indicated. When the arch shape is ovoid to tapered, five anterior implants may be adequate to serve as support for a full arch implant–supported restoration. Therefore the implants replace the teeth extracted from overeruption, and they can also replace the posterior missing teeth. This is usually very helpful, because long-term edentulous posterior segments are usually deficient in bone volume. Thus this approach eliminates the need for posterior bone grafts to restore the lower arch with a fixed implant–supported restoration.

MANDIBULAR INCISOR EDGE POSITION

After the maxillary incisal edge and the OVD are deemed clinically acceptable, the position of the lower anterior teeth is evaluated. When natural teeth are present, or when a fixed prosthesis is planned in the anterior region, the mandibular teeth incisal edge should contact the lingual aspect of the maxillary anterior natural teeth at the desired OVD position. A vertical overlap with the maxillary anterior teeth is usually in the range of 3 to 5 mm. The incisal guidance is defined as the influence of contacting surfaces of the mandibular and maxillary anterior teeth on mandibular movements.[9] The incisal guide angle is formed by the intersection of the plane of occlusion and a line within the sagittal plane determined by the incisal edge of the maxillary and mandibular central incisors when in maximal intercuspation. It is responsible for the amount of posterior tooth separation during mandibular excursions and to do so, it should be steeper than the condylar disc assembly (Christensen's phenomenon). Therefore any planned prosthesis and associated compensating curves should be developed within these confines. If not, the maxillomandibular arch position may be improper (i.e., in the skeletal Class II patient) and the posterior teeth may exhibit lateral contacts during mandibular excursions. Under these conditions, the masseter and temporalis muscles do not reduce their contraction force during these movements (as they do when only anterior teeth occlude in excursions), and the strong muscles of mastication continue to contract and place an increased force on the entire stomatognathic system.

The incisal guidance is evaluated on the mounted diagnostic models. A steep incisal guidance helps in avoiding posterior interferences in protrusive movement. However, the steeper the incisal guide angle, the greater force applied to anterior crowns. This may present a significant problem for an anterior single-tooth implant replacement. On occasion, the tooth is lost as a result of severe parafunction on a tooth with a steep incisal guidance (usually from fracture after endodontic therapy). On the other hand, if the existing incisal guidance is shallow, it may be necessary to plan recontouring or prosthetic restoration of posterior teeth that exhibit contact during excursions. For example, a mesially tipped mandibular third molar is often in this situation and may greatly compromise the implant placed in a maxillary second molar region.

EXISTING OCCLUSAL PLANES (POSTERIOR MAXILLARY AND MANDIBULAR PLANES OF OCCLUSION)

After the maxillary anterior teeth position, OVD, and mandibular anterior teeth position are deemed acceptable, the horizontal occlusal planes are evaluated in

WWW.HIGHDENT.IR

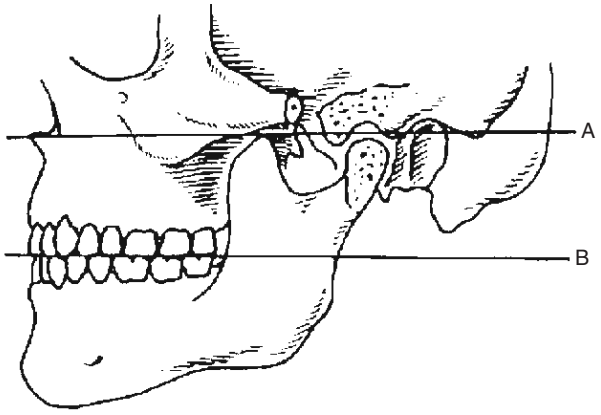

Figure 12-7 The ala–tragus line (Camper's plane) (Line A) is parallel to the occlusal plane of the maxillary teeth (Line B).

the posterior regions of the mouth. Their position related to the curves of Wilson (mediolateral) and Spee (anteroposterior) and to each other should allow harmonious occlusion with maximum occlusal interdigitation and canine or mutually protected occlusion. Ideally, the maxillary posterior occlusal plane should be parallel to the Camper's plane (i.e., to the mid-tragus position) (Figure 12-7). The occlusal plane of existing teeth is especially evaluated in partially edentulous patients in relationship to the final implant prosthesis. Odontoplasty, endodontic therapy, or crowns are indicated to remedy tipping or extrusions of adjacent or opposing natural teeth. A pretreatment diagnostic wax-up is strongly suggested to evaluate the needed changes before implant placement. A proper curve of Spee and curve of Wilson are also indicated for proper esthetics and are reproduced in the compensating curves for complete denture fabrication (Figure 12-8).

The occlusal plane seems like an obvious step in the patient dental evaluation. However, an evaluation of three-unit fixed prostheses in several large dental laboratories revealed most restoring dentists prepare crowns or three-unit fixed prostheses without correcting the opposing occlusal plane. Apparently, the existing occlusal plane is not routinely evaluated before the fabrication of the prosthesis, or the patient and doctor have decided to compromise the final result and restore the missing teeth to the preexisting poor position. Instead, the restoring dentist should highlight to the patient the extrusion or exfoliation of the surrounding teeth, which is often obvious on a panoramic radiograph or diagnostic casts, after it is noted. The need to restore the missing tooth sooner rather than later is apparent to the patient, because the teeth are already shifting as a result of the arch collapse. If the patient cannot afford the complete treatment plan related to the missing teeth, the opposing arch with the poor occlusal plane should be treated first, not the arch with the missing tooth. In this way, opposing quadrants will ultimately be restored to a proper relationship. Of course, the missing

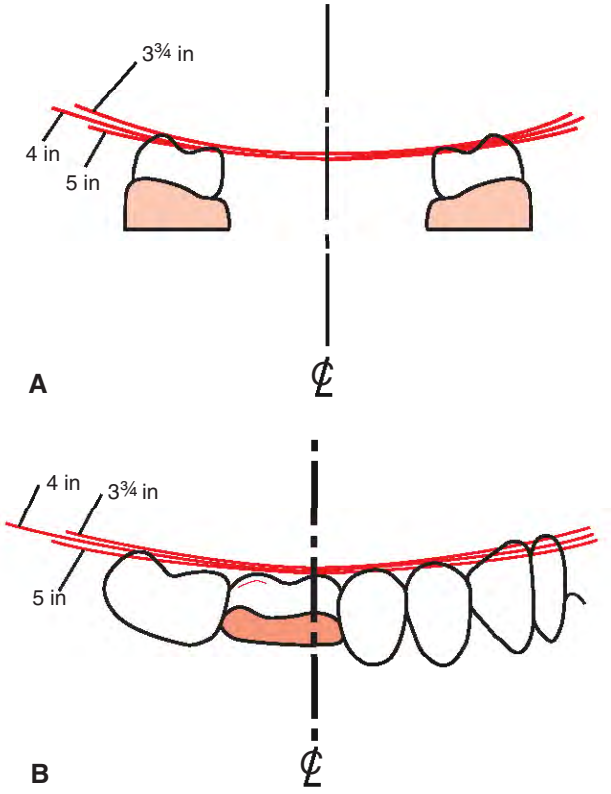

Figure 12-8 **A,** The curve of Spee is also similar to the radius of a 4-inch sphere and is related to skull size. **B,** The curve of Wilson is evaluated before reconstruction in the region. The radius of the average curve corresponds to the radius of a 4-inch sphere.

tooth should be replaced before the occlusal plane is compromised again. An occlusal plane analyzer may be used on diagnostic casts to evaluate pretreatment conditions and assist in intraoral occlusal plane correction. Occlusal analyzers are fabricated in several sizes. The average size corresponds to a 4-inch sphere and provides a starting point for ideal curves of Wilson and Spee. Any discrepancy observed on the cast may be corrected in the mouth. A laboratory-assisted template may be fabricated with this intent. In the laboratory, a vacuum or press fit of an acrylic shell is prepared over the cast. The occlusal plane analyzer is then used to evaluate and correct an improper occlusal plane. A hand piece is used to grind the acrylic shell and protruding occlusal cusps on the duplicate diagnostic cast. The clear acrylic shell is then taken intraorally and inserted over the teeth. Any cusp extending through the acrylic shell is recontoured to the level of the surrounding acrylic. As such, the occlusal plane is rapidly corrected to an ideal condition (Figure 12-9).

The natural dentition opposing a partially edentulous ridge also must be carefully examined and often needs modification before surgical placement of the implants, especially in the posterior regions of the mouth. The opposing teeth have often drifted or tipped into the opposing edentulous site as a result of improper or missing opposing occlusal contacts.

WWW.HIGHDENT.IR

Figure 12-9 **A,** A Misch Occlusal Analyzer is fabricated in three sizes as follows: 3/4-inch, 4-inch, and 5-inch sphere. The occlusal plane of the patient is evaluated before the restoration of the opposing arch. **B,** A press-form (vacuum) shell is placed over a duplicate study cast of the patient. The template and teeth are adjusted so the casts follow the Misch Occlusal Analyzer more accurately. **C,** The areas on the cast are marked to indicate the areas to modify intraorally. The modified template is inserted in the mouth, and the dental regions above the template are recontoured. **D,** Intraorally, the correction is performed using the template.

The CHS in the edentulous site may be significantly reduced as a result of posterior extrusion or exfoliation. The implant drills and implant body insertion often require a posterior crown height space of more than 8 mm from the ideal plane of occlusion, so the hand piece, drill, or implant may be inserted at the correct position and angulation.

The partially edentulous posterior ridge with facial resorption may require implant insertion more medial in relation to the original central fossa of the natural dentition. Enameloplasty of the stamp cusps of the opposing teeth is often indicated to redirect occlusal forces over the long axis of the implant body and may be determined with the diagnostic casts and modified in the mouth before the opposing arch impression and bite registration at the final impression appointment. Then, at the metal try-in or final prosthesis delivery, the final modifications of the opposing dentition are made.

The existing tooth and arch relationships do not need to be perfect before implant treatment. However, because implant dentistry always concerns the replacement of teeth, at least a partial rehabilitation process must occur in the patient before implant placement. The goal would be to identify and restore the prosthetic parameters within normal limits. The correct tooth positions should be first determined, so even if the total treatment time is extended over several years, at least each segment will aim toward a consistent goal. Too often the restoring dentist assumes the patient wants the cheapest or fastest treatment related to each treatment session. As a consequence, the mouth is restored one tooth at a time, fitting the restoration into the patient's present occlusal condition, which usually worsens over time and never improves on its own. As a result, after the patient has been in the same practice for several decades, the mouth is in poorer condition than when the patient started. Although it is easier to restore an entire mouth to the correct occlusal relationships at one time, it is also possible to obtain a similar result one tooth at a time, as long as each step proceeds along the predetermined course of treatment.

WWW.HIGHDENT.IR

SPECIFIC CRITERIA

After the five elements of the existing teeth (restorations) have been evaluated and modified where necessary, several other conditions may modify and hinder the course of implant treatment if overlooked (see Box 12-1 and Appendix A). These conditions should be considered before the final treatment plan is presented to the patient and include the following:

1. Lip lines
2. Maxillomandibular arch relationship
3. Existing occlusion
4. CHS
5. Temporomandibular joint status
6. Extraction of hopeless or guarded-prognosis existing teeth
7. Existing prostheses
8. Arch form (ovoid, tapering, square)
9. Natural tooth adjacent to implant site
10. Soft tissue evaluation of edentulous sites

A large number of these items may be evaluated on the mounted diagnostic casts. Others require the direct observation of the patient. A checklist is helpful to methodically gather the data, which directly influence the treatment plan.

LIP LINES

Lip in Repose

Lip positions are evaluated, including resting lip line, maxillary high lip line (smile), and mandibular low lip line (speech) in relation to the vertical position of the teeth. The lip line positions are especially noted if anterior teeth are to be replaced. The resting lip positions are highly variable, but in general are related to the patient's age. Older patients show less maxillary teeth at rest and during smiling, but demonstrate more mandibular teeth during sibilant sounds.[4] Prosthetic guidelines for incisal edge position established relative to esthetics, phonetics, and occlusion are applied.[1-8,29-35]

A common removable prosthetic guideline is a 1- to 2-mm incisal edge display with the lip at rest, regardless of the patient's age. Instead, the goal should be to position the prosthetic teeth in the most likely location for the patient's natural teeth. A male shows fewer teeth than a female of the same age. In a 50-year-old male, the maxillary incisal edge is often level with the upper lip at rest. This is a similar position for a 60-year-old female. The average upper lip is 20 to 22 mm for women and 22 to 26 mm for men. The maxillary incisal edge is usually at an average of 22 to 24 mm from the floor of the nose depending on the length and contour of the lip. For a short upper lip, the standard guideline for incisal edge of the central incisor would not be acceptable, because this would decrease the height of the maxillary arch.

The position of the maxillary incisor in relation to the maxillary lip and the age of the patient is much more variable than the position of the canine. The lip bow in the center of the upper lip rises several millimeters on some females and is barely obvious on others. The higher the lip bow, the more central incisor surface is seen on the patient, regardless of age. Men rarely exhibit an exaggerated lip bow and therefore have a more consistent incisor edge to lip position. The canine position at the corner of the lip is not affected by the lip bow effect. As such, it is a more consistent position and usually corresponds to the length of the resting lip position from 30 to 60 years of age in both males and females.[8]

In the natural dentition, the maxillary lip is most often longer than the incisal edge after the patient is 65 years old. However, most patients desire the maxillary teeth to be at least slightly visible. Therefore it is not unusual that the restoring dentist will concede this issue. Yet it is risky to extend the maxillary tooth position to decrease the age of the smile without considering the consequences of an increased crown height on moment forces. If pontics rather than implants support the anterior crowns, the poor biomechanical condition is magnified.

An alternative to increasing the length of the anterior teeth may be to increase the thickness of the alveolar ridge. This extra support brings out the lip and also raises the vermillion border. As a result, the teeth are not longer, but the border of the lip is higher. In addition, if the added width to the ridge is with autologous bone, replacing teeth with implants rather than pontics further improves the situation. The fuller maxillary lip may also look younger, because vertical age lines may also be reduced.

High Lip Line

The maxillary high lip line is determined while the patient displays a natural, broad smile.[36,37] There are three categories of maxillary lip lines: low, average (ideal), and high ("gummy"). The low lip line displays no interdental papilla or gingiva above the teeth during smiling. The high lip demonstrates all of the interdental papilla and more than 2 mm of tissue above the cervices of the teeth. The clinical characteristics of the average or ideal esthetic smile include a full length of crown exposure (crowns of normal height), a normal tooth position and alignment (lateral incisors may not be completely straight), a normal tooth form, the interdental papilla, and minimal gingival exposure over the cervicals of the teeth (lip at the free gingival margin of the centrals and canines) (Figure 12-10). Approximately 70% of the adult population has a smile line within a few millimeters of the free gingival margin.

WWW.HIGHDENT.IR

Figure 12-10 **A,** An ideal high smile line exposes the clinical crown and the interdental papillae. **B,** The patient in **A** has a full arch implant–supported FP-3 pink and white porcelain-metal prosthesis (shown here in a retracted position).

Figure 12-11 **A,** A low, high smile line shows no interdental papillae during smiling. **B,** The patient in **A** has a full arch implant–supported FP-3 prosthesis.

The FP-1 prosthesis in implant dentistry attempts to reproduce a normal crown contour. However, with a high lip position during smiling, this goal must also include the soft tissue drape around the crown. As a consequence, the aesthetic requirements are much more demanding and often mandate additional surgical steps to enhance the soft and hard tissues before the crown restoration. The selection of an FP-2 and an FP-3 fixed prosthesis is often based solely on the evaluation of the high lip line. An FP-2 prosthesis is easier to fabricate, because it requires fewer porcelain bake cycles.

Approximately 15 to 20% of adults have a low lip line and do not show the interdental papilla when smiling (more males than females) (Figure 12-11). In these patients, the soft tissue drape does not require a primary focus and can often be compromised with a FP-2 restoration, when the patient is notified before treatment. However, an average to high lip position during smiling contraindicates this restoration type because of poor cervical esthetics. The pink porcelain restoration (FP-3) to replace the soft tissue may be esthetic, but is rarely the treatment of choice for single-tooth replacement. On the other hand, in multiple missing adjacent anterior teeth, the pink porcelain is often the treatment of choice, because the soft tissue drape is usually unable to be ideal, even with bone and tissue grafts.

In a completely edentulous patient, the labial flange of the patient's existing denture may be removed and the lip position evaluated before the completed treatment plan of a fixed restoration. When the lip needs the support of the labial flange for esthetics, yet a fixed restoration is planned, onlay grafts with hydroxylapatite (HA), connective tissue, or autograft or allograft may be indicated to increase labial tissue thickness for proper lip support.

A gummy or high smile line occurs in 14% of the young female patients and 7% of young male patients (Figure 12-12).[36] The normal clinical crown width/height ratio is 0.86 for the central incisor, 0.76 to 0.79 for the lateral incisor, and 0.77 to 0.81 for the canine. If the patient demonstrates a band of gingiva over the cervical areas of the teeth, the height of the clinical crowns are evaluated, relative to their width. Esthetic crown lengthening is often a good option when the height of the central clinical crown is less than 10 mm (and the width is greater than 8 mm). Often the effect of crown lengthening is a dramatic improvement and may be accomplished at the same time as the implant surgery.

In patients with a high lip line who are missing all their anterior teeth, the prosthetic teeth can be made

WWW.HIGHDENT.IR

Figure 12-12 **A,** A high smile line exposes all of the clinical crown, the interdental papillae, and the full gingival margin above the teeth. **B,** This patient has a full arch implant–supported FP-3 porcelain-metal prosthesis.

longer (up to 12 mm) instead of the average 10 mm height to reduce the gingival display and result in a more esthetic restoration. Therefore the height of the maxillary anterior teeth is determined by first establishing the incisal edge by the lip in repose. Second, the high smile line determines the height of the tooth (from 9 to 12 mm). Third, the width of the anterior teeth is determined by the height/width ratios.

The cervical third of the maxillary premolars is also observed during a high smile line. It is not unusual to reveal the cervical third and gingiva of the premolar with a high lip line. These teeth should not appear too long or unnatural in height. Resorption may also cause the implants to be inserted more palatally in this area. The position of these crowns may then be too palatal and therefore affect the esthetic result. Bone grafts are the primary method to eliminate the need for ridge laps or the addition of pink porcelain at the gingiva. They are also indicated to reduce crown height.

Mandibular Lip Line

The mandibular low lip position is often neglected, with disastrous esthetic results. The mandibular incisors are more visible in middle age and older patients during speaking than maxillary teeth. In addition, lower central incisors are often visible in their incisal two thirds during exaggerated smiles.[37,38] Although the maxillary high lip line is evaluated during smiling, the mandibular low lip position should be assessed during speech. In pronunciation of the *S* sound, or sibilants, some patients may expose the entire anterior mandibular teeth and gingival contour. Patients are often unaware of this preexisting lip position and blame the final restoration for the display of the mandibular gingiva, or complain that the teeth look too long. Therefore it is recommended to make the patient aware of these existing lip lines before treatment and emphasize that these lip positions will be similar after treatment. An FP-3 mandibular restoration may be indicated to restore the patient with a low mandibular lip position.

MAXILLOMANDIBULAR ARCH RELATIONSHIP

After the maxillary anterior teeth position, OVD, and mandibular anterior teeth position are evaluated, the maxillomandibular relationships are assessed in the vertical, horizontal, and lateral planes. An improper skeletal position may be modified by orthodontics or surgery. It is far better to discuss these options with the patient before implant surgery, because the implant placement may compromise the final prosthetic result if the arch positions are altered after implant insertion. Compromises of the final result should be discussed with patients when orthognathic surgery or orthodontic therapy is declined by patients with skeletal discrepancies.

Arch relationships are often affected in edentulous ridges. The anterior and posterior edentulous maxilla resorbs toward the palate after tooth loss.[39] The width of the alveolar ridge decreases 40% within a few years, primarily at the expense of the labial plate. Consequently, implants are often placed lingual to the original incisal tooth position. The final restoration is then overcontoured facially to restore the incisal two thirds in the ideal tooth position for esthetics. This results in a cantilevered force on the implant body. The maxilla is affected more often than the mandible, because the incisal edge position in the esthetic zones cannot be modified and is dictated by esthetics, speech, lip position, and occlusion. Anterior cantilevered crowns from maxillary anterior implants often require additional implants splinted together and an increase in the anteroposterior distance between the most distal to most anterior implant positions to compensate for the increased lateral loads and moment forces, especially during mandibular excursions.

An anterior cantilever on implants in the mandibular arch may correct an Angle's skeletal Class II jaw relationship. The maxillary anterior teeth support the lower lip at rest in both Angle's skeletal Class I and Class

WWW.HIGHDENT.IR

II relationships. A traditional complete mandibular denture cannot extend beyond the anatomical support or neutral zone of the lips without decreasing stability of the prosthesis. However, with implants, the denture teeth may be set in a more ideal esthetic and functional position. The anterior cantilever in the mandible is also dependent upon adequate implant number and anteroposterior (A-P) distance between the splinted implants. To counteract the anterior cantilever effect, the treatment plan should provide increased implant support by increasing the surface area by number, size, design, or A-P implant position. In these cases, an RP-4, designed to prevent food impaction, may facilitate daily care and help control the occlusal forces compared with an FP-3 prosthesis.

The palatal resorption pattern of the maxilla, paired with the anterior rotation of the mandible in long-term, complete denture patients may mimic a Class III relationship on a lateral cephalometric radiograph. However, in this condition, Class III mandibular mechanics do not apply (primarily vertical chewers with little to no anterior excursions during mastication or parafunction). On the contrary, these patients exhibit a full range of mandibular excursions and can contribute significant lateral forces on the maxillary restoration, which is cantilevered off the implant base to obtain a Class I esthetic restoration. Therefore additional splinted implants are suggested in the maxilla with the widest A-P distance available. This usually requires sinus grafts and posterior implants in the first or second molar position splinted to the anterior implant support.

Transversal arch relationships include the existence of posterior crossbites, which occur frequently in implant dentistry. Edentulous maxillary posterior arches resorb palatally and medially after tooth loss. Sinus grafts can restore available bone height, but the ridge still remains medial to the opposing mandibular tooth central fossa. This is especially pronounced when opposing a Division C–h or moderate atrophic mandible, because the mandible widens after the residual alveolar ridge resorbs. For example, when mandibular implants are used in C–h bone volume for implant support opposing a complete denture, the posterior teeth may be set in crossbite (especially when out of an esthetic zone) to decrease the moment forces developing on the maxillary posterior teeth, causing denture instability.

EXISTING OCCLUSION

Maximal intercuspation (MI) is defined as the complete intercuspation of the opposing teeth independent of condylar position, sometimes described as the best fit of teeth regardless of the condylar position.[9] *Centric occlusion* is defined as the occlusion of opposing teeth when the mandible is in centric relation (CR).[9] This may or may not coincide with the tooth position of maximal intercuspation. Its relationship to CR—a neuromuscular position independent of tooth contact with the condyles in an anterior, superior position—is noteworthy to the restoring dentist because of the potential need for occlusal adjustments to eliminate deflective tooth contacts and the evaluation of their potential noxious effects on the existing dentition and for the planned restoration. Correction of the problems before treatment presents many advantages and may follow a variety of approaches depending on the severity of the incorrect tooth position: selective odontoplasty (a subtractive technique), restoration with a crown (with or without endodontic therapy), or extraction of the offending tooth. The existing occlusion is best evaluated with facebow mounted diagnostic casts and open-mouth bite registration in CR.

Controversy exists as to the necessity to have MI harmonious with CR occlusion. A vast majority of patients around the world do not have such a relationship, yet they do not exhibit clinical pathology or accelerated tooth loss. Therefore it is difficult to state these two positions must be similar. What is important is to evaluate the existing occlusion and the mandibular excursions to consciously decide whether the existing situation should be modified or be maintained. In other words, dentists should determine whether they are going to ignore or control the occlusion of the patient (Figure 12-13).

As a general rule, the more teeth replaced or restored, the more likely the patient is restored to CR occlusion. For example, if a completely edentulous mandible is to be restored with an implant-supported fixed prosthesis, the CR occlusion position provides consistency and reproducibility between the articulator and the intraoral condition and slight changes in OVD to position anterior implant abutments in a more favorable restoration position may be studied and implemented on the

Figure 12-13 The existing occlusion is evaluated to decide whether the maximal intercuspation (MI) is similar to centric occlusion (the mandible is in centric relation). The mandibular excursions are also evaluated. The lack of canine contact and premature first premolar contact and the uneven occlusal plane indicated correction of the occlusion before final reconstruction.

WWW.HIGHDENT.IR

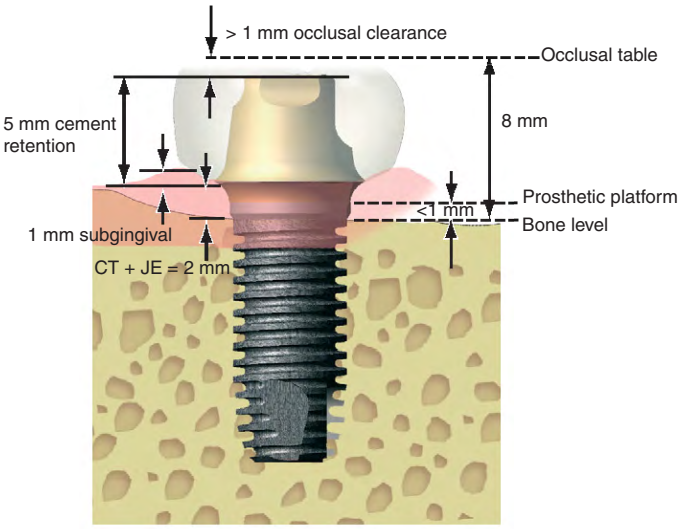

Figure 12-14 The crown height space (CHS) is measured from the occlusal plane to the level of the bone.

articulator without the need to record the new occlusal vertical position on the patient.

On the other hand, when one anterior tooth is being replaced, the existing MI position is often satisfactory to restore the patient, even though a posterior interference and anterior slide into full interdigitation may be present. The underlying question that helps determine the need for occlusal correction prior to restoration of the implant patient is the observation of negative symptoms related to the existing condition. This may include temporal mandibular joint conditions, tooth sensitivity, mobility, tooth fractures or abfraction, or porcelain fracture. The fewer and less significant the findings, the less likely an overall occlusal modification is required before restoration of the patient. However, to properly assess these conditions, the dentist must not ignore them before treatment.

CROWN HEIGHT SPACE

The *interarch distance* is defined as the vertical distance between the maxillary and mandibular dentate or edentate arches under specific conditions (e.g., the mandible is at rest or in occlusion).[9] A dimension of only one arch does not have a defined term in prosthetics; therefore Misch proposed the term *crown height space* (CHS).[40] The CHS for implant dentistry is measured from the crest of the bone to the plane of occlusion in the posterior region and the incisal edge of the arch in question in the anterior region (Figure 12-14). The ideal CHS for an FP-1 fixed implant prosthesis should range between 8 and 12 mm. This space accounts for the biological width, abutment height for cement retention or prosthesis screw fixation, occlusal material strength, esthetics, and hygiene considerations around the abutment crowns. Removable prostheses often require more than 12 mm of CHS for denture teeth and acrylic resin base strength, attachments, bars, and oral hygiene considerations.[41,42]

Biomechanic Consequences of Excessive Crown Height Space

Mechanical complication rates for implant prostheses are often the highest of all complications reported in the literature [43,44] and are often caused by excessive stress applied to the implant-prosthetic system. Implant body or component failure may occur from overload and result in prosthesis failure and bone loss around the failed implants.[43] Crestal bone loss may also be related to excessive forces and often occurs prior to implant body fracture.

The biomechanics of CHS are related to lever mechanics. The issues of cantilevers and implants were demonstrated in the edentulous mandible where the length of the posterior cantilever directly related to complications or failure of the prosthesis.[44] Rather than being a posterior cantilever, the CHS is a vertical cantilever and therefore is also a force magnifier.

When the direction of a force is in the long axis of the implant, the stresses to the bone are not magnified in relation to the CHS (Figure 12-15). However, when the forces to the implant are on a cantilever or a lateral force is applied to the crown, the forces are magnified in direct relationship to the crown height. As discussed in Chapter 6, Bidez and Misch evaluated the effect of a cantilever on an implant and its relation to crown height.[45,46] When the crown height is increased from 10 to 20 mm, two of six of these moments are increased 200%. When the available bone height is decreased, the CHS is increased.

An angled load to a crown also magnifies the force to the implant. A 12-degree force to the implant increases

WWW.HIGHDENT.IR

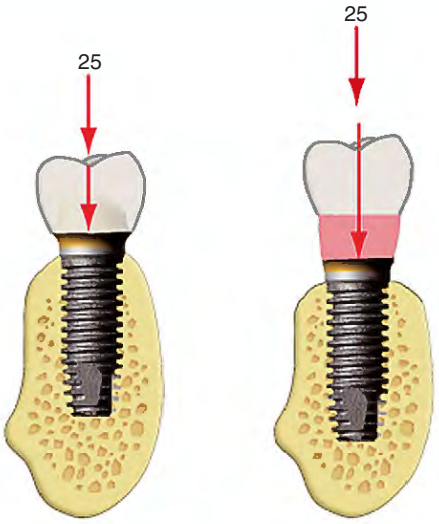

Figure 12-15 The crown height is not a multiplier of force when the load is in the long axis of the implant. However, any angled force or cantilever increases the force and the crown height magnifies the effect.

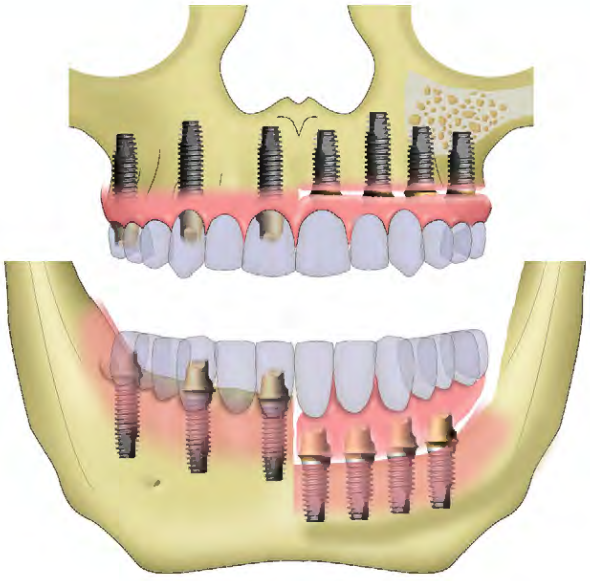

Figure 12-16 The greater the crown height space (CHS), the more implants are required to restore the patient (right side of drawing). The less the CHS (left side), the fewer the implants to restore the patient.

the force by 20%. This increase in force is further magnified by the crown height. For example, a 12-degree angle with a 100-N force will result in a force of 315 N-mm on a crown height of 15 mm.[46] Maxillary anterior teeth are usually at an angle of 12 degrees or more to the occlusal planes. Therefore even implants placed in an ideal position are usually loaded at an angle. In addition, maxillary anterior crowns are often longer than any other teeth in the arch, so the effects of crown height cause greater risk. The angled force to the implant may also occur during protrusive or lateral excursions, because the incisal guide angle may be 20 degrees or more. Anterior implant crowns will therefore be loaded at a considerable angle during excursions compared with the long axis of the implant. As a result, an increase in the force to maxillary anterior implants should be compensated for in the treatment plan.

Most forces applied to the osteointegrated implant body are concentrated in the crestal 7- to 9-mm bone, regardless of implant design and bone density. Therefore implant body height is not an effective method to counter the effect of crown height. Moderate bone loss before implant placement may result in a crown height–bone height ratio greater than 1, with greater lateral forces applied to the crestal bone than in abundant bone (in which the crown height is less). A linear relationship exists between the applied load and internal stresses.[47,48] Therefore the greater the load applied, the greater the tensile and compressive stresses transmitted at the bone interface and to the prosthetic components. The greater the CHS, the greater number of implants usually required for the prosthesis, especially in the presence of other force factors. This is a complete paradigm shift to the concepts advocated originally with many implants in greater available bone and small crown heights and fewer implants with greater crown heights in atrophied bone (Figure 12-16).

Box 12-2 Excessive Crown Height Space: Treatment Planning Options to Decrease Stress

- Shorten cantilever length
- Minimize buccal and lingual offset loads
- Increase the number of implants
- Increase the diameters of implants
- Design implants to maximize the surface area
- Fabricate removable restorations (less retentive) and incorporate soft tissue support
- Remove the removable restoration during sleeping hours to reduce the noxious effects of nocturnal parafunction
- Splint implants together, regardless of whether they support a fixed or removable prosthesis

Because an increase in the biomechanical forces are in direct relationship to the increase in CHS, the treatment plan of the implant restoration should consider stress-reducing options whenever the CHS is increased. Methods to decrease stress are presented in Box 12-2.[40,41]

Excessive Crown Height Space

Crown height space is excessive when greater than 15 mm. Treatment of excessive CHS as a result of vertical resorption of bone before implant placement includes surgical methods to increase bone height or stress reduction methods to the prosthesis. Several surgical techniques may be considered to increase

WWW.HIGHDENT.IR

bone height, including block onlay bone grafts, particulate bone grafts with titanium mesh or barrier membranes, interpositional bone grafts, and distraction osteogenesis.[41,42,49]

Bone augmentation may be preferred to prosthetic replacement. Surgical augmentation of the residual ridge height will reduce the CHS, improve implant biomechanics, and often permit the placement of wider body implants with the associated benefit of increased surface area. Although prosthetics is the most commonly used option to address excess CHS, it should be the last option employed. Gingiva-colored prosthetic materials (pink porcelain or acrylic resin) on fixed restorations or changing the prosthetic design to a removable restoration should often be considered when restoring excessive CHS.

In the maxilla, a vertical loss of bone results with a more palatal ridge position. As a result, implants are often inserted more palatal than the natural tooth position. Removable restorations have several advantages under these clinical circumstances. The removable prosthesis does not require embrasures for hygiene and may be removed during sleep to decrease the effects of an increase in CHS on nocturnal parafunction. It may also improve the deficient lip facial support. The overdenture may have sufficient bulk of acrylic resin to permit denture tooth placement without infringement of the substructure and to decrease the risk of prosthesis fracture. However, it has identical requirements to a fixed prosthesis, because it is rigid during function (hidden cantilever situation).

In the case of removable prostheses with mobility and soft tissue support, two prosthetic levers of height should be considered. The first is the height of the attachment system to the crest of the bone. The greater the height distance, the greater the forces applied to the bar, screws, and implants. The second CHS to consider is the distance from the attachment to the occlusal plane. This distance represents the increase in prosthetic forces applied to the attachment. Therefore in a CHS of 15 mm, an O-ring may be 7 mm from the crest of bone, resulting in a lever action of 7 mm applied to the implants. The distance from the rotation point of the O-ring to the occlusal plane may be an additional 8 mm. Under these conditions, a greater lever action is applied to the prosthesis than to the implant interface. This results in increased instability of the restoration under lateral forces.[42]

A CHS greater than 15 mm means a large amount of metal must be used in the substructure of a traditional fixed restoration to keep porcelain to its ideal 2-mm thickness (Figure 12-17). Control of surface porosities of metal substructures after casting becomes increasingly difficult, because their different parts cool at different rates.[50] If not controlled properly, both of these factors increase the risk of porcelain fracture after loading.[51] For excessive CHS, considerable weight of the prosthesis (approaching 3 oz of alloy) may affect maxillary trial placement appointments, because the restoration does not remain in place without the use of adhesive. Because noble metals must be used to control alloy's heat expansion or corrosion, the cost of such implant restorations is dramatically increased. Proposed methods to produce hollow frames to alleviate these problems include using special custom trays to achieve a passive fit, which can double or triple the labor costs.[52]

An alternative method to fabricate fixed prostheses in situations of CHS 15 mm or greater is the fixed complete denture or hybrid prosthesis, which has a smaller metal framework, denture teeth, and acrylic resin to join these elements together (Figure 12-18). This type of fixed prosthesis is often indicated for implant restorations with a large CHS. On occasion, undercontoured interproximal areas are designed by the laboratory in restorations of large CHS space to assist oral hygiene, and have been referred to as *high-water restorations*. This is an excellent method in the mandible;

Figure 12-17 A large crown height space with a traditional porcelain-metal prosthesis requires a large amount of metal in the substructure with increased risk of complications such as porosities and fracture during cooling.

Figure 12-18 A hybrid prosthesis uses a cast metal substructure (smaller in size than porcelain-to-metal), acrylic, and denture teeth to restore the patient.

WWW.HIGHDENT.IR

however, it results in food entrapment, affects air flow patterns, and may contribute to speech problems in the anterior maxilla.

Because crown height is a considerable force magnifier, the greater the crown height, the shorter the prosthetic cantilever should extend from the implant support system. In crown heights of more than 15 mm, no cantilever should be considered unless all other force factors are minimal. The occlusal contact intensity should be reduced on any offset load from the implant support system. Occlusal contacts in CR occlusion may even be eliminated on the most posterior aspect of a cantilever. In this way, a parafunction load may be reduced, because the most cantilevered portion of the prosthesis is only loaded during functional activity while eating food.

Reduced Crown Height Space

Issues related to CHS are accentuated by an excessive CHS that places more forces on the implant and prosthetic system, and reduced CHS makes the prosthetic components weaker. A reduced CHS has biomechanical issues related to a reduced strength of implant material or prosthetic components, an increased flexibility of the material, and a reduction of retention requirement of the restoration. The fatigue strength and flexure of a material is related to its radius to the power of 4. In fixed restorations, the flexure of the reduced-diameter material may cause porcelain fracture, screw loosening, or uncemented restorations. Therefore in the situation of reduced CHS, material failures are more likely (Box 12-3).

Skeletal discrepancies (deep bite), reduced OVD from attrition or abrasion, minimal bone atrophy after tooth loss, and supraeruption of unopposed teeth may all result in less than ideal space for prosthetic replacement of the dentition. Traditional prosthetic and restorative procedures are indicated to restore the proper OVD and plane of occlusion. However, on occasion, even when the opposing arch is corrected, the CHS may still be less than ideal (<8 mm). The 8-mm requirement for CHS consists of 2 mm occlusal material space, 4-mm minimum abutment height for retention, and 2 mm above the bone for the biological width dimension (which does not include the sulcus, as a crown margin may be 1 mm subgingival for retention or esthetics).

Box 12-3 Reduced Crown Height Space

1. Structural integrity problems of a restoration increase with a reduced CHS.
2. Surgical procedures during implant placement may increase a CHS.
3. Complications of an insufficient CHS may be increased by the surgical position of the implant (i.e., poor angulation, implant platform several millimeters above the bone).
4. Different implant systems have a different minimum CHS related to the height of the prosthetic components.

CHS, Crown height space.

When the reduced OVD is in partially edentulous patients, the OVD may be restored by orthodontics, which is the preferred method. This correction may also require a surgical orthognathic surgery, such as a LeFort I osteotomy and superior repositioning. However, prosthetics is a common approach and may involve an entire arch.

When the opposing teeth are in the correct position and the CHS is insufficient, additional space may be gained surgically with osteoplasty and soft tissue reduction of one arch, provided adequate bone height remains after the procedure for predictable implant placement and prosthetic support (Figure 12-19). If a removable implant-supported prosthesis is planned, an aggressive alveoloplasty should often be performed after tooth extraction to provide adequate prosthetic space.

Additional prosthetic space can also be obtained in many clinical situations by soft tissue reduction, especially in the maxilla. Soft tissue reduction should be performed in conjunction with second-stage surgery if the implants heal in a submerged location. This allows the thicker tissue to protect the implants from uncontrolled loading by a soft tissue–supported prosthesis during healing. If the implants heal permucosally, the reduction procedures should be done during implant placement. Soft tissue reduction procedures may include gingivectomy, removal of connective tissue, or apical repositioning of flaps. Efforts should be made to maintain adequate keratinized tissue around the implants. Soft tissue reduction also has the benefit of decreased probing depths around the implants. However, the definition of CHS is from the bone to the occlusal plane, and, therefore, although the prosthetic space is improved, the CHS remains similar when only soft tissue reduction is performed. Too little CHS can be further complicated when the surgeon places the implant above the bone.

When the CHS is less than ideal, the following prosthetic parameters should be identified[42]:

1. Available space
2. Abutment taper
3. Surface area of abutment
4. Cement type
5. Surface finish
6. Occlusal topography and material
7. Load on final restoration
8. Fit of restoration to abutment
9. Retention of prosthesis
10. Implant manufacturer
11. Implant platform to occlusal plane dimension

The consequences of insufficient CHS include a decrease in abutment height (which may lead to

WWW.HIGHDENT.IR

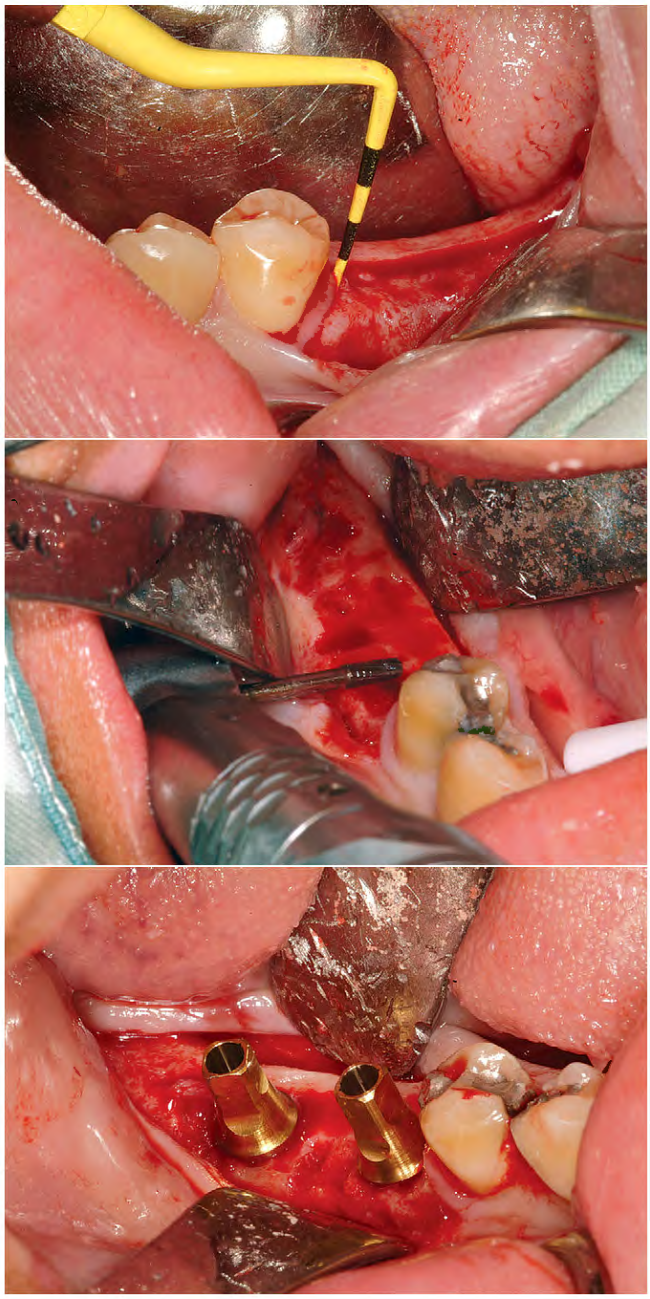

Figure 12-19 **A,** A reduced crown height space (CHS) results in short abutments, less cement retention, and increase of flexibility of the metal in the prosthesis. A mandibular square arch form has a small anteroposterior (A-P) distance. **B,** An osteoplasty increases the CHS before implant insertion. **C,** The implants may be positioned with an increase in CHS and fewer prosthetic complications.

inadequate retention of the restoration), inadequate bulk of restorative material for strength or esthetics, and poor hygiene conditions compromising long-term maintenance.[53] In addition, the final restoration flexes inversely to the cube of the thickness of material. A fixed prosthesis half as thick will flex eight times as much and will further result in loss of cement retention, loosening/fracture of fixation screws, or porcelain fracture.[54] Inadequate thickness of occlusal porcelain or acrylic, or unsupported occlusal material caused by inadequate metal substructure design, may also result in complications such as component fracture.

Minimum restorative requirements vary in function of the implant system. The minimum restoration space may be determined by limiting the occlusal material to 1 mm and reducing the abutment height to the top of the retaining screw. The smallest minimum restoration spaces correspond to 4.21 mm for 3I Osseotite, 4.35 mm for Replace Select (Nobel BioCare), 4.5 mm for Biohorizons, and 4.56 mm for Frialit 2 systems. The greatest restoration space requirements are found in Astra (6.6 mm), Lifecore (6.84 mm), and Straumann (7.05 mm) systems.[42]

When fabricating a cemented restoration, the restoration technique (indirect versus direct) may be influenced by the CHS. Because additional abutment height for retention may be gained by a subgingival margin, the indirect technique (making an implant body level impression) may have an advantage over a direct intraoral impression. An implant body level impression permits the subgingival restoration to be placed more than 1 mm subgingival, with greater accuracy, and therefore represents benefit in a reduced CHS situation, especially when the soft tissue is several millimeters thick. The indirect technique is also used for custom abutments, which can be designed with increased diameter to increase the overall surface area for retention. A custom abutment may also be fabricated to decrease the total occlusal convergence angle to increase retention for cemented prostheses.

The retention and resistance difference between a 3-mm-high and a 5-mm-high implant abutment may be as great as 40% for a 4.5-mm-diameter abutment. Less than 3 mm of abutment height indicates a screw retained crown, 3 to 4 mm requires a screw retained or resin-cemented restoration, and greater than 4 mm of abutment height allows the operator's preference. Splinting implants together, regardless of whether they are screw retained or cement retained, can also increase retention.

Conditions such as cement hardness, surface condition of the abutment, and occlusal material (porcelain versus metal) are also to be considered in limited CHS situations. The occlusal material is important to consider in reduced CHS for two primary reasons. When metal is used as the occluding surface, it is possible to provide greater retention for the prosthesis as a result of an increase in abutment height. The abutment height may be greater because the occlusal space required above the abutment is only 1 mm, whereas porcelain requires 2 mm of occlusal space and acrylic resin requires 3 mm or more. Another factor is the strength of the material. Metal occlusal surfaces provide the greatest resistance to fracture and should be considered when there is limited CHS. When a screw is used to retain the crown, the strength of occlusal porcelain is reduced by 40%. Acrylic resin requires the most dimension for strength and

WWW.HIGHDENT.IR

much more likely to fracture when the CHS is limited. This is why acrylic resin overdentures require more CHS than a porcelain-metal fixed prosthesis.

The surgeon may magnify the prosthetic problem of limited CHS by placing the implant at an angle to the ideal position. Angled abutments lose surface area of retention from the abutment screw hole and further compromise the limited space conditions. In addition, a 30-degree taper on an abutment to correct parallelism loses more than 30% of the abutment surface area and dramatically decreases the retention for the abutment.

Overdentures also exhibit greater complications in situations of reduced CHS. Removable prostheses have space requirements for elements such as a connecting bar, type, and position of attachments and restorative material (metal versus resin). According to English, the minimum CHS for individual attachments is 4.5-mm CHS for locator-type attachments and between 12 and 15 mm for a bar and O-rings.[55] Marinbach reports the ideal CHS for removable prostheses is >14 mm and the minimum height is 10.5 mm.[42] The lowest possible profile attachment should be used in situations of reduced CHS to fit within the contours of the restoration, provide greater bulk of acrylic resin to decrease fracture, and allow proper denture tooth position without the need to weaken the retention and strength of the resin base.

Overdenture bars may be screw retained or cement retained. The most common method of retention for a fixed prosthesis is cement retention. The most common method of bar retention by almost the same percentage for overdentures is screw retention. Yet the advantages of cement retention for a fixed prosthesis also apply to an overdenture bar. Therefore, in minimum CHS situations, the screw-retained bar has a clear advantage, but in ideal to excessive CHS situations, the cemented bar should be considered.

TEMPOROMANDIBULAR JOINT

The temporomandibular joint (TMJ) may exhibit signs and symptoms of dysfunction. Symptoms include pain and muscular tenderness experienced by the patient. Noises or clicking in the joint during opening, deviation of the mandible during jaw opening, and limited jaw movements are signs of potential dysfunction observed during the patient examination. Patient complaints or signs gathered during this phase should be carefully evaluated before further reconstructive treatment.

Palpation of the temporalis, masseter, and internal and external pterygoid muscles is part of the TMJ examination. The muscles should not be tender during this process. Parafunction may contribute to TMJ disorders and is a direct source of muscle tenderness. Under these conditions, the muscles are usually hypertrophied as a result of the excess occlusal forces. The masseter and temporalis muscles are easily palpated. The lateral pterygoid muscle is often overused in this patient profile, yet is difficult to palpate. The ipsilateral medial pterygoid muscles can be as diagnostic and is easier to evaluate in the hamular notch region. It acts as the antagonist to the lateral pterygoid muscle in hyperfunction and, when tender, is a good indicator of overuse of either muscle.

Deviation to one side on opening indicates muscle imbalance on the same side as the deviation and possible degenerative joint disease.[56,57] The patient should also be able to perform unrestricted mandibular excursions. Maximal opening is noted during this exam and is normally greater than 40 mm from the maxillary incisal edge to the mandibular incisal edge in an Angle's skeletal Class I patient. If any horizontal overjet or vertical overbite exists, it is subtracted from the 40-mm minimum opening measurement.[58] The range of opening without regard to overlap or overbite ranges from 38 to 65 mm in men and 36 to 60 mm in women, from one incisal edge to the other.

The practitioner is encouraged to carefully evaluate the TMJ status. It is beyond the scope of this text to address the methods of treatment of TMJ dysfunction. However, many patients with soft tissue–borne prostheses and TMJ dysfunction benefit from the stability and exacting occlusal aspects that implant therapy provides. As such, these patients may benefit from implant support to improve their condition.

EXTRACTION OF TEETH WITH HOPELESS OR GUARDED PROGNOSIS

Maintaining natural teeth in health, function, and esthetics is a primary goal of all dentists. In the past, the maintenance of a natural tooth was paramount, because tooth replacement techniques were costly and not as predictable as repairing the natural tooth. However, advanced repair procedures such as apicoectomy, furcation treatment, or functional crown lengthening may have a lower success rate than an implant to replace the tooth. Therefore, on occasion, the natural tooth is significantly compromised and extraction with replacement of an implant is indicated. A tooth may be considered for extraction because of prosthetic, endodontic, or periodontal considerations. On rare occasions, extraction is considered rather than orthodontics to restore the teeth in a more esthetic or functional position.

Caries on a natural tooth is most often able to be removed and the tooth restored. However, on occasion, the tooth is unrestorable after the decay is removed. A prosthetic axiom is to have at least 1.5 to 2 mm of tooth structure for a crown with a cervical ferule effect. In addition, adequate retention and resistance from the tooth preparation should exist. As a result of the caries, endodontic therapy, post and core, and functional crown lengthening may be required. Thus the procedures to save the tooth are costly and not predictable.

WWW.HIGHDENT.IR

Figure 12-20 **A,** A devital tooth with an endodontic lesion of more than 5 mm has less than an 88% treatment success rate. **B,** The postoperative follow-up of the tooth indicates endodontic success. It may now be restored with less risk of failure. If not successful, extraction rather than retreatment is considered, because the retreatment success rate is 65%.

On occasion, the end result may not be predictable or esthetically pleasing. For example, when a central incisor requires considerable functional crown lengthening, the gingival margin may be compromised and have a poor esthetic result.

A patient with a history of high decay rate with recurrent caries under a crown, requiring endodontics with a post and core before restoration, may also be better served with an extraction and implant insertion. The repeated recurrent decay can be eliminated, at least for that tooth, with an implant. When caries extends within the root canal, the outer structural walls of the natural root may be too thin for a predictable post or restoration. As a result, extraction and implant insertion has a better prognosis.

Endodontic considerations may also consider tooth extraction rather than traditional treatment. When the root canal cannot be accessed because of abnormal root anatomy, an extraction and implant insertion may be considered. On occasion, the endodontic procedure is compromised or an apicoectomy has a moderate to high risk of paresthesia. An implant after extraction may be less invasive and have less risk of paresthesia. A tooth with a "split root" syndrome may have undergone root canal therapy, with pain still present during function. Rather than an apicoectomy, an extraction and implant insertion is usually a definitive treatment that eliminates more predictably pain during function.

A vital tooth has endodontic success rates above 93%, whereas a nonvital tooth has an 89% rate. A large periapical lesion (larger than 5 mm) compromises the success rate of traditional endodontics. A nonvital tooth with large periapical pathology has a success rate of 78% (Figure 12-20).[59,60] Therefore endodontic therapy should be performed and evaluated over several months before post, core, and crown treatment. A retreatment of an endodontic tooth with a periapical lesion has a reported success rate of 65%. As a result, consideration for extraction and implant replacement may be considered for devital teeth with more than 5-mm apical radiolucencies that do not resolve or endodontic retreatment when periapical lesions are present.

The existing teeth in a partially edentulous patient should be evaluated for longevity and existing disease. Implant dentistry has modified the treatment plan philosophy in these patients. Advanced periodontal disease may be addressed with extraction of questionable abutments more frequently than in the past, provided the resulting edentulous area offers sufficient bone for predictable endosteal implant placement and a predictable prognosis.[61] Herodontics are discouraged when the prognosis is poor or failure of treatment may result in inadequate bone for implant placement. The cost of the questionable periodontal treatment may result in the patient's inability to afford the more predictable implant therapy later. This is especially noted when the existing available bone around the tooth roots is compromised in height, especially in the posterior mandible. Unsuccessful periodontal treatment and continual bone loss may render the remaining bone inadequate for extraction and placement of implants. As

WWW.HIGHDENT.IR

a result, when 10 mm of bone is all that remains from the mandibular canal to the remaining bone around the periodontally involved teeth, consideration is given to the projections of periodontal therapy.

The etiology of furcation involvements includes bacteria as well as plaque in the furca with extension of inflammation in the region with loss of interradicular bone. This leads to a progressive and site-specific loss of attachment in most individuals. A first molar furcation entrance cannot be accessed with hand instruments 58% of the time.[62] In addition, pulpal pathoses with accessory canals in the furca may cause problems. Vertical root fracture after endodontic therapy may also occur.

Furcation treatment of molars may include root amputation. The lowest success rate for root resection was found on mandibular distal root resection (75%) (Figure 12-21). Even when successful, the missing root indicates endodontics, core and crown, and the replacement of the distal root. An implant replaces the whole tooth with a higher success rate and often lower cost. A maxillary molar that has lost bone to the furcation has lost almost 30% of the root surface area of support. Therefore when a tooth has a short root or is multirooted, a considerable functional crown lengthening may compromise the remaining support or result in a furcation involvement. The endodontics, post and core, and functional crown lengthening may not be as predictable as extraction and implant insertion. In addition, the cost of conventional treatment may be twice the cost of an implant.

Traditional methods to save a tooth have increased in cost over the years. Multirooted endodontic therapy now approaches the cost of an implant surgery. When functional crown lengthening and endodontic post treatment is also required, the fees are usually greater than extraction and implant insertion. Therefore part of the equation of whether to extract or treat a tooth may also relate to the cost of the service provided. The natural molar tooth that requires endodontics, root amputation, post and core placement, and nevertheless a compromised root with poor root surface area may be cost prohibitive for the service provided.

An implant in the site after tooth extraction is often less expensive and more predictable long term. However, the recent trend to extract teeth with a good prognosis after endodontic or periodontal treatment is discouraged. Implants are not yet 100% predictable, and implants should not be substituted for natural teeth presenting a good or even fair prognosis. Table 12-1 summarizes the decision-making protocol involving a natural tooth abutment.

The dentist evaluates the natural teeth for their quality of health with widely used prosthetic, periodontal, and endodontic indexes. After this is accomplished, the dentist obtains an estimate of longevity and decides whether to extract or to treat and maintain the tooth, following a 0-, 5-, or 10-year rule. If the natural tooth has a favorable prognosis for more than 10 years, it is included in the treatment plan. The decision to use it or not as an abutment requires additional information, but few reasons support removal of the tooth to restore the partially edentulous patient.

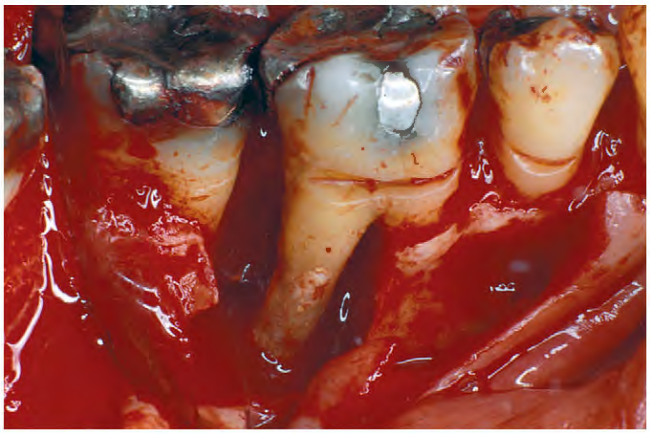

Figure 12-21 A mandibular first molar with a distal root resection generally has a success rate of 75%. Even when successful, the mesial root requires endodontic treatment, core, and crown and the distal root needs replacement. Therefore an implant or three-unit fixed partial denture is indicated. It is more cost-effective to extract, implant, and fabricate one crown, even when bone grafting is indicated.

Table 12-1 Extract or Maintain Natural Tooth: 0-, 5-, and 10-Year Rule

Prognosis	Protocol
>10 years	Keep the tooth and restore as indicated.
5 to 10 years	Independent implant restoration. If the natural tooth must be included with implants in the restoration, make it a "living pontic" by adding implants on each side and splint together.
<5 years	Extract the tooth and graft the site or consider an implant.

If the natural tooth prognosis (after periodontal, endodontic, or restorative therapy when necessary) is in the 5- to 10-year range, independent implant-supported prostheses are indicated. If the edentulous region does not provide sufficient implant support for an independent restoration, then placement of as many implants as possible around the tooth, with treatment alternatives that will permit removal of the tooth without sacrificing the restoration, is indicated. For example, a coping may be placed on the tooth with a 5- to 10-year prognosis, and the tooth may act as "living pontic" in the final restoration, surrounded by sufficient implant support. Whether the tooth is missing or present does not matter. In this way, the prosthesis may be removed in the future and the tooth may be removed (if indicated). The prosthesis essentially is maintained without compromise.[64-66]

WWW.HIGHDENT.IR

The copings on the teeth should be designed with a different path of insertion than fixed partial dentures and should be cemented with permanent cement, whereas the fixed implant prosthesis usually is cemented with a weaker (soft access) or temporary cement. Thus the fixed partial denture path of removal differs from that of the natural tooth coping and, along with the weaker cement, allows the prosthesis to be removed while the coping remains permanently cemented on the tooth. The preparation of copings on natural teeth often requires additional removal of tooth structure to prevent overcontoured restorations and as a consequence may mandate endodontic therapy.

If hygiene is poor with patients with a high caries index or with Grade II or III furca involvement in molars, the tooth most often is considered in the 0- to 5-year category and is considered for extraction, especially when other teeth in the same quadrant are missing or hopeless, or only 8 to 10 mm of bone remains between the crest of bone and the opposing landmark.

A less than 5-year prognosis for a natural tooth adjacent to an edentulous site, despite restorative or periodontal therapy, warrants extraction of the tooth, with grafting and planning for additional implant abutment support as part of the initial treatment plan. This treatment scenario may often be faster, easier, and less costly over a 5- to 10-year period compared with maintaining a questionable adjacent tooth.

Mandibular molars with Grade I furcation involvement often are placed in the 5- to 10-year prognosis category. However, maxillary molars are at higher risk of furca complications and are lost 33% of the time within 5 years. Mandibular molars have a 20% failure at this same reference time. After the molar has a Grade II or higher furca, it has a greater risk of failure and may be placed in the 0- to 5-year category.[67-70]

The dentist should evaluate teeth especially next to multiple edentulous sites. A natural tooth distant from the future implant restoration site is less likely to affect the implant reconstruction and alter the treatment sequences in this site. However, failure of a natural tooth adjacent to an implant site may cause failure of the adjacent implant and almost always (whether failure occurs or not) causes the restoration to be delayed and compromised. Therefore if the practitioner is not sure whether the tooth is in the 0- to 5-year or 5- to 10-year category, the tooth more often should be considered to have the poorer prognosis.

EXISTING PROSTHESES

When present, existing prostheses are evaluated for proper design and function. A removable partial soft tissue–supported restoration opposing the proposed implant-supported prosthesis is of particular interest. The occlusal forces vary widely as the underlying bone remodels. The patient may not even wear the opposing removable partial denture in the future, which will dramatically modify the occlusal conditions. Therefore continued maintenance and follow-up evaluations are indicated, including relines and occlusal evaluation.

The patient should be asked whether esthetic desires are met with the current restorations. It is not unusual that the prosthesis is completely acceptable, yet the patient wishes a different shade or contour for the teeth. If unacceptable to the patient, the reasons for dissatisfaction are noted. In addition, the existing restorations are evaluated throughout the mouth for clinical harmony. It is better to leave a poor esthetic restoration that is in occlusal harmony than to provide one that is esthetic but improper in position, because the latter may influence all future restorations. Pontic regions of existing prostheses may often be improved with the addition of connective tissue grafts.

An acceptable preexisting maxillary removable prosthesis, which will be replaced with a fixed implant prosthesis, may be used as a template for implant reconstruction when fabricating an implant-supported fixed or removable implant prosthesis. The thickness of the labial flange of the existing denture is evaluated and is often removed to evaluate the difference in lip position and support. If implants may be correctly inserted, yet additional lip support is needed once the labial flange is eliminated, an HA, connective tissue, or acellular dermal onlay graft is usually indicated. This graft is not intended for implant support or placement, but to enhance the support of the labial alveolar mucosa to improve maxillary lip support.

ARCH FORM

The edentulous arch form in the horizontal plane is described as ovoid, tapering, or square. In the edentulous patient, the ovoid arch form is the most common, followed by the square, then the tapered form. The square arch form may result from the initial formation of the basal skeletal bone. However, the presence of a square arch form is more common in maxillary implant patients as the result of labial bone resorption of the premaxilla region when anterior teeth are lost earlier than the canine. The tapering arch form is often found in skeletal Class II patients as a result of parafunctional habits during growth and development. It is not uncommon to find different arch forms in the upper and the lower arches.

Two different arch forms are to be considered for implant prostheses. The first arch form is of the residual edentulous bone and determines the A-P distance for implant support. The second arch form is of the replacement teeth position. The dentate and edentulous arch form as not necessarily related, and the worst

WWW.HIGHDENT.IR

situation in the maxilla corresponds to a square residual arch form that supports a tapered dental restoration. The cantilever off the available bone is greatest in this combination (Figure 12-22).

The most ideal biomechanical arch form depends on the restorative situation. The tapering residual ridge arch form is favorable for anterior implants supporting posterior cantilevers. The square dental arch form is preferred when canine and posterior implants are used to support anterior teeth in either arch. The ovoid arch form has qualities of both tapered and square arches.

The arch form is a critical element when anterior implants are splinted together and support a posterior cantilever restoration. For these conditions, a square arch form provides a poorer prognosis than a tapered arch form. The A-P distance or A-P spread is the distance from the center of the most anterior implant to a line joining the distal aspect of the two most distal implants.[55,71] It provides an indication as to the amount of cantilever that can be reasonably planned. When five anterior implants in the mandible are used for prosthesis support, the cantilevered posterior section of the restoration should not exceed 2.5 times the A-P spread, when all patient force and stress factors are low. The actual length of the cantilever depends not only on implant position, but also on other stress factors including parafunction, crown height, implant width, and number.

In other words, the predominant factors to determine the cantilever length are related to stress, not the A-P distance.[45,46] For example, the distance between two implants supporting a cantilever (C) form a Class I lever. For implants 10 mm apart and a 10-mm posterior cantilever, the following forces are applied: a 25-lb force on cantilever C results in a 25-lb force on the most anterior implant from the cantilever (A) and 50 lb for the nearest implant to the cantilever (B), which acts as a fulcrum. An interimplant distance of 5 mm with the same 10-mm cantilever and a 25-lb force applied on C results in a 50-lb force on A and a 75-lb force on B. The diminution in the distance between implants significantly increases the forces to both implants. But, in the first example, if a patient with parafunction bites with a 250-lb force on C, the force on implant A is 250 lb and the force on implant B is 500 lb. In other words, parafunction is much more meaningful in terms of force than the interimplant distance when designing a cantilever. Therefore A-P distance is only one stress factor to evaluate for cantilever length. Parafunction, crown height, masticatory dynamics, arch position, opposing arch, direction of force, bone density, implant number, implant width, implant design, and A-P distance are all factors to be considered. When the force factors are low and the area factors (implant number, width, and design) are high, the cantilever length may be as much as 2.5 times the A-P distance.

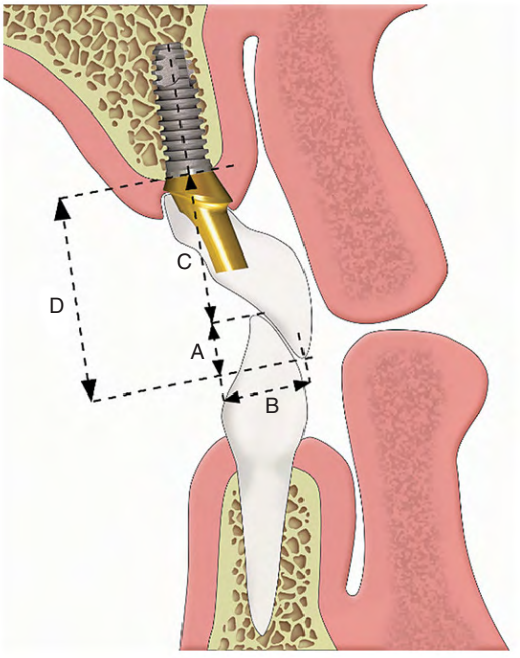

Figure 12-22 The dental arch form may be different than the arch form of the residual arch. A tapered dentate arch form on a square residual bone form is the worst combination, because the anterior teeth are cantilevered from the implant abutments.

As mentioned previously, anterior endosteal implants often may not be inserted in their ideal location in the maxilla as a result of labial plate resorption and inadequate bone width at the implant site. This not only requires implant placement more palatally compared with the original natural teeth, it may also negate the lateral and central positions and require the use of the canine regions in more advanced atrophic arches. The resulting restoration is a fixed, anteriorly cantilevered prosthesis to restore the original arch form. Under these conditions, greater stresses are placed on the dentate tapered arch forms compared with dentate square arch forms, all other factors being identical. The maxillary anterior cantilever to replace teeth in a dentate-tapered arch form requires the support of additional implants of greater width and number to counteract the increase in lateral load and moment force. For example, not only are the canine implants necessary, two more anterior additional implants are suggested, even if bone grafting is required before their placement. In addition, additional posterior implants in the first to second molar region splinted to the most anterior implants are highly suggested. Therefore if a maxillary arch form requires this treatment approach, at least eight implants (four on each side) and an increased A-P distance from molar implants splinted to incisor implants is suggested. In the maxilla, the recommended anterior cantilever dimension is less than for the posterior cantilever in the mandible, because of poor bone density and forces directed outside the arch during excursions (see Chapter 17).

NATURAL TEETH ADJACENT TO IMPLANT SITE

A common prosthetic axiom is to provide the partially edentulous patient with a fixed prosthesis whenever possible. Implant dentistry often may provide the additional abutments necessary to fulfill this goal, regardless of the number of teeth missing. The ability to add abutments in specific locations, rather than being limited to a particular remaining natural abutment that may not always be in optimum health, enables the dentist to expand this prosthetic axiom to most patients. The dentist may use implants as independent support for the restoration or rarely, along with natural teeth in the same prosthesis. In either situation, the treatment plan is strongly influenced by the dental evaluation of the remaining natural abutments adjacent to the edentulous site. Natural teeth may require additional therapy before the final prosthesis can be completed. It is best to communicate with the patient regarding all required treatment involved in the rehabilitation process before the surgical placement of the implants. Otherwise, treatment outcome sequences and cost may conflict with the originally projected result and lead to dissatisfaction, the need to modify the original treatment plan, or a poorer prognosis.

Whether considered for abutment support or not, teeth adjacent to a partially edentulous site are evaluated thoroughly and from a different perspective than the rest of the dentition. Often the adjacent tooth exhibits bone loss next to the edentulous site and presents a less than optimal quality of health. In addition, the available bone characteristics immediately adjacent to the tooth are highly influenced by its presence. Often this is a determining factor in the choice between an independent implant prosthesis, a traditional fixed partial denture, or a removable restoration. When multiple teeth are missing, the treatment becomes even more complex with additional restorative options, such as whether implants and natural teeth may serve as abutments in the same prosthesis.

The dental criteria of the adjacent tooth to an edentulous space addressed in this section are outlined in Box 12-4, as well as important parameters to evaluate in considering implants and teeth in the same restoration. Additional considerations to help assess the restorability of teeth adjacent to potential implant sites appear in Box 12-5.

Abutment Options

Several options are available for the adequate restoration of an edentulous segment. Under ideal conditions, placing implant abutments in sufficient number to fabricate a completely implant-supported prosthesis has several advantages. The most common cause of failure of tooth-supported fixed prostheses is caries of the abutment teeth.[72-74] Unrestored natural teeth do not decay as often as restored teeth, and implant abutments do not decay. The second most common cause of fixed prosthesis failure is endodontic failure or complications of a natural tooth abutment. Implant abutments do not need endodontic therapy. As a result, the 10-year survival rates indicate a greater than 25% improved survival rate for implant prosthesis compared with fixed partial dentures supported by natural teeth.[75,76] Natural teeth abutments compared with unrestored natural teeth are more difficult to clean, collect and retain more plaque, are often more temperature or contact sensitive, and are more subject to future prosthetic periodontal or endodontic treatment. Caries, endodontic problems, or both may cause not only a loss of the fixed prosthesis more than 25% of the time within 10 years, but also almost as often lead to the failure and extraction of at least one of the natural tooth abutments. As a result, an independent implant restoration is the treatment of choice for almost every multiple-tooth edentulous site in a partially edentulous patient.[77]

Natural teeth respond to occlusal forces differently than implants. A light force produces most of the recorded movement of a tooth, whereas the amplitude of implant movement is related directly to the force applied.[78-80] In arches with implant and natural abutments, it is easier to adjust two independent prostheses. When planning an independent implant prosthesis, instead of using a natural tooth as one of the terminal abutments, the dentist usually requires the addition of at least one more implant. An increase in implant

WWW.HIGHDENT.IR

abutment number enhances the implant-bone interface and therefore reduces the stress to the support system and improves the ability of the fixed restoration to withstand additional forces, when necessary. In addition, because of the additional retentive units, uncemented or unretained restorations occur with less frequency. Unretained restorations are the third most common complication reported in fixed prosthodontics.[73,74] Abutment screw loosening is a complication reported for implant prostheses, especially during the first year.[43,81-87] The increase in implant number also decreases the amount of forces on the abutment screws, and thus the risk of abutment screw loosening; as a result, many reasons justify the use of a sufficient number of implants for an independent prosthesis. So many advantages exist for an independent implant-supported fixed prosthesis with multiple units that such a treatment is always the first choice when possible. Unfortunately, completely implant-supported fixed prostheses in partially edentulous patients are not always feasible and carry a higher surgical risk. Thus the natural tooth occasionally may be considered a potential abutment. However, the dentist should consider splinting of implants and natural teeth within the same prosthesis only when the surface area of the implant support does not permit replacement of the total number of missing teeth and additional implant placement is not a possibility.

Transitional Natural Abutments

On occasion, because of the lengthy aspect of implant treatment, when bone regeneration procedures are indicated before implant placement, initially maintaining strategic teeth (even with a poor prognosis) as interim restoration abutments may be desirable. These teeth are often terminal abutments that support a fixed temporary restoration, protect edentulous implant or graft areas from mastication trauma, and avoid the use of a removable soft tissue–borne partial interim prosthesis. After these teeth are extracted after implant healing, their position is often an ideal implant site for the final restoration. The implant then is placed in a second surgical phase. This approach is beneficial to avoid soft tissue–supported restorations on bone augmentation sites but may extend treatment by 6 months.

The transitional abutment scenario is most common in a full-arch rehabilitation patient who has a full-arch fixed restoration on periodontally involved teeth. The prognosis of these abutments may be poor, mandating their extraction (less than 5-year survival category). However, if all these dental elements are extracted, the patient usually is given a full immediate denture as a temporary prosthesis while grafting and implant insertion phases are performed. The psychologic and physiologic changes associated with a denture, even if a temporary solution, may have dramatic consequences for the patient, who may benefit greatly from a stepped approach in which a few poor, short-term, asymptomatic dental elements are maintained while all others are extracted for the sole purpose of providing the patient with a fixed temporary restoration.[88]

The careful selection of the transitional abutments must not hinder the implant treatment. However, an extended treatment time with additional implant placement surgery may be required. For example, four dental elements dispersed throughout the arch may be kept for the temporary restoration. Meanwhile, other sites are extracted, grafted, and implanted. When these implants are healed and ready to be restored, the temporary natural abutments may be extracted and additional implants placed. The healed implants now may support the transitional prosthesis. The new implants, on occasion when the bone density and biomechanical factors permit, may be immediately loaded.

The advantages of the transitional abutment procedures are that a fixed prosthesis maintains the patient throughout treatment, protecting the implant surgical site during the submerged healing phase. Disadvantages include additional cost, increased time, risk of implant site contamination if any problem or flare-up of natural abutments occurs, and increased risk for the initial implants because the foundation is not completely sufficient for support until the additional implants are healed. The dentist should weigh the advantages and risks of such a treatment carefully before proposing it to the patient.

A fixed interim prosthesis also may be supported by three to six additional implants placed in function immediately at insertion to permit the fabrication of a temporary fixed prosthesis while all other implants are submerged. The dentist evaluates these additional implants at the time of final prosthesis fabrication and may or may not include them, depending on their status at that time. Transitional mini-implants also have been developed to that effect.[89] However, caution is needed in using additional implants of normal or minimized dimensions, because the volume of bone used for their placement may be of strategic value during treatment and risks being destroyed by fibrous tissue formation or bone resorption when immediately loaded, which may affect a final implant prognosis. Also, if a final implant fails, the alternate site already has been used and may be unavailable. Further research is needed to establish the exact range of application of these alternatives. Such treatment options are indicated only on a case-by-case basis.

Adjacent Bone Anatomy

The edentulous bony structure adjacent to a natural tooth varies in height, width, length, and angulation and is a reflection of the history of the former tooth.

WWW.HIGHDENT.IR

If the ridge topography is not ideal for endosteal implant placement in the site immediately adjacent to the natural abutment, the dentist should consider a bone graft or a pontic. An osteoplasty needed to obtain adequate bone width in the area adjacent to a natural tooth may compromise the adjacent natural root support, increase the crown height of the final restoration, and affect the esthetic outcome. Therefore osteoplasty to gain additional width is rarely indicated in this situation.

If an ideal prosthodontic abutment position is adjacent to a natural tooth and inadequate bone width is available, augmentation of the edentulous site before implant insertion may improve the bone anatomy without compromising the natural abutment. However, inadequate bone height adjacent to a tooth offers a poorer prognosis for augmentation than in other situations. In general, to grow bone in height is more difficult than to grow it in width. However, when the inadequate bone height of the edentulous site includes the region adjacent to a natural root, the ability to grow additional bone height becomes even more unpredictable and usually unsuccessful. Bone height augmentation is not predictable on a natural tooth root with a horizontal defect. If the natural tooth root has lost bone adjacent to the site, the bone augmentation in height usually will not occur above the position of bone on the root. An alternative for inadequate bone height next to a natural tooth is orthodontic extrusion along with the bone graft. The orthodontic movement will increase bone height next to the tooth and improve the bone graft prognosis. However, the tooth usually requires endodontics and restoration after the orthodontic process.

An implant apically positioned more than 3 mm to 4 mm below the cement-enamel junction (CEJ) and interproximal bone level of the natural tooth root presents potential soft tissue contour problems (Figure 12-23). The soft tissue between the tooth and implant creates a more shallow slope, unlike the steep drop of the level of the bony crest between the elements. Under these conditions, a soft tissue pocket greater than 6 mm may result in the implant crown adjacent to the natural tooth. Therefore when a bone graft for height in a multitooth edentulous site is required to place an implant adequately adjacent to a natural root, the dentist should consider a pontic to replace the missing element next to the natural tooth. The pontic may be supported by a cantilever from implants or teeth or using dual support from teeth and implants.

Figure 12-23 The implant in the mandibular right first premolar site is positioned more than 6 mm below the canine cement-enamel junction. Although bone is present on the distal of the canine, the soft tissue slope around the implant creates a soft tissue pocket greater than 5 mm and increases the risk of peri-implant complications.

In case of inadequate bone volume adjacent to a tooth, the dentist considers treatment options in this order: (1) graft the site if inadequate in width to permit Division A or B implant placement, (2) cantilever a pontic from two or more natural teeth or two or more Division A implants, and (3) fabricate a fixed prosthesis with one pontic connecting an implant with one or two teeth, depending on the adjacent tooth status (Figure 12-24).

Cantilevers

Cantilevers in fixed prostheses result in moment loads or torque on the abutments.[90-94] They are used more frequently for implant-supported prostheses than natural teeth abutments, and several widely diverging guidelines have been recommended for their use, ranging from no extension at all to several teeth.[90-96] The force on the cantilever may be compared with a class I lever. The distance between the most anterior and most distal abutments is divided into the length of the cantilever to determine the mechanical advantage to the farthest abutment from the cantilever. For example, if the implants are 10 mm apart and a distal cantilever of 15 mm is present, the mechanical advantage is 1.5 times. A 25-lb compressive load (chewing force) is magnified to a tensile load of 37.5 lb on the most anterior abutment. The abutment closest to the cantilever acts as a fulcrum and receives the sum of the two loads, or a compressive load of 62.5 lb.

The most common complication for a cantilevered restoration is uncementation of the abutment farthest from the cantilever. This occurs because cement is about 20 times weaker in tension compared with compression forces. For example, the compressive strength of zinc phosphate cement is 12,000 psi, but its tensile strength before fracture is only 500 psi. Takayama has suggested that the cantilever should not extend beyond the distance between the implants to keep the mechanical advantage less than one times this distance.[97] The most common distance between two implant centers is 7 to 8 mm so that the outer dimensions of the implants may be 3 mm apart and the crowns on the implants are similar in size to a premolar. Thus the size of the cantilever should not be greater than a premolar of similar size when two implants support the prosthesis.

Ideally, a cantilever should extend mesially, rather than distally, to reduce the amount of occlusal force

WWW.HIGHDENT.IR

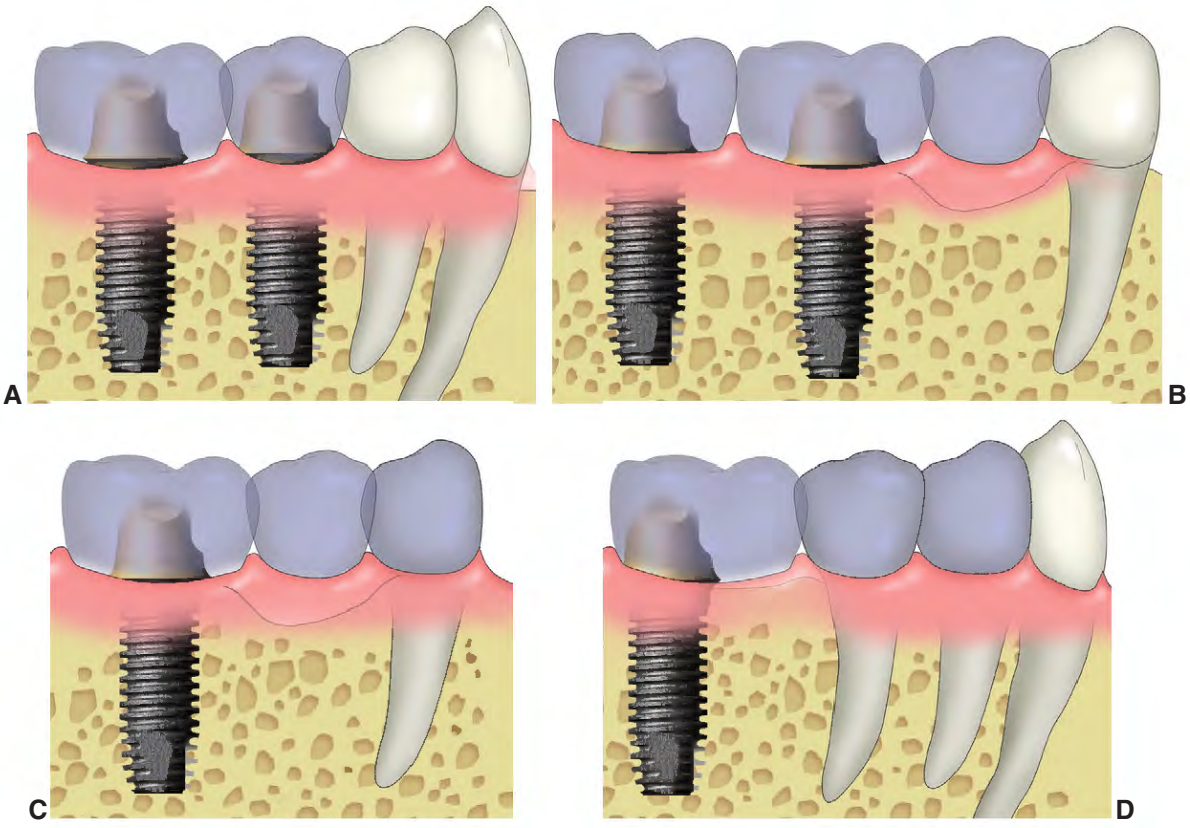

Figure 12-24 **A,** When the inadequate bone adjacent to a tooth can be grafted for implant placement and an independent prosthesis, this is the treatment of choice. **B,** When the inadequate bone adjacent to a tooth cannot be grafted, one option is to cantilever the missing tooth from the anterior teeth or from posterior implants. The posterior implants permit the replacement of more than one tooth but require at least two implants. **C,** When the inadequate bone adjacent to a tooth cannot be grafted, another option is to insert an implant more distal and make a three-unit fixed partial denture by connecting the implant to the nonmobile tooth. **D,** When the inadequate bone adjacent to a tooth cannot be grafted and the tooth is slightly mobile, one option is to insert an implant more distal and make a four-unit fixed partial denture by connecting the implant to two anterior teeth (when the most anterior tooth is nonmobile).

on the lever.[98] The most important factor in determining the length of the cantilever is the amount of force the patient places on the cantilever. In other words, the amount of force generated against the cantilever is more critical than the other factors, including the cantilever length and mechanical advantage. In addition, an angled force is more detrimental than a force in the long axis of the abutments.

The crown height also influences the amount of the force on the cement and bone interface. As such, the cantilever magnifies any other force factor presented and therefore should be used with caution. When cantilevers are used in the final restoration, the occlusion on the cantilevered pontics should be reduced, with no contact on the pontic during mandibular excursions.

Cantilevers on two implants should not be used when force factors are moderate to severe or when other force factors are present (Figure 12-25). Instead, additional implants or grafting and implants positioned without cantilevers typically reduce complications.

When the cantilever forces are too great, the dentist also should consider joining the implants to adjacent teeth to eliminate the cantilever effect.

Implants Connected to Teeth

Although rare, the most common scenario for which a root form implant may be joined to a natural tooth as a terminal abutment is in the posterior regions of the mouth. For example, if a patient is missing the first and second molars in a quadrant (with no third molar present), the segment requires at least two implants of proper size and design to independently restore these two teeth. If adequate bone exists in the second molar and distal half of the first molar but inadequate bone exists in the mesial half of the first molar, a premolar-size pontic is required. The pontic may be cantilevered from the anterior natural teeth or the posterior implants. Either of these options may result in complications because of tensile forces on the cement seal of the abutment farthest from the pontic.

An alternative may be to join the implant to a natural tooth, if all other factors are favorable. This plan is more likely in the presence of a division C–h ridge in the pontic region, when inadequate bone height adjacent to the natural tooth decreases the prognosis of a vertical bone graft. Another scenario in favor of this treatment plan is when the posterior implants are of a

WWW.HIGHDENT.IR

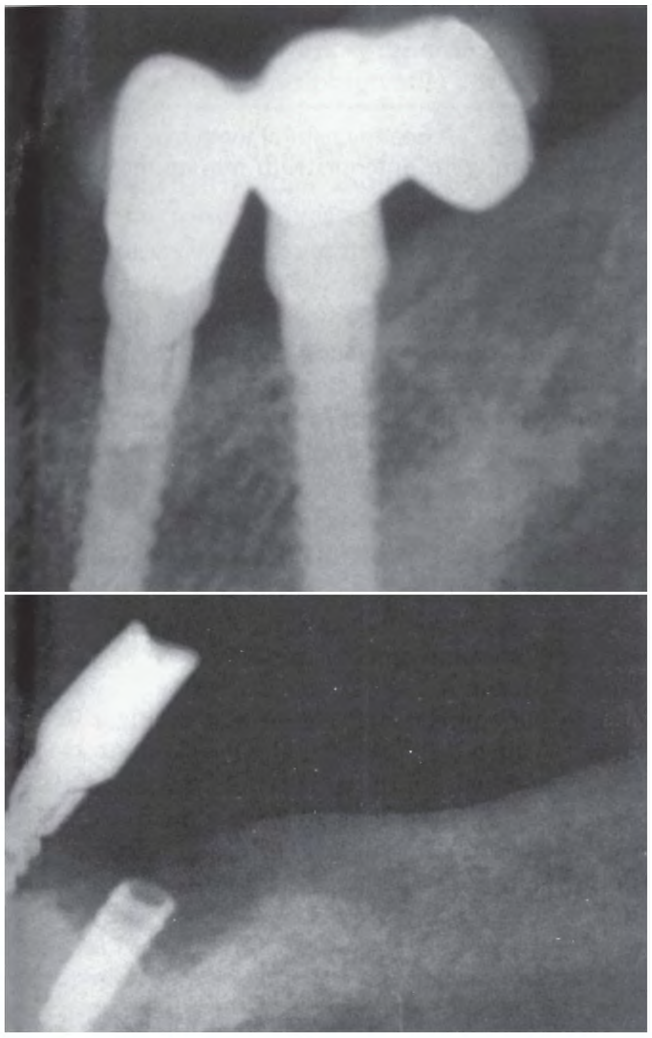

Figure 12-25 **A,** A three-unit fixed restoration with one posterior cantilever. The implants are less than 3.75 mm in diameter. The opposing arch was natural teeth. **B,** The distal implant fractured. Before the fracture, crestal bone loss was evident on both implants. This suggests too great a force was being applied to the support system. The bone loss increases the crown height and directly increases the force to the implants. The smaller diameter implants increase the stress to the bone and have less resistance to fatigue fracture.

more narrow diameter than usual. When two Division B root forms are used in the posterior mandible to replace molars, there should be no cantilever to magnify the force on the implants. Posterior pontics should not be cantilevered from even two splinted Division B root form implants. An additional root form implant or natural tooth is required as an abutment for the fixed prosthesis. When an additional implant insertion is not an option, the posterior implants may be joined by a rigid connector (i.e., a solder joint) to natural teeth within the prosthesis, provided all dental factors are favorable.

The connection of natural teeth and osteointegrated implants within a single rigid prosthesis has generated concern and publications, with studies and guidelines for both extremes (Figure 12-26).[99-106] In other words, some articles report problems, whereas others state that

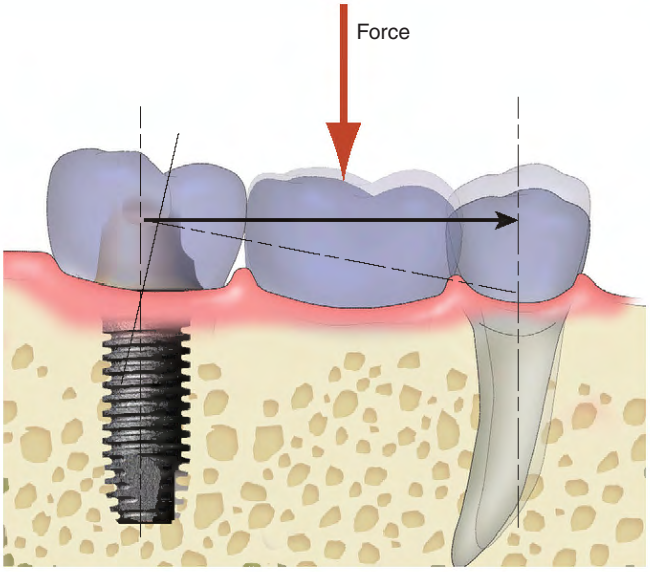

Figure 12-26 Splinting a rigid implant to a natural tooth has caused concerns relative to the biomechanical differential in movement between the implant and tooth. Because the tooth moves more than the implant, the implant may receive a moment force created by the "cantilever" of the prosthesis.

no problem exists. To be more specific to a particular situation, more information is required to design a successful treatment plan. Two designs are available for the connection of implants and teeth within the same prosthesis: a conventional fixed partial denture or a fixed partial denture with a nonrigid connector. To address this issue, the mobility of the natural abutment must be assessed.

Mobility

The mobility of potential natural abutments greatly influences the decision to join implants and teeth more than any other factor. In the implant-tooth rigid fixed prosthesis, five components may contribute movement to the system: the implant, the bone, the tooth, the prosthesis, and implant/prosthetic components.

Vertical Movement

The tooth exhibits normal physiologic movements in vertical, horizontal, and rotational directions. The amount of movement of a natural tooth is related to its surface area and root design. Therefore the number and length of the roots; their diameter, shape, and position; and the health of the periodontal ligament primarily influence a tooth mobility.[107] A healthy tooth exhibits no clinical mobility in a vertical direction. Actual initial vertical tooth movement is about 28 µm and is the same for anterior and posterior teeth.[80] The immediate rebound of the tooth is about 7 µm and requires almost 4 hours for full recovery, so additional forces applied within 4 hours depress the tooth less than the original force.[78] The vertical movement of a rigid implant has been measured as 2 to 3 µm under a 10-lb force and is due mostly to the viscoelastic properties of the underlying bone (Figure 12-27).[80]

WWW.HIGHDENT.IR

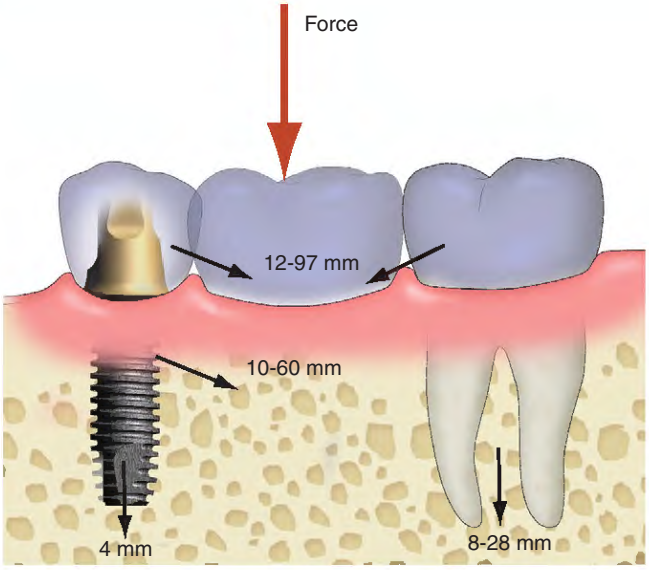

Figure 12-27 A three- or four-unit precious metal prosthesis with an implant and a posterior tooth rigidly splinted has some inherent movement. The implant moves apically 0 to 5 µm, and the tooth moves apically 8 to 28 µm but can rotate up to 75 µm toward the implant because of a moment force. The metal in the prosthesis can flex from 12 to 97 µm, depending on the length of the span and the width of the connecting joints. The abutment-to-implant component movement may be up to 60 µm because of abutment prosthetic screw flexure. As a result, a vertical load on the prosthesis creates little biomechanical risk when joined to a nonmobile tooth, because of the design.

Prosthesis Movement

The fixed prosthesis that connects a tooth and implant also illustrates movement. Under a 25-lb vertical force, a prosthesis with a 2-mm connector fabricated in noble metal results in a 12-µm movement for one pontic and 97-µm movement for a two-pontic span.[108-110] Therefore the fixed partial denture movement helps compensate for some difference in vertical mobility of a healthy tooth and implant. Rangert et al.[106] reported an in vitro study of a fixed prosthesis supported by one implant and one natural tooth and showed that the abutment/gold cylinder screw joint of the system acts as a flexible element. The inherent flexibility matched the vertical mobility of the natural tooth. Therefore the minimal movement of the tooth and the fact that implant, prosthesis, and abutment components have some mobility indicates the risk is small in the vertical direction with the biomechanical difference of implant and tooth in the same prosthesis when one or two pontics separate these units.

Horizontal Movement

Horizontal tooth mobility is greater than vertical movement. A very light force (500 g) moves the tooth horizontally 56 to 108 µm (Figure 12-28). The initial horizontal mobility of a healthy, nonmobile posterior tooth is less than that of an anterior tooth and ranges from 56 to 75 µm, which is two to nine times the vertical movement of the tooth. Initial horizontal mobility is even greater in anterior teeth and ranges from 90 to 108 µm in healthy teeth.[79]

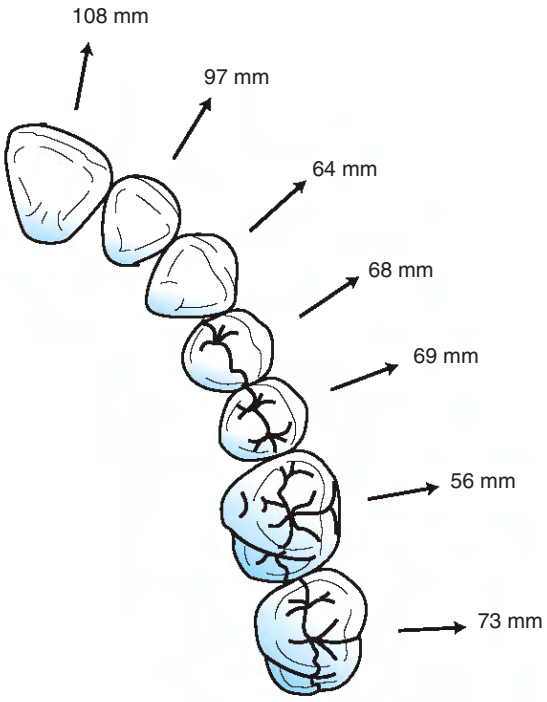

Figure 12-28 A healthy natural tooth may move laterally from 56 to 108 µm, with anterior teeth moving more than posterior teeth.

Muhlemann found that tooth movement may be divided into initial mobility and secondary movement.[78] The initial mobility is observed with a light force, occurs immediately, and is a consequence of the periodontal ligament. If an additional force is applied to the tooth, a secondary movement is observed, which is related directly to the amount of force. The secondary tooth movement is related to the viscoelasticity of the bone and measures up to 40 µm under considerably greater force.

Implant Movement

The implant-bone interface also exhibits lateral movement. Sekine et al.[80] evaluated the movement of endosteal implants with rigid fixation and found a range of 12 to 66 µm of movement in the labiolingual direction. Komiyama[111] measured 40 to 115 µm of implant movement in the mesiodistal direction under a force of 2000 g (about 4.5 psi) and a labiolingual range of 11 to 66 µm. The greater implant movement in the mesiodistal dimension corresponds to the lack of cortical bone between the implants in this direction compared with the thicker lateral cortical plates present in the labiolingual dimension. Therefore the mobility of implants varies in direct proportion to the load applied and the bone density and reflects the elastic deformation of bone tissue.

An interesting note in implant mobility is that no significant difference was related to implant length. This finding further confirms that implant length is not the primary factor for implant support, even in the presence of lateral loads. Bone density affects this condition more than implant length. These mobility

WWW.HIGHDENT.IR

Figure 12-29 An implant joined to an anterior tooth is at greater risk of biomechanical overload. The lateral force on the tooth causes greater movement than a vertical force. Anterior teeth receive more lateral loads than posterior teeth. The lateral loads are transferred to the implant. Lateral loads on the implant increase the amount of crestal bone stresses.

characteristics corroborate the findings of Fenton et al.,[112] who applied a 500-g load for 4 seconds to maxillary anterior teeth and osseointegrated implants. The implants were displaced a mean 10 µm with a rapid elastic return (less than 1 millisecond), whereas the teeth showed a mean displacement of 57 µm with a prolonged viscoelastic return. Therefore when all factors are considered, an implant moves vertically and horizontally, the abutments and prosthesis flex, and the tooth has apical and lateral movements.

Guidelines for Joining Implants to Teeth

A vertical movement/force placed on a posterior implant joined to a healthy posterior tooth causes mesial tension on the implant. The implant can move vertically 3 µm and mesially 40 to 115 µm, and a noble metal-fixed prosthesis with one pontic allows mesiodistal movement of 6 µm. Therefore a natural tooth with no clinical mobility could be connected rigidly to an osseointegrated implant because the implant, bone, and prosthesis compensate for the slight tooth movement. There is extensive documentation that implants can be connected rigidly to stable teeth.[84,85,106,113-116] However, the occlusion should be modified to allow the initial occlusal contacts on the natural tooth so that the implant does not bear the major portion of the initial load.[117]

The mobility of healthy anterior incisor teeth often is recorded as 1 with a range of movement from 90 to 108 µm. Therefore visual clinical evaluation by the human eye can detect movement greater than 90 µm. When the mobility of a natural tooth can be observed, mobility is greater than 90 µm and too great to be compensated by the implant, bone, and prosthesis movement. When the vertical posterior tooth movement, vertical implant movement, mesiodistal implant movement, and prosthesis movement are compared with the same conditions of an anterior tooth with lateral loads, the biomechanical risk factors do not correlate. Therefore one primary condition for joining an implant to natural teeth is the lack of observable clinical movement of the natural abutment.

Another requisite to join an implant to a natural tooth is that no lateral force should be designed on the prosthesis. Lateral forces increase the amount of tooth movement and decrease the amount of implant movement (faciolingual versus mesiodistal). Horizontal forces placed on an implant also magnify the amount of stress at the crestal bone region.[117] Therefore implants rarely should be connected to anterior teeth because (1) anterior teeth often exhibit greater clinical mobility than the implant can tolerate and (2) the lateral forces applied to the restoration during mandibular excursions are transmitted to the natural tooth and implant abutments (Figure 12-29).

When the natural abutment exhibits clinical horizontal movement or conditions promote horizontal forces against the abutment tooth, two options can be selected for the final prosthesis. The first, and the option of choice, is to place additional implants and to avoid the inclusion of natural abutments in the final prosthesis. The other option is to improve stress distribution by splinting additional natural abutments until no clinical mobility is observed.

Guidelines for Splinting Dental Units

Splinting natural teeth does not decrease the mobility of a tooth significantly after the prosthesis is removed; however, the overall prosthesis movement is decreased, especially when the splinted units form an arch. If posterior contacts cannot be eliminated in lateral excursions as a result of skeletal relationships or when opposing a removable prosthesis, splinting often is safer to reduce the risk of long-term complications. In addition, splinting natural abutments also decreases the amount of load to each abutment (when a 150-psi load is distributed to all splinted abutments, the resultant force on each abutment is decreased).[118,119]

The number of teeth to splint together is the number required to eliminate prosthesis movement. The initial dental evaluation may include acid etching and bonding potential mobile natural abutments to each other to determine how many teeth must be joined to reduce the prosthesis clinical mobility to zero. The dentist applies the following prosthetic guidelines:

1. The last tooth connected in the splint should not be mobile. In other words, to decrease mobility, at least the last tooth in the splint (and sometimes more) should be rigid.

WWW.HIGHDENT.IR

2. The terminal abutments in the splint should not have poor retention form.

The natural abutment connected to a rigidly fixated implant should not exhibit clinical mobility or poor retentive form. These same two criteria should be considered for the natural tooth used as a secondary abutment when splinting teeth in a fixed partial denture. A classic axiom for splinting teeth in prosthodontics reads, "It is unadvisable to employ the last tooth as a splinted abutment if it lacks a degree of firmness comparable to its healthy neighbor, because the strain on the firm abutment could be destructive."[120] Implant prostheses may use additional secondary natural abutments to decrease the movement of the prosthesis so that rigid fixation of the implant will not be compromised. However, if the last abutment is mobile, it does not serve the intended purpose. A general guideline is not to end a fixed prosthesis on the weakest splinted abutment. The weak tooth does not offer additional support and further burdens the healthier abutments.[121,122]

In addition, if cement failure occurs or the restoration needs retrieval, the partially retained prosthesis is more difficult to retrieve from the mobile abutment, resulting in more frequent coronal fracture and other complications. The natural teeth exhibit some faciolingual movement, which varies from 56 to 108 µm in health. The discussion here is to reduce tooth movement when it is visible so that the mobile teeth may be connected to the implants. Although the teeth move in a faciolingual direction, different regions of the arch have different directions of movement relative to each other. In other words, the faciolingual direction of the anterior teeth corresponds to the mesiodistal direction of the posterior teeth; therefore, if these dental units are splinted to each other, the splint may become nonmobile.

A dental arch may be described as a five-sided structure. The posterior teeth move in a similar direction to each other, the canines move in a different direction, the anterior teeth move in a third direction, the contralateral canine moves in yet a different direction in comparison, and the other posterior component of the arch moves in a similar direction as the first. The more dental sections are connected, the more rigid the structure. As a general rule, three or more sections rigidly connected create an overall nonmobile dental structure. Even mild to moderate mobile dental units may become a nonmobile unit. This approach to joining implants to mobile teeth usually is limited to conditions when the multiple sections of the dental arch already require restoration. Rarely would one consider crowning eight or more teeth solely to splint to the implant component. Instead, the use of a natural tooth pier abutment may be indicated.

Nonrigid Connectors

Although nonrigid connectors have been advocated in the literature,[67] a nonrigid connector in a unilateral prosthesis rarely is indicated in fixed prostheses[122] and has proved detrimental in implant- and teeth-supported restorations.[103,123] Nonrigid connection reportedly does not improve the stress distribution between the different abutments[124-126] and also has been reported to have caused migration of the natural teeth.[99,103-105,127] If the nonrigid connector exhibits any clinically observed mobility, it moves more than the implant. As such, the implant-supported part of the restoration is cantilevered to the attachment. In addition, the nonrigid, or mobile, attachment adds cost, creates overcontoured abutments, impairs daily hygiene, and does not decrease the clinical tooth movement.

Implants should not be joined to mobile teeth with rigid attachments, which basically add a cantilever on the implant (the tooth acting as a living pontic). If the natural teeth are too mobile in relation to the implant in the same prosthesis, several complications may occur and be detrimental to tooth and implant.[128,129] If the prosthesis is cemented, movement may break the cement-implant abutment seal. Cement does not adhere as well to titanium as to dentin. In addition, the mobile tooth will move rather than break the cement seal. In a screw-in prosthesis, the coping screw often will loosen or break in the implant.

After the prosthesis is loose from the implant, greater stress is applied to the natural mobile tooth. However, until the implant retainer attachment is lost, the greatest stress is transmitted through the prosthesis to the implant and bone section. Crestal bone loss or implant breakage from fatigue are then likely complications.

Regardless, when implants are joined to teeth that act as a terminal abutment, a definitive cement should be used for the natural tooth. Reports of intrusion of the natural tooth connected to an implant include the use of temporary cement to lute a coping to the natural abutment, leaving the final restoration uncemented on the coping,[103-105,127] or the use of a nonrigid connector.

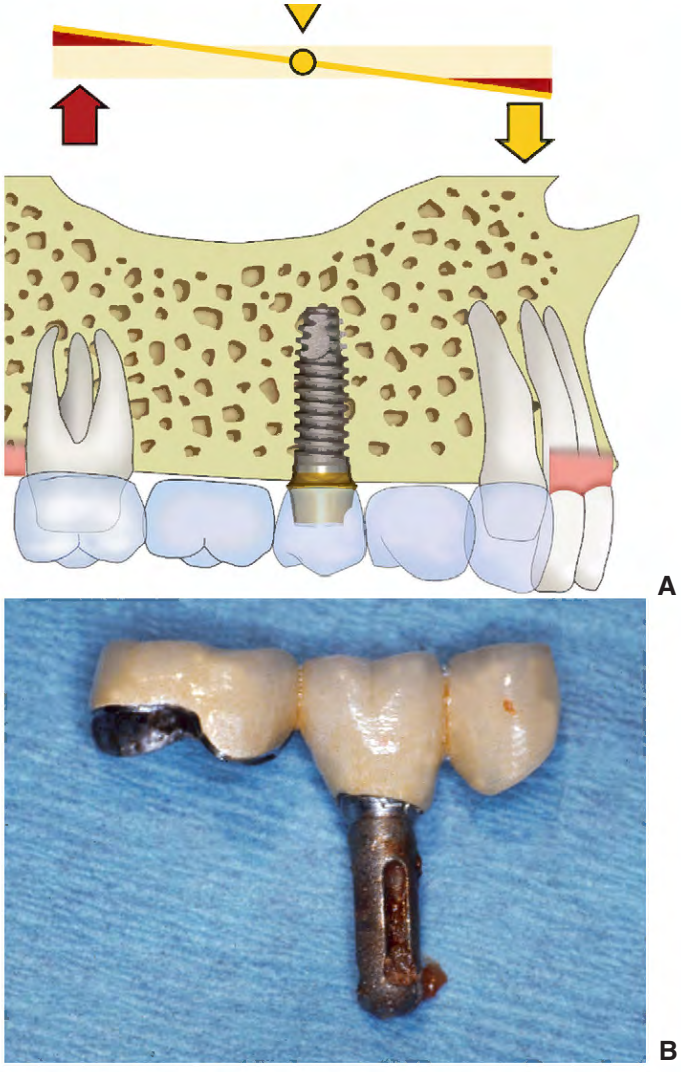
A possible explanation for tooth intrusion could be that the tooth is pushed vertically 28 µm, but wants to rebound only 8 µm. The fixed prosthesis rebounds immediately and pulls on the tooth. The cement seal eventually breaks, causing a space to develop, which is first occupied by air. The prosthesis then acts as an orthodontic appliance and continually pushes the tooth in a vertical direction. Eventually, the space is occupied by saliva, and hydraulics continue the downward force during mastication. The tooth eventually submerges or intrudes from the prosthesis (Figure 12-30).

Pier (Intermediary) Abutments

A pier abutment is one between two other abutments, sometimes referred to as intermediate abutment. The intermediate abutment may be an implant or a natural tooth, and each type plays a different role in the overall treatment. When an implant serves as a pier abutment between two natural teeth, the difference in movement between implant and tooth may increase the

WWW.HIGHDENT.IR

Figure 12-30 An implant should be joined to a natural tooth with a rigid connection, and the natural tooth crown should be cemented with definitive cement. If the cement seal fails, the tooth may intrude from the prosthesis.



A

B

Figure 12-31 **A,** When an implant acts as a pier abutment, the biomechanical risk of uncemented restorations is increased, especially under lateral loads. The more rigid implant may act as the fulcrum of a class 1 lever. The cement seal breaks on the more rigid tooth or the least retentive abutment. **B,** This implant was overloaded and failed because the cement seal broke on the natural tooth. The compressive force on the pontic led to a tensile force on the tooth, and the implant acted as a fulcrum. Cement is 10 times weaker under tension. After the cement seal broke from the tooth, all the loads were applied to the implant only, which then failed from overload.

complication rate compared with one tooth joined to two implants. The pier implant exhibits less movement than a terminal abutment and acts as the fulcrum of a Class I lever (Figure 12-31).

This problem is magnified by a longer lever arm such as a pontic between the implant and tooth. A pier implant abutment may cause complications even when joined to nonmobile teeth as terminal abutments. The cement tensile strength is often 20 or more times less than the compressive strength. Therefore when the implant acts as a fulcrum, an uncemented abutment (usually the least mobile tooth or least retentive crown) is a common consequence, with decay being the next most common occurrence.

Uncemented restorations are a common complication in fixed partial dentures, even when all aspects of treatment are within acceptable limits. Any condition that may increase this problem, such as the one presently addressed, should be carefully avoided. For most clinical situations, an additional implant can be placed in at least one of the sites next to a tooth to provide the support needed to fabricate an independent, cantilevered, implant-supported prosthesis. The better option is to perform bone grafting, place implants in both terminal abutment locations next to the natural teeth, and avoid connecting implants to teeth (Figure 12-32).

When bone grafting is not an option and additional implants cannot be inserted, a mobile attachment can be used to restore the implant pier abutment between two natural nonmobile teeth (Figure 12-33). The nonrigid attachment may connect the implant and the least retentive crown to prevent the implant pier abutment from acting as a fulcrum. In conventional fixed prostheses, the "male" portion of a nonrigid attachment usually is located on the mesial aspect of the posterior pontic, whereas the "female" portion is in the distal aspect of the natural pier abutment tooth. This prevents mesial drift from unseating the attachment.[122] However, an implant does not undergo mesial drifting, and the nonrigid connector location is more flexible.

When a natural tooth rather than an implant serves as a pier abutment between two or more implants, the situation is completely different from the previous scenario. When the two or more implants may support the load of the prosthesis alone, the natural tooth becomes a living pontic. In other words, in absence of the tooth, the dental unit would be a pontic.

Because the tooth has greater mobility than the implant and does little to contribute to the support of the prosthetic load, it is referred to as a pontic with a root, or a living pontic (no more than one adjacent site

WWW.HIGHDENT.IR

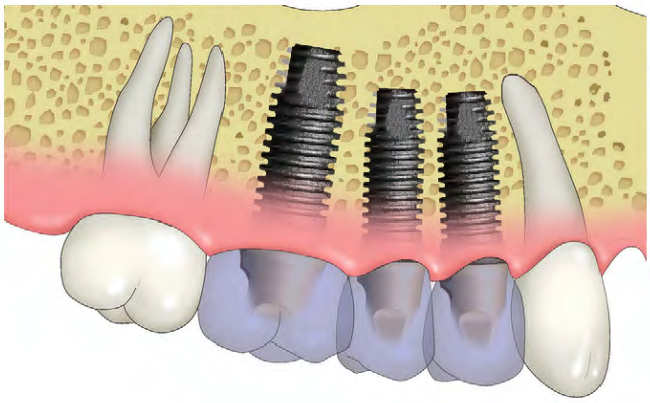


Figure 12-32 A better option is to graft the sites and place implants in terminal abutment locations and to fabricate an independent prosthesis.

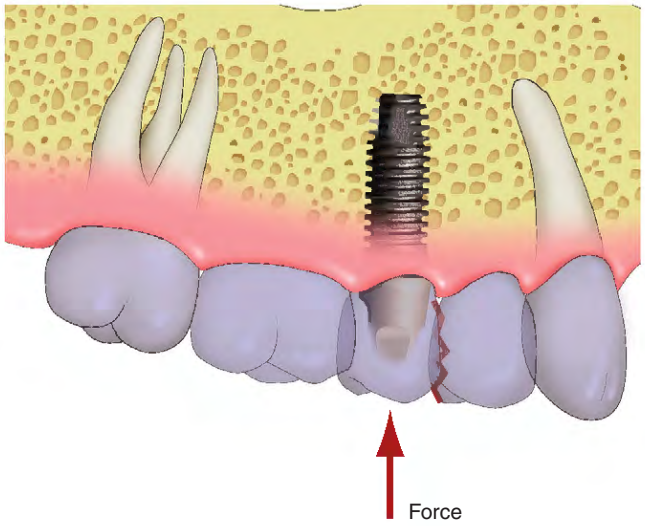

Figure 12-33 When grafting and additional implants are not an option, a mobile attachment may be used to prevent the pier implant from acting as a fulcrum.

should be a pontic) (Figure 12-34). This scenario is best when no additional pontics are between the implants and the tooth. On occasion, multiple implants are splinted together to cantilever one or two pontics, yet a healthy, natural tooth is positioned among the implants. The tooth essentially is ignored in the development of the treatment plan, other than the dentist having to fabricate a crown rather than a pontic in the splinted prosthesis (Figure 12-35).

For a natural pier abutment between two implants, a stress breaker is not indicated. One advantage of keeping the natural tooth, even though it does not contribute to the support of the prosthesis, is the proprioceptive aspect of the periodontal complex.[123,128] Implant prostheses have higher bite forces during mastication than natural tooth restorations because of the decrease in occlusal awareness. A living pontic may decrease the interaction of the forces found during function.

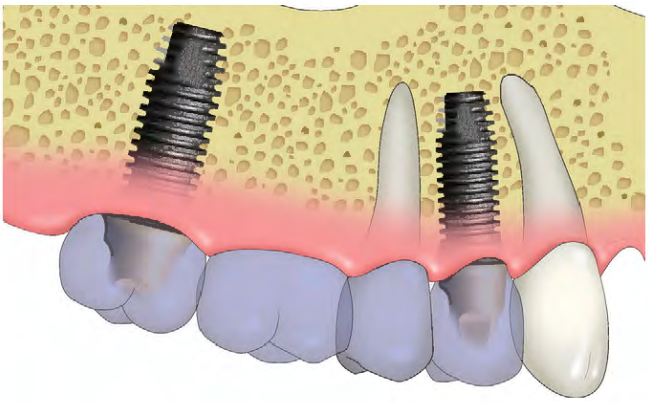

Figure 12-34 When a natural tooth serves as a pier abutment between two or more implants, the tooth may act as a living pontic. No stress breaker is needed in this situation.

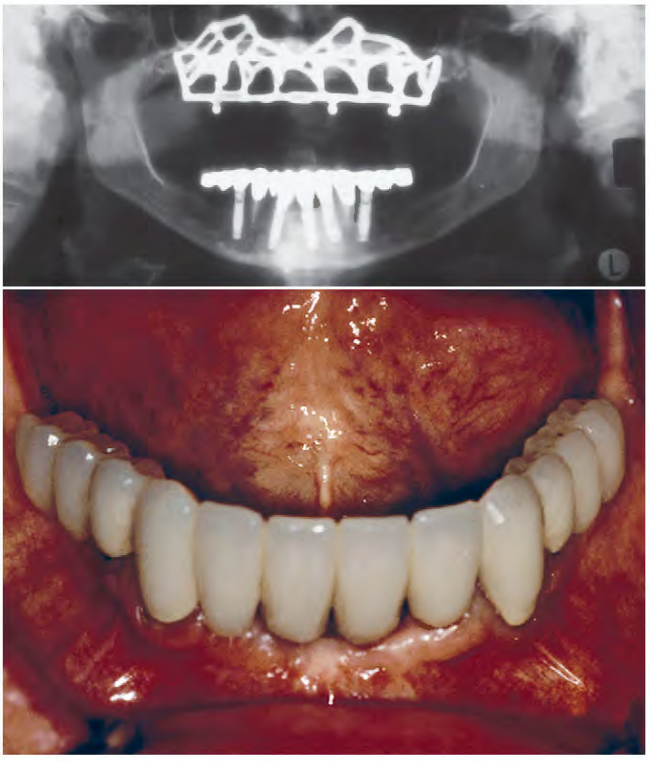

Figure 12-35 **A,** The mandibular restoration has five implants and two natural teeth splinted together, so a cantilever may be used to replace the posterior teeth. The five implants support the load of the restoration. The natural teeth pier abutments act as living pontics. **B,** An intraoral view of the fixed prosthesis. The natural teeth may give some proprioception to the restoration, especially when in the canine position. The support of the restoration is primarily from the implants, which surround the teeth and are splinted together.

Natural Abutment Evaluation

The evaluation of a potential abutment adjacent to an edentulous site includes the following: (1) abutment size, (2) crown/root (implant) ratio, (3) tooth position, (4)parallelism, (5) caries, (6) root configuration, (7) root surface area, (8) endodontic status, and (9) periodontal status.

Abutment Size

Uncemented restorations are one of the most common complication of fixed prostheses.[72-74] After the

WWW.HIGHDENT.IR

crown on the natural abutment becomes uncemented, a significant concern is caries. Decay may proceed rapidly and result in loss of the abutment, creating a need for endodontic treatment, post and core, a new prosthesis, or an abutment with even poorer retention. These same conditions exist if the natural retainer becomes uncemented from an implant-tooth restoration. In addition, the implant is at greater risk. The fixed prosthesis then acts as a cantilever with a dramatic increase in moment force on the implant. Crestal bone loss, prosthesis or abutment screw fracture, implant fracture, or mobility and failure of the implant are likely complications.

When natural and implant abutments are combined in the same prosthesis, uncementation occurs more frequently on the implant. Tooth mobility fatigues the cement seal and increases the forces on the implant. The parameters of retention are similar for a tooth or implant and mainly are influenced by the diameter and height of the abutment.[129-131] Molars are more retentive than premolars because of their increased surface area, all other factors being equal. Wider implant abutments are more retentive than narrower ones. Limited crown height because of limited interarch space also decreases retention. Splinting of teeth with limited crown height to improve retention often compromises access for hygiene in the interproximal areas. Instead, crown lengthening is often indicated in case of limited interarch space to improve the retention of the prosthesis and the esthetic result without compromising home care. A customized abutment of larger diameter can be used on an implant abutment of reduced height. Crowns of reduced size require minimal tapering and additional retentive elements such as grooves or boxes to limit the path of insertion and direction of dislodgment.[130-132]

Crown/Root Ratio

The crown/root ratio represents the height of the crown from the most incisal or occlusal position to the crest of the alveolar ridge around the tooth compared with the height of the root within the bone. This criterion is most important when lateral forces are expected against the crown, as in mandibular excursions. The lateral forces act as a Class I lever on the tooth, with the fulcrum at the crest of the bone. As the crown height increases, the root height decreases, creating a force multiplier.

The crown/root ratio is indicative of the risk of mobility and amount of additional stress the tooth may sustain when used as a fixed partial denture abutment. A patient with a history of periodontal disease may show an increased crown/root ratio, yet no abutment mobility. However, the long-term risk of mobility is increased if the tooth is used as an abutment for a prosthesis. Lateral forces are most detrimental in this situation because of the increased moment force. Splinting may be indicated to distribute stress, and occlusal schemes must be modified to protect these abutments from horizontal stresses.[133] The most ideal crown/root ratio for a fixed prosthetic abutment is 1:2, but this is rarely observed. A more common condition is 1:1.5, and a 1:1 ratio is the minimum requirement when opposing natural teeth or implants and when serving as an abutment for an implant-tooth prosthesis.[134] In addition, the doctor and patient must realize that teeth with an increased crown/root ratio often are restored with a FP-2 or FP-3 prosthesis. A high lip line during smiling and low lip line during speech should be evaluated carefully to determine the prosthetic design. Crown/implant ratio is not considered in a similar way as a crown/root ratio. The implant does not rotate around a center located two thirds down the endosteal/root portion, as does a tooth. Instead, it captures the force at the crest of the ridge. The implant length does not affect its mobility and does not affect its resistance to a lateral force. Although a minimum height requirement does exist and approaches 9 mm, implants greater than 12 mm in healed bone sites do not demonstrate clinical benefit. This is not to say crown height is not important. Crown height is a vertical cantilever on a tooth or implant and will magnify angled, lateral, or cantilever forces. However, the effect of crown height cannot be reduced by increasing the length of the implant. Instead, the dentist should consider reduced cantilever lengths or reduction of angled forces on the prosthesis.

Tooth Position

The dentist considers tooth position next to the edentulous site, including whether the tooth is in the anterior region of the mouth, the intermediate position, or the posterior region. Regardless of arch position, some considerations remain similar. When the natural tooth adjacent to the implant site is in the anterior region, greater mobility and often lateral directions of force are present. Therefore under these conditions the implant is rarely connected to a natural tooth as a terminal abutment. The most common situation in which an implant may be connected rigidly to a natural tooth as a terminal abutment is in a posterior edentulous site with a second or first premolar adjacent to the potential implant site.

The bone adjacent to a natural tooth often is compromised, especially in the long-term edentulous Kennedy-Applegate Class I or Class II patient. Under these conditions, the edentulous site is often deficient in width and height. As previously mentioned, bone grafting in width is much more predictable than height, especially in the posterior mandibular regions.

A sinus graft may provide adequate height of bone for endosteal implants in the posterior maxilla, but onlay grafts on the posterior mandible are much less predictable, and nerve repositioning before implant placement is fraught with potential complications. Bone width augmentation is a usual treatment plan, and bone grafting for height in the posterior maxillas has become a routine procedure, but the posterior mandible is less often a candidate for height augmentation, unless block grafts or more advanced grafting techniques are selected.

WWW.HIGHDENT.IR

When adjacent teeth have been missing for a long time, the remaining natural abutment often has drifted from its ideal position and frequently exhibits tipping, tilting, rotation, or extrusion. The dentist should consider correction of the natural abutment position in the original treatment plan for the partially edentulous patient, whether or not the natural abutment is joined to the implant. A good habit to form is to evaluate and correct any dental unit that will contact the new restoration. Enameloplasty to improve the occlusion or change the contact shape and position next to the implant prosthesis is not unusual. The path of insertion of the implant prosthesis and the size and shape of the interproximal space also may require modification. Treatment also may consist of a crown when beyond the ability merely to reshape the tooth. Orthodontic movement to correct interarch or gross occlusal correction, especially when skeletal patterns require improvement, may be indicated. One can plan orthodontic treatment along with the healing phase for rigid fixated implants. One also may use orthodontic treatment to develop available bone for an implant next to a natural tooth. Moving the tooth slowly through the bone to a more remote position generates bone growth and an improved implant site.

Parallelism

As previously discussed, clinical movement can be eliminated by splinting natural abutments. As such, splinting mandibular incisors is more common in implant dentistry than traditional prosthodontics. These teeth often are crowded or rotated. In addition, the path of insertion of a prosthesis that includes anterior and posterior dental units often requires more extensive tooth preparation.

Some of the indications for attachments in a fixed or removable partial denture include joining nonparallel teeth or splinting anterior and posterior teeth in the same prosthesis. The attachment should usually be rigid in design, size, and fabrication. All of these factors limit the path of insertion of the final prosthesis. Several abutments may need endodontic therapy to achieve this goal. If this is not explained to the patient before treatment begins and endodontic therapy is required, the patient often feels that inadequate treatment has been rendered.

Endodontic therapy or posts and crowns for overlapping anteriors still may provide inadequate embrasures for hygiene. This condition not only compromises esthetics but also may result in the loss of more than one tooth because of periodontal disease. Selective extraction of incisors may even be indicated if rotations or overlapping of teeth creates an unfavorable environment for daily maintenance.[118]

Caries

The dentist should eliminate all carious lesions before implant placement, even when the teeth will be restored with crowns after implant healing for the final prosthesis. Rigidly fixated implants usually require several months of healing after initial placement. The progression of the decay may alter the final treatment plan, with a decrease in crown retention and increased risk for endodontic therapy, posts, cores, or even loss of a desired abutment. Should endodontic therapy be indicated, the obturation of the canals ideally should be completed before implant surgery to avoid possible confusion in the differential diagnosis, if both treatments were overlapping in time and location. If caries are eliminated at the same time as implant surgery, elimination of caries should be performed before reflection of any tissue.

Root Configuration

The natural root configuration may affect the amount of additional stress the tooth may withstand without potential complications.[118] Tapered or fused roots and blunted apexes are examples of decreased ability to withstand the additional occlusal loads required for a fixed prosthesis. The maxillary second molar often presents these varied root configurations. Additional implants and independent implant-supported restorations usually are indicated in the presence of these conditions, rather than the use of these teeth as terminal abutments. Root dilaceration or curvatures improve the support quality of an abutment tooth. However, such root morphology also is likely to encroach on the adjacent available bone volume and increase the risk of implant placement. This is exemplified best in the maxillary canine and first premolar region.

The canine presents a distal angulation of 11 degrees and has a distal root curvature in 60% of the cases. As such, the first premolar edentulous site is limited. An implant inserted into this site usually should be shorter and should follow the angulation of the canine rather than that of the second premolar. The dentist must evaluate carefully any adjacent natural tooth with curved roots at the apex before implant placement.

Roots with a circular cross section do not represent as good a prosthodontic abutment as those with an ovoid cross section. Therefore the maxillary premolar is a better abutment than the maxillary central incisor, although their root surface areas are similar.[130]

The maxillary lateral incisor may exhibit less lateral mobility than the central incisor as a result of its cross-sectional anatomy.[79] All these factors from traditional prosthodontics are also part of the implant candidate's dental evaluation.

Root Surface Area

In general, the greater the root surface area of a proposed abutment tooth, the greater the prosthetic support. Posterior teeth provide greater periodontal surface area and greater support than anterior teeth. Teeth affected by periodontal disease lose surface area and represent poorer support elements for a prosthesis. For a maxillary first molar, bone loss to the beginning of the root furcation corresponds to a root surface area loss of 30%.[134] Ante's law requires the root surface area of the abutment teeth to be equal to or greater than that of the teeth replaced by the pontics of the fixed restoration.[135] Although empirical at its inception,

WWW.HIGHDENT.IR

Ante's law has withstood the test of time and still serves as a clinical guideline.

Endodontic Evaluation

The natural abutment adjacent to or included in a combined tooth and implant-supported prosthesis should present a healthy pulpal status or successful endodontic treatment. If the pulpal or endodontic status of an abutment is questionable, the prudent treatment is endodontic therapy. In this way, the abutment crown may be evaluated for retention, need for post and core, and any other related criteria before final prosthodontic treatment. Potential lesions of endodontic origin are evaluated best before implant surgery because an exacerbation of the lesion during early implant healing may result in a pathway of destruction to the adjacent implant site, implant failure, and extensive bone loss.

In the literature, success has been reported as low as 47% to as high as 98%. However, most studies report success in the range of 85% to 90% at 5 or more years.[136-138] As such, when endodontic treatment has a good prognosis and the tooth may be restored adequately, root canal treatment is in order. However, a number of implant failures each year are attributed to adjacent tooth endodontic failure. At first, this may seem contradictory. Implant healing failures are rare in most practices and account for less than 2% of implants inserted, when using a classic two-step approach. However, when these 2% failures are evaluated, a large number of failures occur next to natural teeth that had an endodontic complication during early implant healing.

Assessment of endodontic success before implant surgery often is difficult.[139-141] The patient may be symptom free, yet a low-grade infection is present at the apex. The healing implant interface is more prone to complications with such a tooth having this condition because the healing interface is weaker than the previous bone condition and a pathway may exist to the developing implant interface. If a tooth is asymptomatic, but has a past endodontic treatment and periapical radiolucency, consideration should be given to retreatment or extraction. When the periapical lesion is 5 mm or greater, the success of endodontic retreatment is not predictable.

During the treatment planning phase, teeth adjacent to the edentulous segment should be scrutinized for potential endodontic problems, keeping in mind that the preparation of a tooth for a crown has a 3% to 6% risk of pulpal death as a consequence of the procedure. In addition, past periodontally involved teeth are at greater risk of pulpal disease after tooth preparation.

Periodontal Status

The periodontal evaluation of natural abutments to be connected to implants is identical to the evaluation of other fixed partial denture abutments. Special attention may be directed to the adjacent implant site, which may be contaminated by bacteria during periodontal surgery.

The incision line and flap design for implant placement often includes the abutment teeth. The implant surgeon should decide whether periodontal therapy is indicated on the abutment teeth before or at the same time as implant placement. A reduction in the number of surgical procedures is a noteworthy benefit to the patient; however, active infection should be minimized during implant placement. Therefore the pathologic condition of the abutment teeth most often is addressed before the soft tissue reflection in the region of the implant osteotomy. Dental prophylaxis and oral hygiene considerations are usually scheduled before implant surgery.

In summary, a completely implant-supported restoration is desirable. Grafting the edentulous site or the use of additional implants is the treatment of choice.

However, when insufficient implant support is available, the natural teeth may be considered as potential abutments. The most important natural tooth criterion for implant-tooth–supported restorations is tooth mobility. A clinical assessment of zero mobility often allows a rigid connection between the tooth and implant. However, if mobility is present, the practitioner should design the prosthesis to include more natural abutments and return the dental elements to zero mobility or consider an independent implant restoration. Splinting natural teeth is the usual method to reduce mobility.

Several additional factors are critical for dual implant-tooth support of a fixed prosthesis: crown size, crown/root ratio, tooth position, parallelism, caries, root configuration, root surface area, endodontics, and periodontal status. Although these same criteria are important for any fixed restoration, each presents unique aspects in implant- and tooth-supported prostheses.

SOFT TISSUE SUPPORT

The evaluation of the soft tissue support is primarily concerned with the treatment planning of RP-5 (overdenture) prostheses, which gain dual support from implants and edentulous ridges. The following factors need to be evaluated: ridge shape, size, parallelism, and palate shape. Large jaws with little resorption provide a better support than smaller sized ones with greater atrophy, in either the maxilla or mandible. The size of the soft tissue can not be solely evaluated on a radiograph, because it is highly dependent on the position of the muscle attachments. High muscle attachments on abundant to moderate bone (Division A or B) may be lowered by vestibuloplasty procedures in conjunction with implant surgery.

Prosthesis support depends on the shape of the residual ridge and, in the maxilla, the palatal vault. A square ridge form yields optimal resistance and stability. A relatively flat one represents a compromised factor for retention and stability, although support is still adequate. Tapering ridges on the palatal vault usually equate with poor stability.[142-144] Ridge parallelism is also evaluated. The edentulous ridge parallel to the occlusal plane is

WWW.HIGHDENT.IR

Figure 12-36 **A,** The patient has a collapsed occlusal vertical dimension and a poor occlusal plane. When the final result is not clear to the restoring dentist, a treatment prosthesis is often a benefit to assess and reestablish prosthetic parameters. **B,** An acrylic removable partial denture in place is used as a treatment prosthesis to reestablish the proper occlusal vertical dimension, jaw position, plane of occlusion, temporomandibular joint status, speech, and potential prosthetic result.

most favorable for soft tissue support. If ridges are divergent, stability of the denture will be greatly affected.

The lateral throat form in a maxillary denture or RP-5 restoration is evaluated. A soft palate slope is favorable when it has a long, gradual slope from the junction of the hard and soft palate,[145] which allows a greater extension of the posterior palatal seal and enhances retention. On the other hand, a soft palate Class III, which drops abruptly, may lead to soreness, loss of valve seal, and gagging. These elements are of great diagnostic value in the evaluation of the maxillary fully edentulous patient who may consider an implant-supported overdenture. A greater number of unfavorable anatomical structures may direct the treatment plan toward an RP-4 prosthesis with greater implant support and no soft tissue support to address all the needs of the patient.

It must be emphasized to the patient that a partial or total soft tissue–borne prosthesis will not stabilize bone loss. To the contrary, bone loss will continue and may even be accelerated, because the prosthesis is more often worn and bite forces are increased. As a result, all soft tissue–borne devices should be considered transitional dentures. They all require repeated relines, rebasing, and refabrication to replace the missing bone. A totally implant-supported restoration (fixed or removable) does not require soft tissue support and may be considered a definitive restoration.

Many soft tissue–supported restorations are fabricated because the patient can not afford a totally implant-supported restoration, especially in the completely edentulous patient. However, the doctor often forgets that if a patient cannot afford the ideal treatment today, it does not mean the patient cannot afford any further treatment later. For example, if a patient needs four first molars replaced, but cannot afford all restorations at this time, the doctor most often can still restore one of the molars. Then a few years later the next tooth may be restored. Eventually, the four molars are treated and the arch form and occlusion restored. In similar fashion, a patient who can afford only two implants to retain a mandibular denture could possibly afford further treatment later. Therefore a lifetime strategy for health should be established, which may include the addition of more implants in the future to reduce and eventually halt the continued bone loss and consequences on esthetics and function.

PRETREATMENT PROSTHESES

FIXED RESTORATIONS

Pretreatment prostheses in restorative dentistry are often indicated to obtain a diagnosis, improve soft tissue health before fabricating soft tissue–borne restorations, reestablish the OVD, evaluate esthetic considerations, or treat TMJ dysfunction (Figure 12-36). Restoration of implant patients may also require treatment prostheses for similar reasons. In addition, the pretreatment prosthesis may be used to select a prosthetic option, to progressively load bone to improve its strength, and as a transitional restoration to protect a healing bone graft or implant. Immediate loading of an implant system often uses a transitional prosthesis out of occlusion in a partial edentulous situation. In the completely edentulous immediate load restoration, the transitional prosthesis has no cantilevers in nonesthetic areas. Treatment prostheses may also help evaluate the psychologic attitude of a patient before irreversible implant procedures (Box 12-6).

Diagnosis in medicine is the first step to establishing a treatment for a disease or disorder. Likewise, to establish a treatment plan for a partially or completely edentulous patient, a proper diagnosis should be established. A treatment prosthesis may be required to help in this process. For example, questionable teeth

WWW.HIGHDENT.IR

Box 12-6 Implant Treatment Prostheses

1. Help with diagnosis
   a. Crown lengthening
   b. Occlusal plane
   c. Hopeless teeth
2. Evaluate the psychologic profile of the patient
   a. Denture before implant surgery
3. Improve soft tissues before final impression for implant overdentures
4. Postoperative to implant surgery
5. Evaluate occlusal vertical dimension
6. Evaluate temporomandibular joint dysfunction
7. Improve implant position related to final tooth position
8. Evaluate esthetics before surgery
9. Evaluate hygienic contours of fixed restorations
10. Determine whether removable restoration is required for maxillary lip support (RP versus FP)
11. Protect bone graft or implants during healing
12. Patient's financial and compliance management
13. Progressive bone loading
14. Phonetics and esthetics for full arch implant–fixed prostheses on complete edentulous patients

RP, Removable prosthesis; *FP,* fixed prostesis.

may require initial restoration to assess their prognosis related to whether or not the extraction of the tooth and implant replacement therapy is required.

A treatment prosthesis may correct the existing occlusal plane, identify extruded teeth, and indicate whether endodontic therapy, crown lengthening, or extraction is required to complete the final treatment plan. Remember, after prosthetic crown lengthening is performed, at least 4 mm of tooth structure is supracrestal (2 mm for connective tissue and junctional epithelial attachment and 2 mm to create a ferrule effect with the crown to reduce the risk of root fracture). Also, the crown/root ratio is increased and the mobility of the tooth should be evaluated. Excessive mobility may require additional implants, splinting teeth, or even extraction and additional implant insertion.

A long-span partially edentulous patient often wears a fixed-treatment prosthesis, which also acts as an interim prosthesis. Metal-reinforced transitional prostheses may be used when four or five pontics are present. These fixed, transitional treatment restorations may be used during bone grafts or healing of implants to decrease forces on the soft tissues and on the graft or healing implants.

REMOVABLE PROSTHESES

Treatment prostheses may be used to improve the soft tissues used for support, stability, or retention before RP-5 overdenture or complete denture restorative procedures. The first evidence of residual ridge destruction by an ill-fitting denture is often deformed and traumatized overlying soft tissue.[146] The soft tissue bed may exhibit different degrees of redundant hyperplasia, epulis, hypertrophy, or abrasions.[147,148] A tissue conditioning treatment is usually indicated to restore soft tissue health before making the final impression for the soft tissue bone prosthesis. The soft tissue conditioner may need to be replaced every 2 to 3 days, although 10 to 14 days are usually sufficient to return the soft tissue to normal condition. The existing denture can often be used as the treatment prosthesis. Additional treatment such as surgical removal of excessive hypermobile tissues is often warranted before soft tissue conditioning.

It should be noted that soft tissue conditioners are different from soft liners used in soft tissue support areas of removable prostheses. Tissue conditioners change dimensions during the first 18 to 24 hours. As such, as the tissues return to a more normal condition, the material changes dimension to allow and encourage these changes. However, the modifiers required for this reaction leach out of the material, halt the process within a day, and result in a stiff material. Soft liners, on the other hand, stay soft longer than tissue conditioners, especially when coated with a sealer. However, the material does not change dimension during the first day and therefore will not accommodate a changing tissue condition.

Most often, tissue conditioners are used to improve abused tissues before a final soft tissue impression for a removable prosthesis. In addition, these materials are used after implant surgery in regions under a removable prosthesis, while the implant-bone interface heals. The tissue conditioner may respond to the swelling and tissue changes immediately after soft tissue reflection. In addition, it is relieved over the implant site. At the suture removal appointment, the tissue conditioner is removed and replaced with a sealed soft liner. This material stays soft during extended periods and is less likely to load the implant through the soft tissue.

OCCLUSAL VERTICAL DIMENSION

Long-term edentulous patients who have been wearing the same denture may require a treatment prosthesis to restore the OVD and ridge relationship before implant treatment.[149] The OVD may gradually collapse, especially in the completely edentulous patient, as a result of continued bone loss and prosthesis occlusal wear. TMJ and myofacial dysfunction may be the further consequence of this condition. A treatment prosthesis to reestablish the proper OVD or assess a symptomatic joint helps determine the patient's specific needs regarding the dysfunction.

As the OVD decreases, the mandibular jaw rotates forward and closes in a more prognathic pseudo–Class III relationship. To place the implants in the correct angulation, the OVD should be reestablished before implant surgery so the correct position of the teeth

WWW.HIGHDENT.IR

relative to the arch is established. In the case of immediate implant loading, a treatment prosthesis is delivered at or soon after the implant surgery. The design of the prosthetic superstructure concomitant with the implant substructure is necessary for immediate loading in implant overdentures. Therefore a treatment prosthesis is indicated to establish the proper OVD and tooth position before the placement of the implants and fabrication of the superstructure bar.

As the OVD increases, the maxillomandibular relationship evolves toward a Class II relationship. This influences the position or angulation of the implant. In addition, the location of an overdenture bar may be equally influenced by variations of the OVD. The treatment prosthesis may be used to establish prosthetic position of teeth.

A pretreatment prosthesis for a completely edentulous patient before the delivery of a fixed- or removable-implant prosthesis is most often a complete denture. It is fabricated with acrylic teeth to facilitate recontouring and the addition of cold-cured acrylic for repairs or to change the OVD or lip support.

ESTHETIC ASSESSMENT

On occasion, a patient's desire for esthetic improvement may be very demanding or unrealistic. In the completely edentulous patient, a treatment denture (partial or complete) may be used to satisfy those esthetic concerns before implant surgery. Tooth shape, surface quality, size and position, tooth color, lip and soft tissue contour, tooth position, gingival color, soft tissue contour, and papilla support may all be evaluated. If the patient cannot be satisfied with the pretreatment prosthesis, it is far better to realize this before implant placement. Although demanding patients may not be satisfied with the pretreatment prosthesis, they can decide to lower expectations and continue with treatment or be referred to another dentist. If the latter is chosen, it is prudent to contact the next practitioner and inform them that another pretreatment prosthesis is indicated before implant placement.

A high lip line in the maxilla or low lip line position in the mandible may influence the need for a specific gingival contour and color in the restoration, yet the maintenance needs of the restoration may compromise the final esthetic result. A fixed restoration must be designed to allow access for proper hygiene procedures around the teeth and implants. A pretreatment prosthesis may help determine whether an implant-supported removable prosthesis rather than a fixed restoration is required to satisfy the patient's esthetic goals and desires for the restoration, yet may be removed to allow proper daily maintenance.

The maxillary vermillion border of this lip is usually altered by the loss of the maxillary anterior teeth. After bone is also lost, the natural support of the entire lip is often deficient and depends on the labial flange of the prosthesis. A fixed partial denture may require an anterior cantilever away from the soft tissue in a horizontal and vertical dimension to provide this support. A pretreatment prosthesis can provide the information required to determine whether a fixed prosthesis will compromise esthetics, support, or hygiene in this region above the teeth.

PSYCHOLOGIC ATTITUDE

The finalized treatment plan and patient's physical and mental evaluation should be assessed before implant surgery. If the restoring dentist is not sure the planned final prosthesis is compatible with the desires of the patient, or the patient's attitude and demand do not seem reasonable, further evaluation is required. A pretreatment prosthesis provides additional appointments and time for these evaluations.[150,151]

FINANCIAL BARRIERS

An additional benefit of pretreatment prostheses is that patient financial management may be facilitated and compliance issues resolved before more irreversible phases of treatment are rendered. However, it is beneficial to clearly establish the cost and emphasize the need to progress forward with treatment in an orderly fashion. Very few pretreatment or transitional restorations may be worn for years without risk of fracture, uncementation, or compromises in the bone graft or implants.

PROGRESSIVE LOAD

A pretreatment prosthesis to improve the quality of bone is most always used in D3 or D4 bone-supporting implants before the fabrication of the final restoration. Interim (provisional) acrylic restorations that gradually load bone for progressive loading may be considered pretreatment prostheses. A decrease in crestal bone loss and decrease in implant failure, especially in soft bone types, are particular advantages with progressively loaded treatment prostheses. Pretreatment prostheses also assist in the determination of the final form and function of the final prosthesis, especially for completely edentulous patients, for whom the "pretreatment" prosthesis may be the first full arch–fixed restoration they have worn after several years of wearing a complete denture.

SUMMARY

Preimplant prosthodontics for partially edentulous patients include overall evaluation of five intraoral segments as: (1) the maxillary incisal edge, (2) the OVD, (3) the

WWW.HIGHDENT.IR

mandibular incisor edge, (4) the maxillary occlusal plane, and the (5) mandibular occlusal plane. In addition, there are 10 specific criteria that affect a treatment plan: (1) lip lines, (2) maxillomandibular relationships, (3) existing occlusion, (4) crown height space, (5) TMJ status, (6) extraction of hopeless or guarded-prognosis teeth, (7) existing prosthesis, (8) arch form, (9) natural tooth adjacent to an edentulous space, and (10) soft tissue evaluation. Pretreatment prostheses are also used in an implant prosthetic evaluation process (Box 12-7).

The prosthodontic evaluation of the implant candidate borrows several conventional criteria from the evaluation of natural abutments. In addition, many of these situations require a unique approach for implant prosthodontics and may influence the implant treatment plan. The goal of the implant surgeon is to achieve predictable, rigid fixation of endosteal implants. The restoring dentist's responsibility is to maintain the implant-bone interface in an environment that satisfies all the traditional prosthodontic criteria.

Box 12-7 Treatment Sequence for Implant-Supported Reconstructions

The proposed treatment for implant-supported reconstructions performed by the implant team can be as follows:

Initial appointments

Medical and dental history
Dental evaluation and x-ray examinations
Diagnostic casts
Preliminary discussion of treatment alternatives
Decision to proceed with treatment
Initial treatment plan, case presentation, and alternatives
Clinical/laboratory procedures prior to additional diagnostic records
Extra office diagnostic orders (e.g., setup, computed tomography scans, tests for medical evaluation, consultation, and team members)
Diagnostic wax-up of final results on duplicate diagnostic casts
Final treatment plan and alternatives
Medical laboratory tests evaluated
Prescriptions and postoperative instructions
Consent forms and request for treatment forms
Pictures of existing condition

Phase I dentistry

Presurgical restorative appointment—initial caries removal, extractions, temporary teeth
Periodontal treatment, endodontic therapy, orthodontics
Occlusal vertical dimension
Occlusal plane correction, treatment prosthesis, recontour existing teeth, enamoplasty
Transitional prosthesis (removable or fixed) or diagnostic try-in; tissue conditioning
Impression for surgical guide template (if oral condition altered from initial diagnostic cast)

Preimplant reconstructive surgery osseous (grafting), soft tissue

Implant surgery

Stage I: implant placement

Healing phase

Stage II: secondary permucosal extension, initial loading

Prosthodontics: progressive bone loading
Initial abutment preparation and impression
Final abutment preparation and impression
Metal try-in or waxed teeth try-in
Initial delivery—occlusal
Final delivery—occlusal adjustment
Night guard

Maintenance

First year: every 3 to 4 months
Radiographs at 6 months, then annually for 3 years, then as required
Home care education
Fluoride on teeth
Chlorhexidine on implants

Chapter 13

Diagnostic Casts and Surgical Templates

David P. Sarment, Carl E. Misch

Diagnostic casts are critical to preimplant and treatment prosthodontics. Once the preimplant phase is satisfactory, prosthetically driven implant placement must also accommodate anatomical limitations, and possible adaptations of the original planning may be necessary. This set of requirements can be achieved using precise surgical guides. In recent years, advanced guidance has been developed to achieve predictable, precise placement. This chapter emphasizes important components of the diagnostic phase and then describes how guided placement can overcome anatomical limitations.

DIAGNOSTIC CASTS

The value of diagnostic casts or study models is critical in all of dentistry and especially in oral implantology. Many patients have been partially edentulous for an extended time. The combination of continued bone loss and dentition changes related to missing teeth greatly increases the number of factors that must be considered for oral rehabilitation compared with traditional prosthodontic treatment. The dentist selects the final prosthesis, the number and location of ideal and optional abutment sites, and the occlusal schemes before surgery. Ninety percent of dentists in the United States use a team approach to insert implants and restore implant patients.

Diagnostic casts enable the dentist to evaluate several prosthodontic criteria in the absence of the patient. These casts permit an open discussion of treatment with other practitioners and laboratory technicians for consultation. In addition to all the data provided that are similar to nonimplant treatment evaluation, the casts also assist in implant site selection and angulation requirements during the surgical phase. Surgical templates often are designed from the diagnostic casts or after diagnostic wax-up of the designed prosthesis. One set of casts may be used as a permanent record of pretreatment conditions for dental–legal issues because nonreversible procedures may be performed. The diagnostic casts and pretreatment setups also may be used for presentations to motivate the patient's acceptance of the proposed treatment (Figure 13-1).[1]

Diagnostic casts mounted using an accurate record of centric jaw relationship and maxillomandibular occlusion on a semiadjustable articulator provide much information related to treatment that influences the final prosthodontic treatment plan.[2-4] Important factors include the following:

1. Occlusal centric relation position, including premature occlusal contacts
2. Edentulous ridge relationships to adjacent teeth and opposing arches
3. Position of potential natural abutments, including inclination, rotation, extrusion, spacing, parallelism, and esthetic considerations
4. Tooth morphology, structure of potential abutments, and overall conditions (e.g., wear facets, fractures)
5. Direction of forces in future implant sites
6. Present occlusal scheme, including the presence of balancing or working contacts
7. Edentulous soft tissue angulation, length, width, locations, permucosal esthetic position, muscle attachments, and tuberosities
8. Interarch space

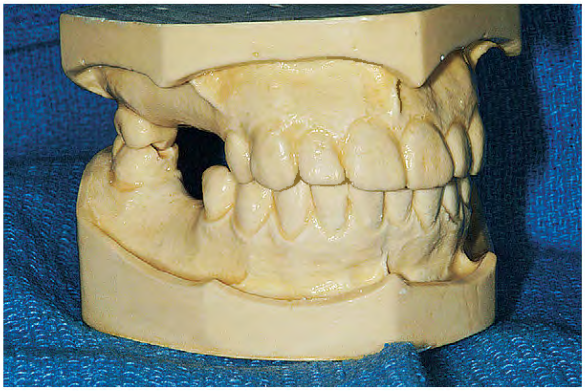

Figure 13-1 Diagnostic casts allow the dental team to evaluate a patient's intraoral condition and plan treatment. However, unmounted casts cannot be used to evaluate the relationship of one arch to another.

WWW.HIGHDENT.IR

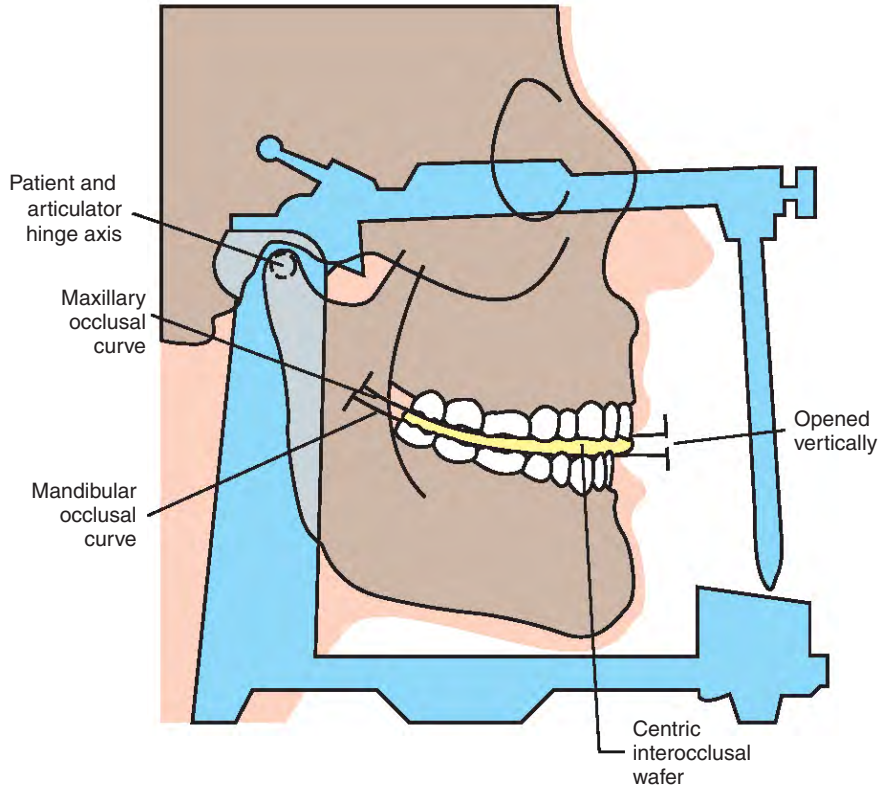

Figure 13-2 Diagnostic casts should be mounted with an open bite registration in centric relation. When the registration material between the teeth is removed, the arch of closure of the mandible should simulate that of the patient. This requires a facebow mounting from the patient to the articulator.

9. Overall occlusal curve of Wilson and curve of Spee
10. Arch relationships
11. Opposing dentition
12. Potential future occlusal schemes
13. Number of missing teeth
14. Arch location of future abutments
15. Arch form and asymmetry

The dentist should evaluate the existing occlusion before implant placement. Partially edentulous patients often have occlusal interferences as a result of tooth migration. The dentist identifies and eliminates deflective contacts before the implant prosthodontic phase. A facebow transfer and centric and eccentric occlusal records should help in mounting the casts on a semiadjustable articulator (Figures 13-2 to 13-5). Occasionally a panographic recording of mandibular movements and a fully adjustable articulator may be indicated. The diagnostic casts are mounted in centric relation occlusion with a wax spacer between the arches. Premature contacts can be detected on removal of the wax spacer. The dentist then may perform an occlusal adjustment on duplicates of the diagnostic casts and replicate them in the mouth.[5]

Research has shown almost 75% of earbow transfers are within 5 mm of the axis of the temporomandibular joint. Almost 25% of individuals have one ear higher than the other, in relation to the occlusal plane. The distance from the hinge axis to the central incisors range from 87 to 120 mm, with more than 80% within 100 to 105 mm.[5]

Kois has developed a unique facebow transfer that corresponds to the facial midline and horizontal plane to the 100-mm distance of the conditional hinge position. This technique simplifies the process of the facebow transfer and ensures the occlusal plane of the teeth is evaluated and fabricated correctly (Figures 13-6 to 13-8) (Kois Dento-Facial Analyzer System, Panadent Corp., Grand Terrace, Calif.).

A considerable prosthetic advantage is present when centric relation occlusion is harmonious with centric relation. Lack of change in the occlusal vertical dimension permits a closed-mouth centric recording during prosthetic reconstruction for the fabrication of the prosthesis, without the need for an accurate hinge axis recording of the condyles or fully adjustable articulators. When incisal edge position of the maxilla is determined, its position usually causes a steeper protrusive or excursive position than the condylar disk assembly. As a result, posterior disocclusion can be established easily. These conditions permit the reconstruction to be fabricated in the laboratory and transferred accurately to the patient.

The occlusion may require complete rehabilitation to eliminate potential unfavorable forces against the implant. Both arches may require prosthodontic treatment to establish the desired occlusal schemes. Parafunctional bruxism with loss of incisal guidance from attrition or an opposing single denture are the most common conditions that mandate more involved opposing dentition modification. The first condition often indicates a need to increase the anterior guidance

WWW.HIGHDENT.IR

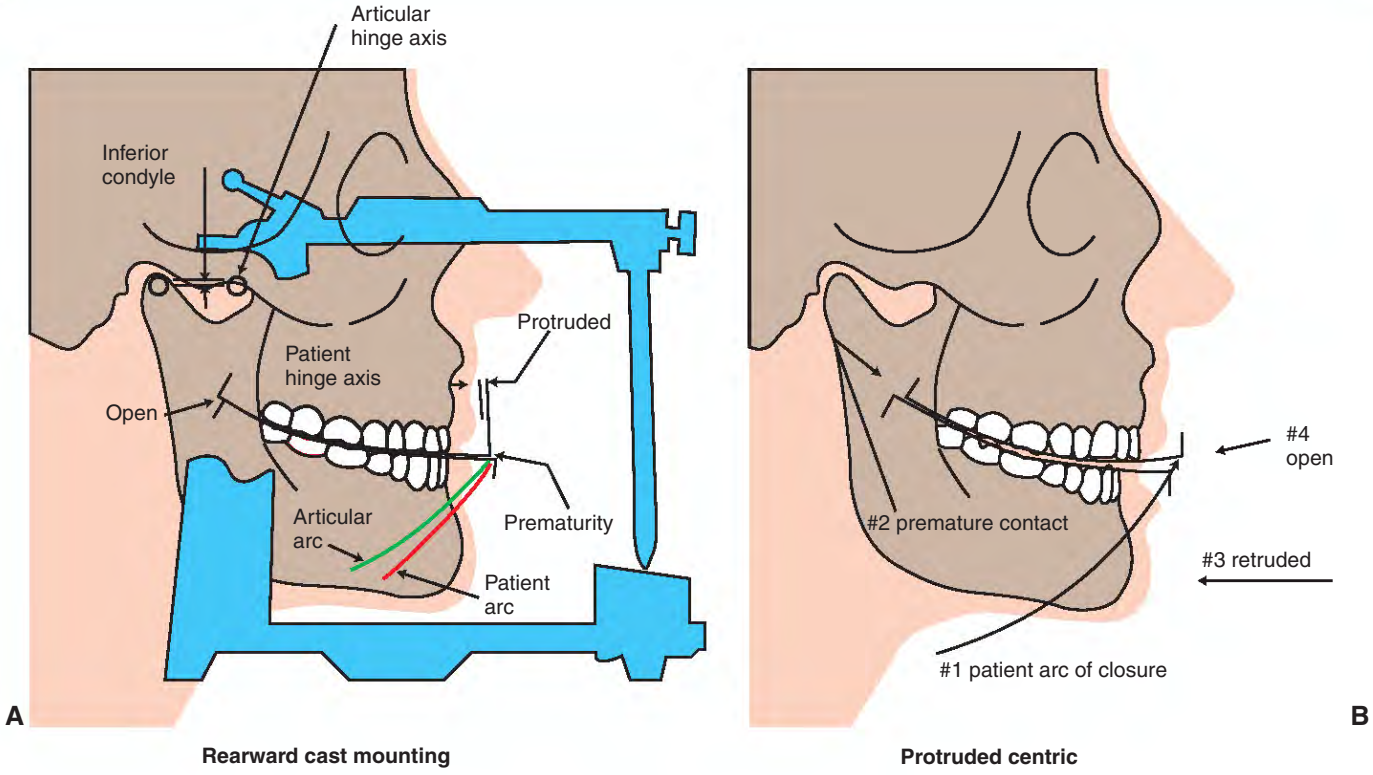

Figure 13-3 **A,** A mounted maxillary cast without a facebow and an open bite mandibular relationship do not allow proper evaluation or reconstruction of the patient's intraoral condition. For example, a maxillary cast mounted to the rear causes premature anterior contacts when the bite registration is removed. **B,** When a reconstruction fabricated on models mounted as in part **A** is placed intraorally, a posterior premature contact is observed and the anterior teeth have no contact. A maxillary cast mounted too high on an articulator also exhibits premature anterior contacts when the open bite registration is removed. When the reconstruction is placed intraorally, a posterior premature contact is observed, similar to the previous scenario. The reverse scenario is observed when the maxillary cast is mounted too far forward or inferior to the hinge axis of the patient.

Figure 13-4 An ear-mounted facebow is acceptable in most situations. However, in almost 25% of patients one ear is higher than the other. In these situations, the cross member still should be made parallel to the horizon.

for posterior disclusion in excursions, whereas the second warrants bilateral balance occlusion.

Duplicate diagnostic casts also may be mounted on an articulator for selective alterations and prewaxing to determine the desired contour, occlusal scheme, and esthetic aspects of the final restoration. The diagnostic wax-up usually is described in detail and performed by the laboratory technician. The specific laboratory communicative processes are thereby begun before actual treatment and may be modified during treatment as required. These considerations include occlusal plane correction, edentulous ridge position and its effect on implant placement, occlusion, esthetic considerations, and interarch distance. The dentist may use the altered diagnostic wax-up casts to provide a guide for provisional restorations and may evaluate them during the provisional stages of reconstruction.

The dentist, in addition to using radiographic surveys, may also use the diagnostic casts to estimate the underlying bone volume. The dentist inserts a needle equipped with an endodontic stop through the patient's mucosa overlying the implant site and measures the mucosal thickness on the crest, facial, and lingual areas. The dentist also can use a bone caliper that contains sharp beaks penetrating soft tissues at a known height. Once the calipers are inserted, bone width can be measured with the calibrated instrument.[6] The edentulous region of the diagnostic cast is cut perpendicular to the ridge. The diagnostic cast cross section then is shaded with a pencil to represent the tissue thickness observed while probing. The remaining cross section of the cast roughly estimates the bony contours under the soft tissue.[6-8]

WWW.HIGHDENT.IR

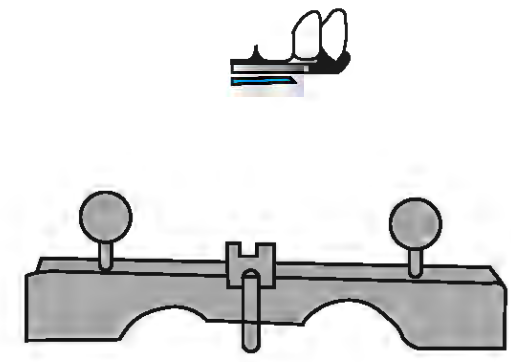

Figure 13-5 When the facebow is not parallel to the horizon with the patient, when placed onto the articulator, the maxillary cast is mounted with an incline that does not represent the patient's intraoral condition.

Figure 13-6 The maxillary incisal edge is 100 mm from the hinge axis in 80% of patients (± 5 mm). *(Courtesy Panadent Corporation, Grand Terrace, Calif.)*

RESTORATIVE DIAGNOSIS VERSUS SURGICAL DIAGNOSIS

Although a prosthetically driven implant placement is best for simplification of abutment selection, ideal force distribution,[9] and long-term success, anatomical limitations may force the surgeon to redirect the implant angulation. When buccal bone loss has occurred, modification of the treatment plan and placement of a bone graft for better implant angulation may be necessary. However, other areas such as lingual concavities cannot

Figure 13-7 Most facebows use the ear canal as a posterior reference point, because the hinge axis is within 5 mm of this point in more than 75% of the patients.

Figure 13-8 The Kois Dento-Facial Analyzer System facebow uses the midline of the face and a parallel reference plane with the incisal edge 100 mm from the hinge axis.

be grafted, and a change in angulations or implant selection is the only option. A typical instance of such limitation is in the mandibular first molar area. A panoramic or periapical radiograph does not show a possible severe lingual concavity, which can be depicted only with careful clinical examination or cross-sectional imaging. Prosthetically driven implant placement would lead only to a risk of lingual perforation. If a concavity is suggested, further radiographs such as a traditional tomogram or a computed tomography scan, together with a diagnostic radiographic template, will reveal the angulation dilemma and allow for clear communication between the restorative dentist and the surgeon. The example in Figure 13-9 represents an actual case in which the diagnostic wax-up was transferred to a scannographic template,[10] but the prosthetic requirement cannot be met surgically—an implant placed in the long axis of the diagnostic tooth would force the surgeon to perforate the lingual cortical bone. In addition, the mandibular nerve is relatively high. Therefore the dentist must make a decision to modify the angulation and later redirect the implant path with an angulated abutment, position

WWW.HIGHDENT.IR

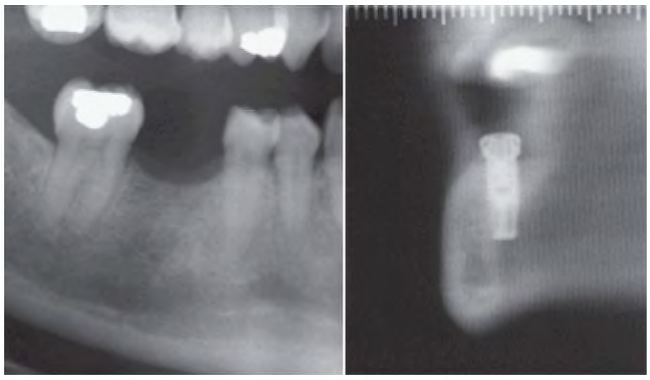

Figure 13-9 An implant following an ideal prosthetic position must have ideal bone volume and angulation. In many situations the bone width or angulation requires slight modification of the implant to avoid perforations of the lateral cortical plates. In this case, the vertical implant insertion caused a perforation through the lingual cortical plate of the posterior mandible.

Figure 13-10 A template for a partially edentulous patient should engage the teeth for stabilization and fixation during surgery. Templates for the anterior regions of the mouth should indicate the facial contour of the restoration.

a shorter implant, or avoid this site all together. A careful clinical examination with the diagnostic template in place would reveal the issue as well, but radiographic visualization is more ideal to ensure surgical success, limit liability, and communicate and discuss planning. Unfortunately, such anatomical limitations often are revealed during surgery, when decision making is more difficult and debate is impossible. Other common locations for similar limitations include the prominent premaxilla or the severely resorbed anterior part of the mandible. As discussed subsequently, precise diagnosis to rule out anatomical limitations can be followed by a thorough plan that can be transferred to the surgical field using surgical guidance.

SURGICAL GUIDES

To establish a logical continuity between diagnosis, prosthetic planning, and surgical phases, use of a transfer device is essential. The restoring dentist fabricates the surgical guide template after the presurgical restorative appointments, once the final prosthetic design, occlusal scheme, and implant location, size, and angulation have been determined. The surgical template dictates the implant body placement that offers the best combination of (1) support for the repetitive forces of occlusion, (2) esthetics, and (3) hygiene requirements. A well-developed plan should be transferred precisely, leaving little decision at the time of surgery.

Several methods of fabricating the surgical template are available. The requirements are more relevant than the options of fabrication. The template should be stable and rigid when in the correct position. If the arch being treated has remaining teeth, the template should fit over or around enough teeth to stabilize it in position (Figure 13-10). When no remaining teeth are present, the template should extend onto unreflected soft tissue regions (i.e., the palate and tuberosities in the maxilla or the retromolar pads in the mandible). In this way, the template may be used after the soft tissues have been reflected from the implant site.

The dentist should determine the ideal angulation for implant insertion on the diagnostic wax-up, and the template should relate this position during surgery. This requires at least two reference points for each implant. For that purpose, the surgical guide must be elevated above the edentulous bone. The distance between two points located respectively on the occlusal surface (central fossa or incisal edge) of the planned abutment crown and the crest of the ridge represents about 8 mm. As a result, these two points of reference can be joined by a line that represents the path of ideal implant insertion. The ideal angulation is perpendicular to the occlusal plane and parallel to the most anterior abutment (natural or implant) joined to the implant.

Other ideal requirements of the surgical template include size, surgical asepsis, transparency, and the ability to revise the template as indicated. The template should not be bulky, be difficult to insert, or obscure surrounding surgical landmarks. The surgical template must not contaminate a surgical field during bone grafts or implant placement; it should also be transparent and allow easy access for the surgeon and the assistant. Consideration of which side of the arch is being treated, where the surgeon and assistant will be seated, and whether the surgeon is right- or left-handed is recommended. In this way, the bony ridge and drills can be more easily visualized when the template is in place, and the assistant can position the irrigation without blocking the surgical view.

The surgical template should relate to the ideal facial contour. Many edentulous ridges have lost facial bone, and the template can assist in determining the amount of augmentation required for implant placement or

WWW.HIGHDENT.IR

support of the lips and face (see Figure 13-10). The surgical template may be used for a bone graft, and later the same template may be used for insertion of implants and again for implant uncovery. A study template facilitates sterilization and use for several procedures.

To construct a surgical guide, modification of the radiographic guide is often possible if an ideal wax-up of the teeth was used as a template for the radiographic guide. Ideal tooth position is already present, and enlargement of the access hole and buccal or lingual opening is achieved easily. When the long axis of the teeth is visible and can be maintained, after verifying bone availability, then enlargement of the long axis channel guarantees accurate implant guidance.[11]

An easy method to fabricate a surgical guide is to use a modification of Preston's clear splint for the diagnosis of tooth contours, tooth position, and occlusal form.[12] The diagnostic wax-up is completed to preview the tooth size, position, contour, and occlusion in the edentulous regions where implants will be inserted. No selective grinding or modification is performed on any teeth that have not been altered before surgery; otherwise, the template will not fit correctly in the mouth. A full-arch, irreversible, hydrocolloid impression is made of the diagnostic wax-up and poured in dental stone. On the duplicate cast of the wax-up teeth, a vacuum acrylic shell (0.060 to 0.080 inch) is pressed and trimmed to fit over the teeth and gingival contours of the buccal aspect of the ridge. If no natural teeth remain, the posterior portion of the template should be maintained and cover the retromolar pads or tuberosities and palate to aid in positioning.

The occlusal surface is trimmed over the ideal and optional implant sites, maintaining the facial and facioocclusal line angle of the surgical template (Figure 13-11). A black line then is drawn on the template with a marker to indicate the center of each implant and the desired angulation. This provides maximum freedom for implant placement yet communicates the ideal tooth position and angulation during surgery.

A surgical guide template with 2-mm holes through the occlusal surface of a denture tooth is too limiting for the surgeon, although it precisely identifies the ideal implant placement. While the template is in position, the crest of the edentulous ridge should be visible to avoid stripping of the facial plate of bone during the osteotomy.

In the edentulous arch the vacuum form may be fabricated from the existing removable prosthesis, if within accepted guidelines. A soft tissue liner then may be added in the tuberosity or retromolar pad regions and other soft tissue areas not involved in surgery. Acrylic resin then is added over the occlusal portion of the template where no implants are planned. The patient then occludes into this index after using petroleum jelly over the opposing teeth. In this manner, the template can be correctly positioned over the edentulous ridge during surgery once the tissue is reflected. Otherwise, a template position set too far facially or off to one side is likely (Figures 13-12 to 13-15).

Figure 13-11 A press form is made over a duplicate cast that replaces the missing teeth. The template is trimmed in the edentulous sites to indicate the teeth position and the lingual contour in the posterior regions and facial contour in the anterior region. Adjacent teeth are used to stabilize the template, and the soft tissue regions are avoided.

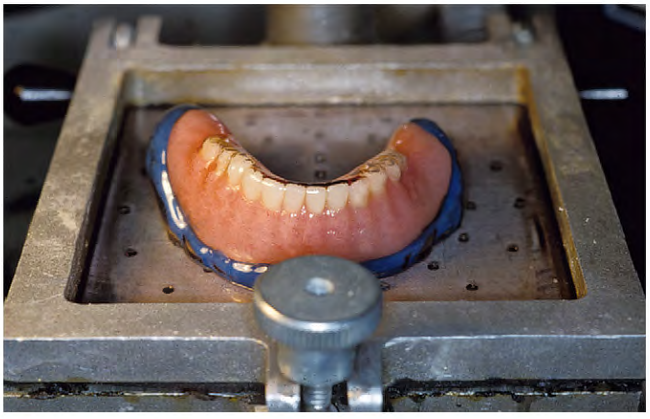

Figure 13-12 The complete edentulous template can be fabricated from a press or vacuum form over the patient's denture.

Figure 13-13 A soft tissue liner is added in the area that will not be reflected during surgery. An index also is made of the opposing dentition.

WWW.HIGHDENT.IR

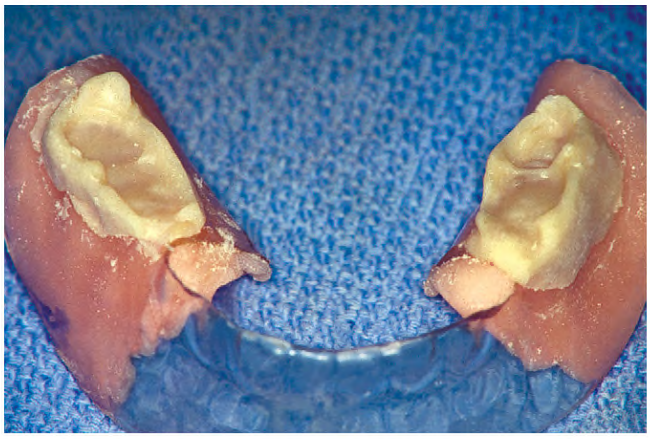

Figure 13-14 The complete edentulous template is trimmed to indicate the facial contour of the restoration in the anterior regions of the mouth. The crestal and lingual contour is completely visible for surgical access.

Figure 13-15 The template is indexed to the opposing arch once the tissue is reflected. The template then is held in position while the patient opens the mouth. The maxillary denture is removed (when present) and the mandibular bone width and angulation are noted before the initial osteotomy. The 2-mm direction indicator then may be inserted and evaluated with the template in position.

A surgical template for the complete edentulous arch also may engage the occlusal aspect of the opposing teeth.[13,14] The following are the fabrication steps on the edentulous cast mounted against the opposing dentition at the proper final occlusal vertical dimension and occlusal relationships:

1. A full wax-up of the missing teeth in the edentulous regions is performed. A hole is prepared through the middle of the central fossa of each future posterior abutment tooth and through the incisal edge position of anterior teeth.
2. On the stone model, each site chosen is drilled to a depth corresponding to the approximate soft tissue thickness measured on a panoramic radiograph (approximately 2 to 3 mm). An orthodontic wire is passed through the teeth and into the holes. This allows each pin of the template to contact bone, once the tissue is reflected during the surgery, without modifying the occlusal vertical dimension and consequently the emergence position of the implant. A small loop is made at the other end of the wire to create a retention form. The wire should approach within 1 to 3 mm of the opposing arch (Figure 13-16).
3. On the antagonist model painted with separator, an acrylic resin template is built on the occlusals that embed the retention loops of the indicator pins. Each pin must be embedded fully in the acrylic at the proper centric and vertical relationships (Figure 13-17).

Figure 13-16 A Laney-Poitras template for the edentulous arch provides complete surgical access. The denture teeth are positioned on the arch. A hole is drilled through each prospective implant site and into the cast 2 to 3 mm. *(Courtesy Yvan Poitras.)*

Once the soft tissue is reflected, the template is positioned over the teeth of the opposing arch. The patient may occlude on the pins, and each one determines the ideal center position of the teeth (Figures 13-18 and 13-19). A pilot drill can be used to mark each implant body position. The angulation of the osteotomy also can be determined with the template. The surgical guide easily determines the implant position, yet the surgeon can have the patient's mouth open and drill into the bone with complete access and vision. This template also may be used with a panoramic radiograph before surgery to determine vertical magnification or horizontal distortion (Figure 13-20). The template also may be used at stage II uncovery to find the position of each implant when soft tissue carving for fixed prosthesis type 1 (FP-1) restorations are indicated, rather than complete reflection of the tissue.

The FP-1 and FP-2 restorations require more ideal implant placement. The ideal implant position allows

Figure 13-20 The template can be used with a panoramic radiograph. Because the height and mesiodistal position can be measured on the cast, the distortion and magnification at each implant site may be determined. *(Courtesy Yvan Poitras.)*

the placement of a straight abutment directly under the incisal edge of the final crown for a cemented prosthesis. For screw-retained prostheses, the implant should emerge toward the cingulum of the anterior tooth so that the access hole does not affect the esthetics. In an FP-3 restoration, the mesiodistal position of implant abutments may be placed without regard to the actual position of the crowns, because the soft tissue replacement region separates the crowns from the implant abutment.

An implant placed adjacent to a natural tooth should remain 1.5 to 2 mm away from the interproximal cement-enamel junction (CEJ) in esthetic regions, where the contour of the interdental papilla is a determining factor. Therefore the pilot hole should be almost 4 mm away from the natural tooth to place a 4.1-mm-diameter implant at the crest module. This requires at least a 7-mm mesiodistal space. In unesthetic regions, where the interdental papilla is not as critical, an implant placed at least 1.5 mm away from an adjacent tooth minimizes the risk of surgical error and provides easier access for hygiene and long-term maintenance.

A maxillary anterior implant placed for an FP-1 restoration requires the most careful pretreatment planning and precise implant placement. The incisal edge of the final crown, emergence profile, and labial cervical position are related to implant position.

The treatment plan for an implant in the maxillary first premolar position must reflect careful consideration for the angulation of a natural canine when present. The 11-degree average distal inclination and distal curvature of the canine root bring the apex of the root into the first premolar implant area. Therefore the implant should be angled to follow the root of the canine and prevent contact with or perforation of the natural root. A shorter implant often is indicated, especially when a second premolar is also present.

ADVANCED SURGICAL GUIDANCE

Diagnosis and implant planning for complex cases with anatomical limitations and poor bone quality now can be evaluated using sophisticated radiographic techniques. Although precise positioning has long been recognized as an important goal,[15] transfer of detailed information to the surgical phase has been at best a difficult task. In fact, a single-tooth implant also requires placement accuracy, even when diagnosis is simple. A surgical guide should be used to guarantee precise placement. Studies show that modification of the radiographic guide to a surgical guide allows for a precision of less than 1 mm at the implant apex and a good control of the angulation.[11,16] However, these preclinical and clinical studies assume no modification of angulation compared with the ideal prosthetic alignment. As discussed previously, the angulation often must be modified to account for anatomical limitations. Until recently, no method existed to transfer an ideal implant position precisely to a surgical guide, especially if the long axis of the diagnostic teeth could not be used.

To refine surgical guidance, innovative developments in software technology and manufacturing techniques have been applied to fabricate highly accurate templates. More recently, peroperative surgical navigation assistance has been introduced with potential for wider acceptance in the near future (Figure 13-21).[17] These technologies allow for more accurate implant positioning by guaranteeing transfer of the implant planning to the surgical field and by forcing the surgical drills into a steady position. These technologies also open venues to new surgical techniques, such as flapless osteotomies, while improving operative timing.

Advanced surgical guides require computed tomography (CT) scanning as a prerequisite for analysis, because of the superior precision of CT compared with all other radiographic techniques.[18-20] These guides also necessitate a software-supported rendering to improve planning by using three-dimensional (3D) visualization,[21] as demonstrated by Jacobs et al.,[22,23] who reported that dentists using two-dimensional (2D) cross sections make numerous modifications during the surgical phase of treatment, whereas the addition of a three-dimensional representation improves the correlation between planned and actual placement. Jacobs et al. also found little correlation between foreseen anatomical complications and the presence of these complications at the time of surgery when only flat projections were used. Verstreken et al.[24] also found that planning was improved in regard to position, considerations of biomechanical spread, and esthetics. More importantly, software rendering that includes CT data and implant planning can be exported later to computer-aided design (CAD) software. For these applications, scannographic templates with precise visualization of diagnostic teeth are strongly recommended to visualize the prosthetic plan together with the osseous topography.[25] In addition, when advanced surgical guidance is considered, several techniques require specifically designed scannographic templates, as described subsequently. Therefore dentists who intend to use one of these methods first must be aware of the entire sequence before the diagnostic stage.

Surgical guidance can be classified in two categories. The first category includes the use of computer-aided manufacturing of guides, using virtual planning of implant positions. Guides are delivered to surgeons

WWW.HIGHDENT.IR

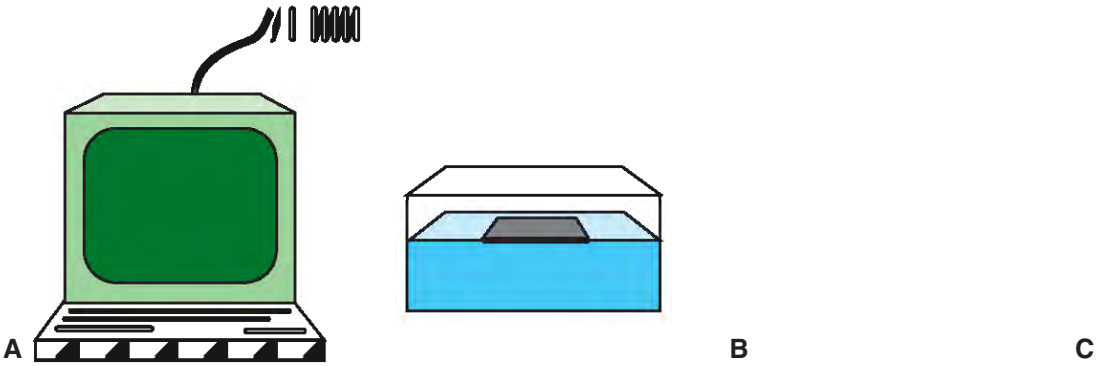

Figure 13-22 Stereolithographic fabrication of surgical guides. After scanning and planning, files are submitted to the manufacturing facility. **A,** A computer-driven laser cures a thin layer of liquid polymer. **B,** A moving table is lowered, another layer is applied, and **(C)** the process is repeated until completion of the surgical guide.

before the procedure, and no modification is possible during surgery. The second category is the use of navigation techniques. There is no guidance of the drill, but software provides real-time feedback to the surgeon in order to compare execution with planning. Therefore modifications are possible during surgery if necessary. The following sections provide a more detailed description of these modalities.

Computer-Assisted Design and Manufacturing of Surgical Guides

Multiple engineering techniques such as laser sintering[26] are available to fabricate 3D models. One of the systems (Surgiguide, CSI Materialise, Glen Burnie, Md.) uses a computer-aided manufacturing (CAM) process called *stereolithography* (Figure 13-22).[27] This rapid prototyping process has been used largely in the manufacturing industry to obtain 3D models.[27,28] A layer of liquid polymer is deposited and cured by a computer-driven laser. Additional layers or sections are stacked and polymerized until a final model is generated. For medical or dental application, the data source is a CT scan file. The accuracy of anatomical models generated by this method depends on the quality of the CT scanner and the thresholding method (the computer process that determines what is bone and what is soft tissue), but studies have shown a dimensional stability in the range of 0.6 mm.[29] Stereolithographic anatomical models have been used to anticipate reconstructive surgeries.[30,31] Santler et al.[32] and Heissler et al.[33] took advantage of 3D models to better prepare for large reconstructions on more than 300 trauma and cancer cases, whereas Runte et al.[34] used optical images as a source to build models of soft tissue contours and fabricate facial prostheses. Use of an anatomical model also has been suggested for diagnosis before sinus elevations[35] and for preparation of subperiosteal[36,37] or ramus implants.[38] Choi et al.[29] evaluated the accuracy of these acrylic models by taking linear measurements of multiple identical sets and found that it was in the range of 0.5 mm.[28] Erickson et al.[39] surveyed surgeons who used stereolithographic methods for diagnosis of surgical reconstruction and fabrication of custom implants. They found that a majority of surgeons had changed their surgical approach once they evaluated the model and thus reduced surgical time for the procedure.

For fabrication of dental implant surgical guides, the dentist's plan is used to design the guides, and CT files are used to prepare the guides to be borne on hard or soft tissue. Software programs are capable of maximizing stability and implant retention by detecting the best insertion path while avoiding undercuts within the bone (Figure 13-23). Designs also include irrigation holes, sufficient surface areas to maintain figure pressure while performing osteotomies, and other specific features such as buccal extensions if a transversal retention screw is desired. In addition, serial templates are fabricated to accommodate increasing drill diameters. Once designs are completed, the guides are processed with the stereolithographic method, and stainless steel tubes are later pressed into place.[40,41] The dentist receives the anatomical model and surgical guides by mail and can observe the anatomy before proceeding with surgery (Figure 13-24, *A*).

Because the topography is obtained from the CT scan data, this process is best suited for osseous-supported templates with wide edentulous areas (Figure 13-24, *B*). When teeth are present, high radiopacity creates blurry outlines, and stereolithographic rests cannot be contoured precisely. This is even more critical when metal-containing restorations such as crowns are present, and severe scattering masks the contours. Similarly, soft tissue surfaces are usually difficult to visualize on CT scan images. However, visualization of ridges is possible by providing a scannographic template containing a

WWW.HIGHDENT.IR

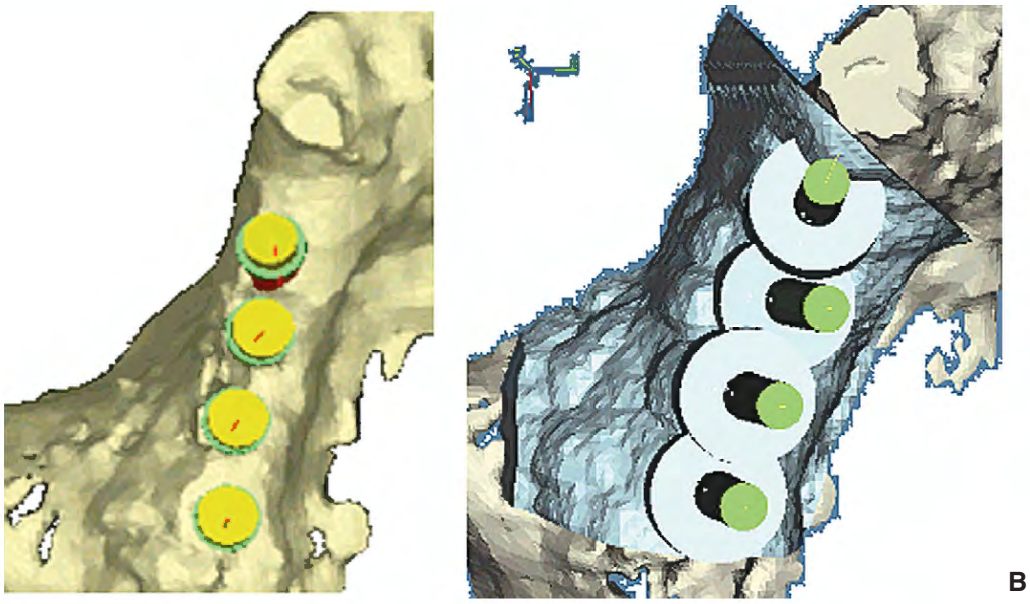

Figure 13-23 **A,** Planning has been forwarded for design and manufacturing of surgical guides. **B,** The surgical guides first are designed virtually to maximize stability and retention and then are sent for processing using the method previously described.

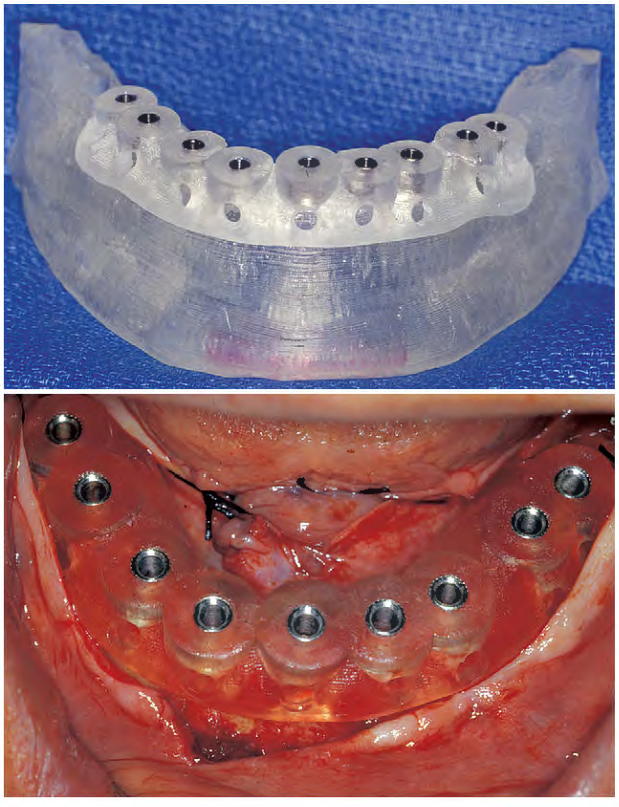

Figure 13-24 **A,** The dentist receives the anatomical model and surgical guides by mail and can observe the anatomy before proceeding with surgery. **B,** Because the topography is obtained from the computed tomography scan data, this process is best suited for osseous-supported templates with wide edentulous areas.

radiopaque base.[42] This approach is most appropriate for edentulous cases: a duplicate of the denture is processed with a radiopaque medium so that the base is visible, representing soft tissues. The surgical guides therefore can be soft tissue supported and incisions may be avoided, keeping in mind that mucosal stability is inferior to bone. Surgical guides also can be fabricated for various maxillofacial implants, such as pterygoid or zygomatic implants, where access and visualization is difficult. Finally, similar surgical guidance is applicable to the medical field, such as fusion of vertebrae in which precise osteotomies are necessary to avoid vital structures.[43,44]

A similar method uses 3D printers to fabricate guides, instead of stereolithography. A medical-grade polymer is also used to fabricate guides layer by layer. Such printers are more readily available, with the potential to be installed in dental laboratories or practices (Figure 13-25). The approach taken by i-dent Imaging (Fort Lauderdale, Fla.) is that software imports CT data, provides virtual implant planning, and is able to export a computer file to a 3D printer. The process requires CT scanning of the patient with a scannographic guide in place as well as scanning of the appliance. This guide, made by the dental technician, must contain gutta-percha landmarks simply inserted in the acrylic at the end of the guide preparation. The purpose of the double scanning is to match patient data and an accurate scannographic guide, which is then used to forward information to the 3D printer. Three-dimensional printing has the advantage of being financially accessible to dental laboratories. Technicians can become integral to the implant team by being involved in planning, guide preparation, and prosthesis fabrication after implant placement.

In contrast to systems described previously, alternative methods (Compu-Guide, Implant Logic Systems, Cedarhurst, N.Y.; and CADImplant, Burlington, Mass.) use drilling of guides.[45,46] The method necessitates the

WWW.HIGHDENT.IR

Figure 13-25 Use of three-dimensional printing for guide fabrication. After double scanning of patient and guide, data were imported and implant planning was performed using software. Note that the virtual surgical guide is immediately visible for verification before fabrication. Three-dimensional printing is performed locally, and the guide is used during flapless.

incorporation of metal markers at specific locations in the scannographic guide that therefore must be provided by the manufacturer. Once the guides are returned and used during CT scanning, the dentist creates a surgical plan using a software (SimPlant, CSI-Materialise, Leuven, Belgium) in a traditional manner. The dentist then returns the plan, model, and scannographic template for conversion of the template into the surgical guide. To achieve transfer of the plan, the model is set onto a computer-controlled milling machine, which matches the fiducial landmarks to their CT-scanned images. The plan then is transferred to the guide using the computer-driven drill press (Figure 13-26). Metal guide sleeves then are added for an ideal guidance of surgical drills. In this system, only one template is fabricated, but drill guides with incremental diameters are inserted sequentially into receiving master cylinders. Because of the ability of the guide to rest on natural teeth, this method can be applied to small edentulous spans. If increased stability is needed when few or no teeth are present, a tacking system can be added away from implant sites. Finally, the surgical guide can be converted into a provisional restoration for immediate loading cases. A similar technique has been described by Fortin et al.,[47,48] who placed reference tubes in the scannographic guide. After scanning and planning, the template also is positioned on a computer-driven drilling table to modify the appliance into a precise surgical guide.

Although these advanced methods aim at improving surgical guidance, accuracy rarely has been measured objectively. Unpublished data from the manufacturers and clinical experience (Figure 13-27) support the hypothesis that planning and actual placement are related more closely in terms of horizontal positioning (mesiodistal and buccolingual) and implant angulation. Similar results were found using a preclinical study design to compare traditional surgical guides modified from scannographic templates with SurgiGuides (Materialise). Coronal osteotomy was improved from an average of 1.5 to 0.9 mm, and the apical position at 10 mm was improved from 2.1 to 1 mm, and this improvement was due to a better angulation (from 8 to 4.5 degrees). An important note is that average enhancements also were accompanied by overall decrease in standard deviations, revealing minimization of surgical errors.[49] In another publication, van Steenberghe et al.[50] evaluated placement of 45-mm-long zygoma implants on human cadavers. They reported less than 3 degrees of deviation, and no more than a 2.7-mm discrepancy at the apex. Fortin et al.[47] found that the transfer error was less than 0.2 mm and 1.1 degrees. More recently, Di Giacomo et al. reported on a case series in which patients received CT scanning before and after implant placement, using SurgiGuides. They found that

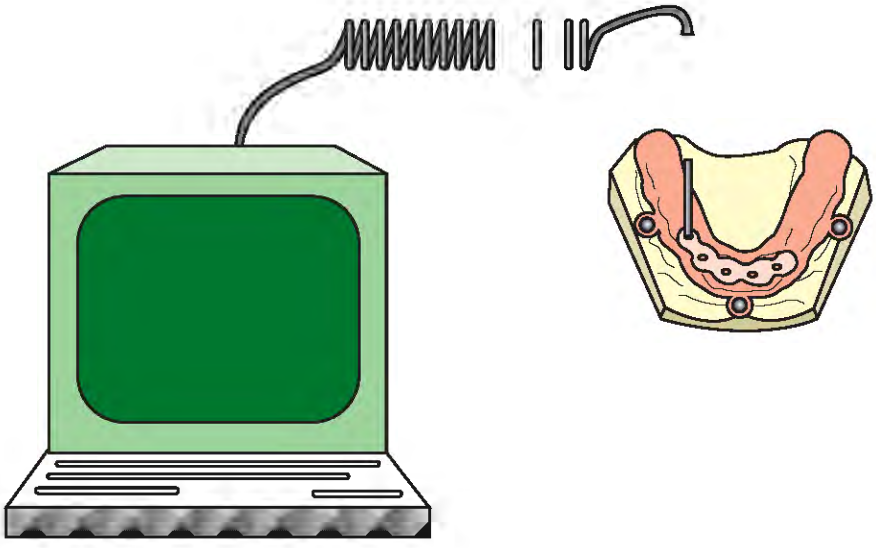

Figure 13-26 CAD/CAM computer-driven drill press system. Similar to the method shown in Figure 13-22, planning takes place on a computer. The scannographic template is repositioned on the model and registered using fiducial markers. A computer drives the table angulations to reproduce planning and convert the template into an accurate surgical guide.

WWW.HIGHDENT.IR

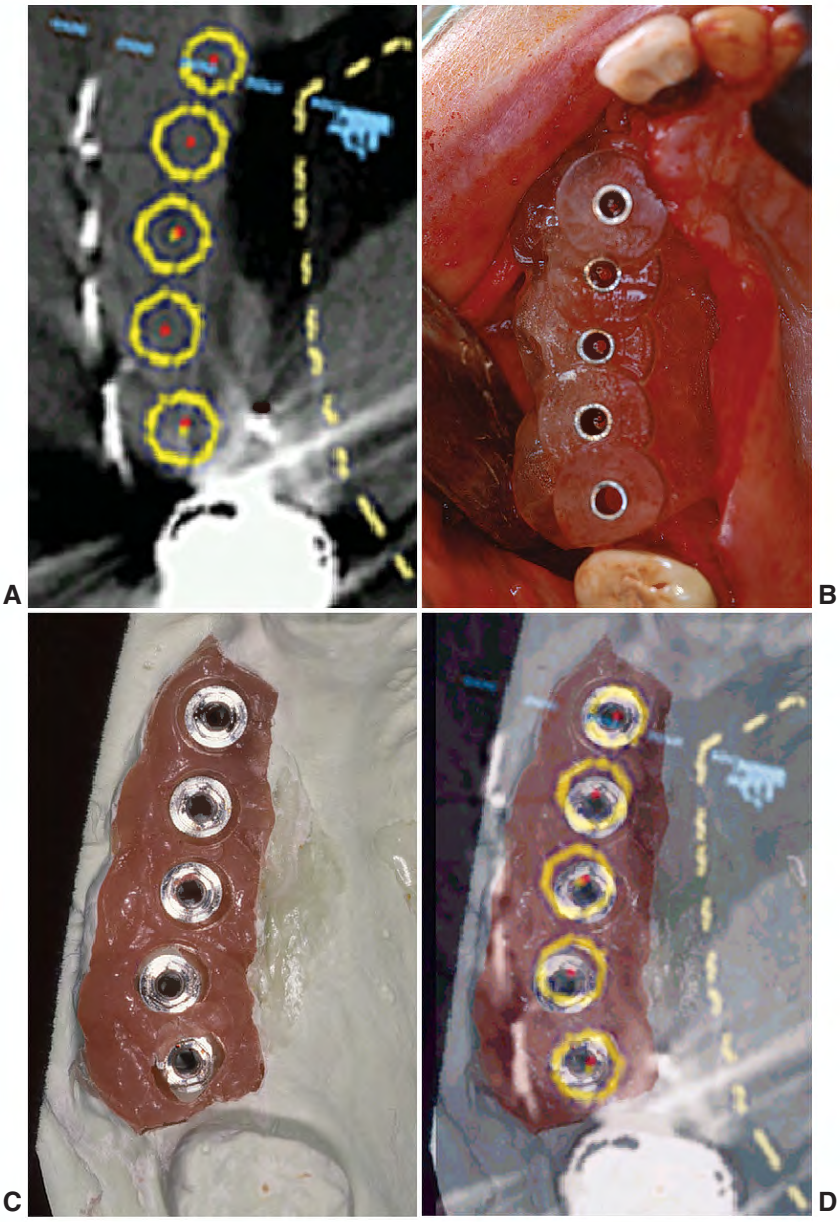

Figure 13-27 **A,** Virtual implant placement was forwarded for fabrication of surgical guides. **B,** The first surgical guide containing 2-mm metal guides is followed by identical guides with wider diameters. **C,** For comparison of planning and execution, the implant level impression was overlaid by virtual implant plan **A** to create the image **(D),** demonstrating a clinical accuracy.

placement is on average 7 degrees from planning, with the implant shoulder being a mean 1.45 mm from planning.[51]

Improvements of these surgical guides are ongoing, in particular for control of the coronoapical positioning. In a recent development, Tardieu and Vrielinck[52] proposed a modification to the first method described. These new templates (SAFE, Materialise) are secured onto the bone surface using tacking screws. Only one template is used and cylinders are replaced. This protocol also includes a limited sequence of specially designed surgical burs with stops, as well as implant carriers allowing for control of the insertion depth. Therefore another potential benefit to CAD/CAM surgical templates could be the elimination of sequential osteotomy drills, because their accuracy precludes the need for angulation correction offered by multiple enlarging osteotomies. Further research is warranted because single, larger drill osteotomies potentially can overheat the osseous surface.[53]

Surgical Navigation

Image-guided surgery, first developed for medical applications, recently has been introduced to implant dentistry.[54] The close surgical field and difficult accesses drove the need for computer guidance in medical applications such as neurosurgery, and dental implant placement may benefit from these technologies by offering a peroperative 3D assessment of osteotomies. Similar to the techniques described before, a CT scan is necessary. The scannographic guide includes fiducial markers for cross-referencing jaw positions with the CT scan, and virtual implant planning is performed

WWW.HIGHDENT.IR

using software. For surgery the handpiece is equipped with a 3D positioning device, such as electromagnetic digitizers[55] or light-emitting diodes.[56] Extraoral markers attached to the surgical guide are also necessary so that the computer can analyze the positions of the jaw and the handpiece relative to each other. Continuous reevaluation of locations and matching to the CT scan data during surgery allow for visualization of osteotomies and comparison of planning and drilling. Some computer systems are equipped with audible or visual warnings when osteotomies deviate from planning or when a vital structure is about to be entered. Research is showing that this approach, although complex, can yield favorable results perhaps, in the vicinity of 0.5 mm.[57,58]

One example of such application is marketed under the name *IGI* (Image Guided Implantology, DenX, Jerusalem, Israel). To perform a surgery using this system, a CT scan must be processed in the presence of a scannographic template attached to a manufactured arch registration device. The CT scan data is then transferred to custom software, and implant planning takes place using virtual implants. Before surgery, the registration device is repositioned, and a preliminary matching process is performed by locating radioopaque markers. Both the registration device attached to the patient and the handpiece possess light-emitting diodes (LEDs) that can be located in space via infrared cameras mounted above the dental chair. Once this registration has taken place, the surgery may begin using the reference body to locate the patient's jaw and the diode-equipped handpiece to locate the surgeon's movements. A computer screen displays real-time positioning of the drill in the mesiodistal, buccolingual, and coronoapical planes (Figure 13-28). For edentulous patients, temporary implants must be inserted because of the necessity to obtain a stable reference guide containing the markers.

Another similar system is the VirtualScope (Areall, Neuilly-sur-Seine, France), which features an advanced registration method allowing for elimination of positioning markers during CT scanning (Figure 13-29). The rationale for not using fiducial radiopaque landmarks in the scannographic template is that although matching of the markers and their CT image is possible, a small distortion at their level may become a severe mismatch at a distance from them. For instance, an implant's coronal position may remain accurate, whereas its apex is 2 to 3 mm from its intended location. Instead, this system offers a real-time 3D capture of the arch via an ultrasound probe. Mapping of the clinical image can be matched to the CT-scanned data and updated continuously, thus creating an accurate registration independent from a guide.[59] Flags are attached to the handpiece and the ultrasound probe, and their position in space is located by two sets of cameras above the surgeon. The reformatted CT scan, the implant plan, and the actual drill position are viewed at all times through glasses worn by the surgeon. In future versions, a semirigid arm also will connect to the handpiece so that position and angle will be guided by the computer while the surgeon applies the pressure. In addition, a similar registration approach will be used for periapical radiographs. The film holder position will be recorded in relation to an edentulous space. Multiple films will be taken at various angles, and the computer will be able to create a 3D view of the site, thus eliminating the need for a tomogram or a CT scan for small-span implant restorations. Interestingly, this

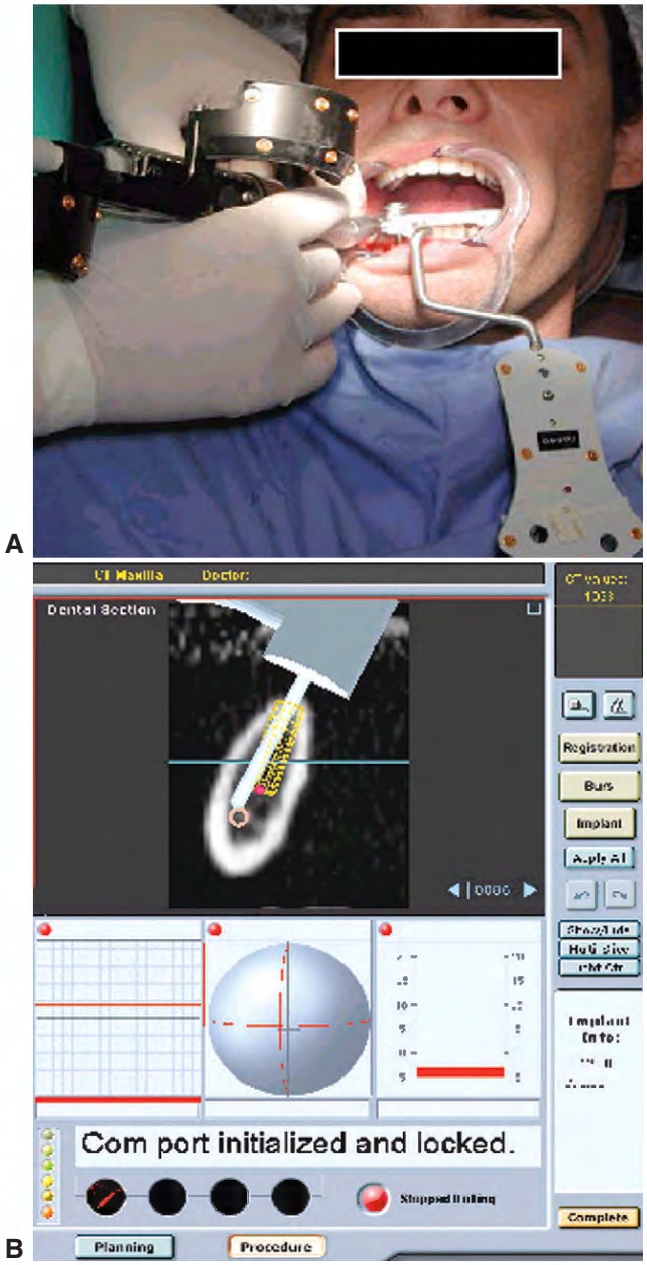

Figure 13-28 Image-guided surgery. **A,** The surgical handpiece and patient arch are registered in real time, allowing for **(B)** visualization and comparison of drilling with preplanning. Significant deviations are avoided by using an alarm or automatic handpiece shutdown.

system is being developed for dental applications but is also of interest for medical applications, such as for the ear, nose, and throat or neurosurgery.

Other similar methodologies are available, such as the system reported by Wanschitz et al.,[60] in which the handpiece and mandible are positioned using LEDs. In the latest version, the surgeon wears an optical tracking system that allows simultaneous visualization of the surgical field and the plan in the glasses.[61]

These promising computer-guided technologies are currently under development, although most are marketed already. Manufacturers claim a precision within less than 1 mm at the osteotomy entrance and high control of angulations.[43,62] Using the LED localization approach and a tracking system, Wanschitz et al.[60] performed an in vitro test of accuracy and found it to be within less than 1 mm. Further studies are necessary, but clinical application is beginning and will likely grow rapidly once costs are reduced.

SUMMARY

Surgical models and guidance have acquired a new dimension with the integration of CAD/CAM technology and computer-guided surgery. With the advent of low-radiation cone-beam computed tomography, now available in small practical units, access to CT data is simplified and, in turn, advanced diagnosis and fabrication of CAD/CAM surgical guides becomes more realistic. Precision has been improved and uncertainty and surgical time have been reduced, thus addressing complex rehabilitation with greater confidence. In addition, predictable positioning allows for better prosthetic outcome by simplifying abutment selection and avoiding complex laboratory fabrication when misalignment must be corrected. In addition, novel techniques are emerging that may enable the preparation of the final prosthesis before implant placement. Precise guidance is crucial to such complex reconstruction so that minimal adaptation is performed after surgery. Future technical improvements likely will allow dentists to access these technologies while controlling costs, reducing surgical time, and minimizing restorative steps.

Chapter 14

The Edentulous Mandible: An Organized Approach to Implant-Supported Overdentures

Carl E. Misch

The dental profession and the public are more aware of the problems associated with a complete mandibular denture than any other dental prosthesis. The placement of implants enhances the support, retention, and stability of an overdenture. As a result, patients are very willing to accept a treatment plan for a mandibular implant overdenture. There is greater flexibility in implant position or prosthesis fabrication with a mandibular implant overdenture, and, as a result, it is also an ideal treatment modality to begin a learning curve in implant dentistry. Therefore one of the most beneficial treatments rendered to patients is also one of the best introductions for a dentist into the discipline of implant dentistry. In comparison, maxillary implants for overdentures are not used as often and are also more difficult to place and restore.

The concept of mandibular implant–supported overdentures has been used for many years. Successful reports were published originally with mandibular subperiostal implants or with immediately loaded and stabilized root form implants in the anterior mandible.[1,2] An increased awareness from the profession and patients allows a variety of clinical situations, bone densities, biomechanics, and patients' desires to restore an ever-growing number of patients with implant-supported overdentures.[3-32] As the data gathered on this prosthetic modality grow, overdentures are gaining even greater acceptance and justifying their place in the armamentarium of the implant dentist.

From a bone volume conservation standpoint, complete edentulous patients should be treated with enough implants to support overdentures in the maxilla and mandible. The continued bone loss after tooth loss and associated compromises in esthetics, function, and health make all edentulous patients implant candidates. The average denture patient does not see a dentist regularly. In fact, 10 or more years usually separate dental appointments of edentulous patients. The more often a patient wears a denture, the greater the bone loss. Yet 80% of denture patients wear their dentures day and night, which accelerates the bone loss.

Because of the long hiatus between dental visits, the amount of resorption from initial denture delivery to the next professional interaction already has caused the destruction of the original alveolar process. The bone loss that occurs during the first year after tooth loss is 10 times greater than in following years. In the case of multiple extractions, this often means a 4-mm vertical bone loss within the first 6 months. As the bony ridge resorbs, the muscle attachments become level with the edentulous ridge.[33-35]

Rather than waiting until the patient has lost most of the residual bone, the dentist should inform and emphasize to the patient the benefits of implants and why they should be inserted before the bone is lost. Therefore the profession should treat bone loss from extraction in a similar fashion as bone loss from periodontal disease. Rather than waiting until the bone is resorbed or the patient complains, the dental professional should educate the patient about the bone loss process caused not only by periodontal disease, but also by the lack of stimulation and its consequences of bone resorption, and explain how implants are available to treat the condition. Therefore most completely edentulous patients should be informed of the necessity of dental implants to maintain bone volume, function, masticatory muscle activity, esthetics, and psychologic health. Ideally, patients who have unsalvageable teeth should be given the option to include implants to support the future prosthesis. The traditional complete denture may be presented as a temporary measure to provide cosmetic and oral function during implant treatment.

The next progression in the implant philosophy is to convert all mandibular implant and soft tissue–supported

WWW.HIGHDENT.IR

restorations to a completely implant-supported prosthesis. The majority of mandibular overdentures are supported by two implants anterior to the foraminae and soft tissue support in the posterior regions (Figure 14-1). Yet posterior bone loss occurs four times faster than anterior bone loss. In the completely edentulous patient, the eventual paresthesia and mandibular body fractures are primarily from posterior bone loss. The anterior implants allow improved anterior bone maintenance, and the prosthesis benefits from improved function, retention, and stability. However, the lack of posterior support in two- and three-implant overdentures may cause accelerated posterior bone loss. To the contrary, studies by Wright et al.[30] and Reddy et al.[36] found prostheses completely supported by implants in the edentulous mandible actually may increase the posterior bone volume (even though posterior implants are not inserted). As a result, complete implant-supported restorations should be the restoration of choice.

Financial considerations have been identified as the reason for the selection of a limited treatment, which may consist of two or three implants to support the overdenture.[37-39] These restorations may be used as transitional devices until the patient can afford to upgrade the restoration. When a partially edentulous patient cannot afford to replace four missing first molars, the dentist often will replace one at a time over many years. Likewise, the dental implant team can insert one or two additional implants every few years until finally a complete implant-supported prosthesis is delivered.

The ultimate goal may be designed in the beginning of treatment and may take many years to complete. However, the advantage of developing a treatment plan for long-term health, rather than short-term gain, is beneficial to the patient. As such, if finances are not an issue, the dentist should design a prosthesis that is completely supported, retained, and stabilized by implants. If cost is a factor, a transitional implant-retained restoration greatly improves the performance of a mandibular denture. Then the dentist may establish a strategy for the next one or two steps for the final restoration.

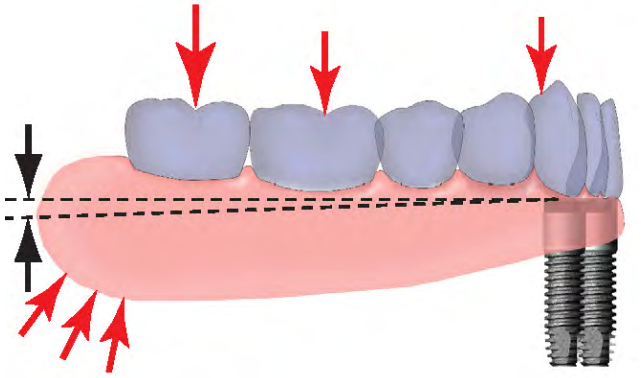

Figure 14-1 The majority of mandibular overdentures performed by dentists are with two implants, regardless of factors such as the remaining bone, the opposing arch, and patient complaints. Although this treatment is an improvement compared with a denture, the posterior bone loss continues and the anterior implants may experience greater problems than when additional implants are used.

REVIEW OF THE LITERATURE

In 1986 a multicenter study reported on 1739 implants placed in the mandibular symphysis of 484 patients. The implants were loaded immediately and restored with bars and overdentures with clips as retention. The overall success rate was 94%.[2] Engquist et al.[3] reported a 6% to 7% implant failure for mandibular implant–supported overdentures and a 19% to 35% failure for maxillary implant overdentures. Hyperplasia below the bar occurred in 25% of the patients. Prosthetic complications were not reported. Jemt et al.[4] reported on a 5-year prospective, multicenter study on 30 maxillae (117 Brånemark implants) and 103 mandibles with 393 implants. Survival rates in the mandible were 94.5% for implants and 100% for prostheses; in the maxilla, the survival rates were 72.4% for implants and 77.9% for prostheses. Higher failure rates in the maxilla were related directly to poor density and quantity of bone with a characteristic cluster failure pattern.

Wismeijer et al.[5] reported on 64 patients with 218 titanium plasma-sprayed implants, with a 97% survival with overdentures in a 6.5-year evaluation. Naert et al.[14] found 100% implant success at 5 years for overdentures with different anchorage systems. In Belgium, Naert at al. reported on 207 consecutively treated patients with 449 Brånemark implants and Dolder-bar overdentures. In this report, the cumulative implant failure rate was 3% at the 10-year benchmark.[9,10] In this long-term report, prosthetic complications related to overdenture relining and loose retention occurred 10% of the time. More care was needed if ball attachments were used rather than a Dolder bar.[9] In a 10-year study reporting on attachment methods, balls provided the greatest retention and magnets always scored the lowest.[10] Similarly, Hutton et al.[11] reported 97% survival rates for mandibular overdentures.

Misch[12] reported less than 1% implant failure and no prosthesis failure over a 7-year period with 147 patients when using the organized treatment options and prosthetic guidelines presented in this chapter. Kline et al.[13] reported on 266 implant-supported overdentures for 51 patients, with an implant survival rate of 99.6% and a prosthesis survival rate of 100%. Mericke-Stern et al.[16] reported 95% implant survival with two implant overdentures. In a randomized clinical report, Awad et al.[6] compared satisfaction and function in complete dentures (48 patients) versus two implant-supported overdentures (IODs) in 56 patients. There was significantly higher satisfaction, comfort, and chewing ability in the IOD group. A similar study in a senior population yielded similar results.[7] Thomason et al.,[8] in

WWW.HIGHDENT.IR

the United Kingdom, reported a 36% higher satisfaction for the implant IOD patients than the complete denture wearers in the criteria of comfort, stability, and chewing. In Canada, Attard and Zarb[40] followed IOD wearers for 20 years with a success rate of 84% and 87% for prosthesis and implants, respectively. In a 10-year study of IODs in Israel, with 285 implants and 69 implant over dentures, Schwartz-Arad et al. reported implant survival was 96.1% with higher success rates in the mandible.[41] Many reports have been published over the last two decades that conclude that implant-supported overdentures represent a valid beneficial option for denture wearers.[3-41] It should be noted that the majority of reports are for implant overdentures supported by only two implants.

ADVANTAGES OF IMPLANT OVERDENTURES

Traditional overdentures must rely on the remaining teeth to support the prosthesis. The location of these natural abutments is highly variable, and they often comprise past bone loss associated with periodontal disease. For a mandibular implant–supported overdenture, the implants may be placed in planned, specific sites, and their number may be determined by the restoring doctor and patient. In addition, the overdenture implant abutments are healthy and rigid and provide an excellent support system. As a result, the related benefits and risks of each treatment option may be predetermined.

The patient gains several advantages with an implant-supported prosthesis (Box 14-1). Minimal bone resorption of the anterior residual ridge occurs with the placement of implants. After the extraction of mandibular teeth, an average of 4-mm vertical bone loss occurs during the first year after treatment. This bone loss continues over the next 25 years, with the mandible experiencing a fourfold greater vertical bone loss than the maxilla.[35] The bone under an overdenture may resorb as little as 0.6 mm vertically over 5 years, and long-term resorption may remain at less than 0.05 mm per year.[4,40,42,43]

Box 14-1 Implant Overdenture Advantages

- Minimum anterior bone loss; prevents bone loss
- Improved esthetics
- Improved stability (reduces or eliminates prosthesis movement)
- Improved occlusion (reproducible centric relation occlusion)
- Decrease in soft tissue abrasions
- Improved chewing efficiency and force
- Increased occlusal efficiency
- Improved retention
- Improved support
- Improved speech
- Reduced prosthesis size (eliminates palate, flanges)
- Improved maxillofacial prostheses

Bone loss dictates the appearance of the inferior third of the face. A maxillary overdenture often provides improved support for the lips and soft tissues of the face compared with a fixed prosthesis because the prosthesis contour does not have to accommodate daily hygiene requirements. Denture teeth also provide an esthetic replacement for the natural dentition, which is more challenging for the technician to recreate with porcelain-fused-to-metal restorations. For the laboratory to create pink interdental papilla, as well as replace the soft tissue drape, is easier with an overdenture compared with porcelain-metal fixed restorations. In addition, the teeth can be positioned in the most esthetic position, without any restriction as to the relationship to the atrophied crest, because stability now is provided by the implant and does not depend on tooth position on the crest of the ridge.

Soft tissue abrasions and accelerated bone loss are more symptomatic of horizontal movement of the prosthesis under lateral forces. An implant-supported overdenture may limit lateral movements and direct more longitudinal forces. A mandibular denture may move 10 mm during function. Under these conditions, specific occlusal contacts and the control of masticatory forces are nearly impossible. An implant overdenture provides stability of the prosthesis, and the patient is able consistently to reproduce a determined centric occlusion.[44]

A study of chewing efficiency compared wearers of complete dentures with wearers of implant-supported overdentures. The complete denture group needed 1.5 to 3.6 times the number of chewing strokes compared with the overdenture group.[45] The chewing efficiency with an implant overdenture is improved by 20% compared with a traditional complete denture.[6,7,46,47]

Higher bite forces have been documented for mandibular overdentures on implants. The maximum occlusal force of a patient with dentures may improve 300% with an implant-supported prosthesis.[48] Mericke-Stern[49] and Mericke-Stern et al.[50] compared mastication between root overdentures and implant overdentures. The former was more discriminative, whereas the latter developed slightly harder chewing strokes and tended to masticate more vertically. Jemt et al.[51] showed a decrease in occlusal force when the bar connecting implants was removed, which they attributed to the loss of support, stability, and retention. If enough implant support is provided, the resulting prosthesis may be completely supported, retained, and stabilized by the implant (removable prosthesis type 4 [RP-4]).

The complete mandibular denture often moves during mandibular jaw movements during function

WWW.HIGHDENT.IR

and speech. The contraction of the mentalis, buccinator, or mylohyoid muscles may lift the denture off the soft tissue. As a consequence, the teeth may touch during speech and elicit clicking noises. The retentive implant overdenture remains in place during mandibular movement. The tongue and perioral musculature may resume a more normal position because they are not required to limit mandibular denture movement.

The implant overdenture may reduce the amount of soft tissue coverage and extension of the prosthesis. This is especially important for new denture wearers, patients with tori or exostoses, or patients with low gagging thresholds. Also, the existence of a labial flange in a conventional denture may result in exaggerated facial contours for the patient with recent extractions. Implant-supported prostheses do not require labial extensions or extended soft tissue coverage.

Soft and hard tissue defects from tumor excision or trauma do not permit the successful rehabilitation of the patient with traditional denture support. Hemimandibulectomy patients and other maxillofacial patients also may be restored successfully with an implant overdenture.[52,53]

The implant overdenture also provides many practical advantages over the implant-supported complete fixed partial denture (Box 14-2). Fewer implants are required, because soft tissue areas may provide additional support. Regions of inadequate bone for implant placement therefore may be eliminated from the treatment plan, rather than necessitating bone grafts or placing implants with poorer prognosis. Abutments do not require a specific mesiodistal placement because the prosthesis completely covers the implant abutments.

The esthetics for many edentulous patients with moderate to advanced bone loss are improved with an overdenture compared with a fixed restoration. Soft tissue support for facial appearance often is required for an implant patient because of advanced bone loss, especially in the maxilla. Interdental papilla and tooth size are easier to reproduce or control with an overdenture. Denture teeth easily reproduce contours and esthetics compared with time-consuming and technician-sensitive porcelain-metal fixed restorations. The labial flange may be designed for optimal appearance, not daily hygiene.

Hygiene conditions and home and professional care are improved with an overdenture compared with a fixed prosthesis. Peri-implant probing is diagnostic and easier around a bar than a fixed prosthesis because the crown often prevents straight line access along the abutment to the crest of the bone. The overdenture may be extended over the abutments to prevent food entrapment during function. Speech is not compromised because the denture may extend onto the soft tissues in the maxilla and prevent air and saliva from escaping.

An overdenture may be removed at bedtime to reduce the noxious effect of nocturnal parafunction, which increases stresses on the implant support system. The overdenture may provide stress relief between the superstructure and prosthesis, and the soft tissue may share a portion of the occlusal load. The prosthesis is usually easier to repair than a fixed restoration. Reduced laboratory fees and fewer implants allow the restoration of patients at reduced costs compared with a fixed prosthesis. In addition, long-term denture patients do not appear to have a psychologic problem associated with the ability to remove their implant prostheses.[54-62]

When cost is a factor, two implant-retained IODs may improve the patient's condition at a lower overall treatment cost than a fixed implant–supported prosthesis.[42,44,63] A survey by Carlsson et al.[64] in 10 countries indicated a wide range of treatment options. The proportion of implant overdentures selection versus fixed implant dentures was highest in the Netherlands (93%) and lowest in Sweden and Greece (12%). Cost was cited as the number one determining factor in the choice.

The primary indications for a mandibular implant overdenture are problems often found with lower dentures, such as lack of retention or stability, decrease in function, difficulties in speech, tissue sensitivity, and soft tissue abrasions. If an edentulous patient is willing to remain with a removable prosthesis, an overdenture is often the treatment of choice. In addition, if cost is a problem for the patient, the overdenture may serve as a transitional device until additional implants may be inserted and restored.

Box 14-2 Implant Overdenture Advantages versus Fixed Prosthesis

- Fewer implants (RP-5)
  - Less bone graft
  - Less specific placement
- Improved esthetics
  - Labial flange
  - Denture teeth
  - Soft tissue drape
- Soft tissue considerations
  - Improved peri-implant probing (follow-up)
  - Hygiene
- Reduced stress
  - Nocturnal parafunction (remove prosthesis, at night)
  - Stress-relief attachment
- Lower cost and laboratory cost (RP-5)
  - Fewer implants (RP-5)
  - Less bone grafting (RP-5)
  - Easy repair
  - Laboratory cost decrease (RP-5)
- Transitional device until fixed restoration guidelines are complete

WWW.HIGHDENT.IR

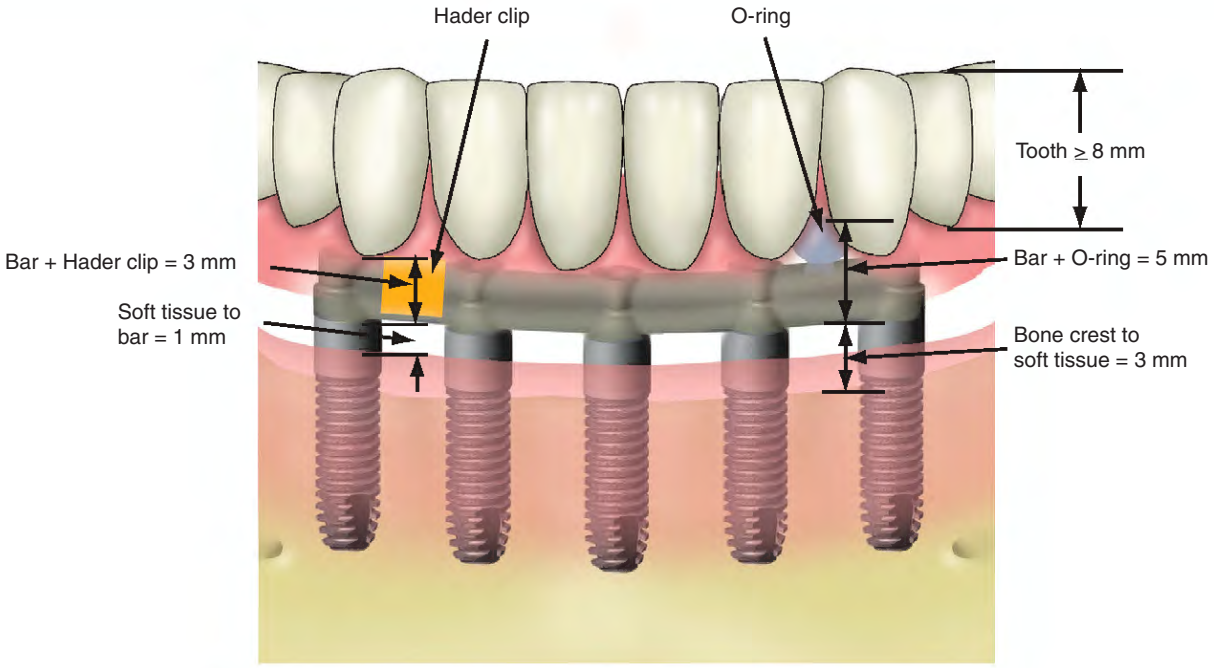

Figure 14-2 The mandibular overdenture requires at least 12 mm between the soft tissue and the occlusal plane to provide sufficient space (15 mm from bone level to occlusal plane) for the bar, attachments, and teeth.

DISADVANTAGES OF IMPLANT OVERDENTURES

The primary disadvantage of a mandibular overdenture is related to the patient's desire, primarily because they do not want to be able to remove the prosthesis. A fixed prosthesis often is perceived as an actual body part of the patient, and if a patient's primary request is not to remove the prosthesis, an implant-supported overdenture would not satisfy the psychological need of this patient.

The mandibular overdenture treatment plan requires more than 12 mm of space between crestal bone and the occlusal plane (Figure 14-2). When sufficient crown height space is lacking and the prosthesis is more prone to component fatigue and fracture, an overdenture is more difficult to fabricate than a porcelain-to-metal fixed prosthesis. The 12-mm minimum crown height space provides adequate bulk of acrylic to resist fracture, space to set denture teeth without modification, and room for attachments, bars, soft tissue, and hygiene. In the mandible, the soft tissue is often 1 to 3 mm thick above the bone, so the occlusal plane to soft tissue should be at least 9 to 11 mm in height. An osteoplasty to increase crown height space before implant placement or a fixed restoration is often indicated when abundant bone height and width are present.

Mandibular overdenture wearers often incur greater long-term expenses than those with fixed restorations. Attachments such as O-rings or clips wear and must be replaced regularly. Replacements appear more frequent during the first year, but remain a necessary maintenance step.[17,20,34,65-72] Denture teeth wear faster on an implant overdenture than with a traditional denture because bite force and masticatory dynamics are improved. A new overdenture often is required at 5- to 7-year increments because of denture tooth wear and soft tissue support changes. Therefore patient education of the long-term maintenance requirement should be outlined at the onset of implant therapy.[73]

A primary concern for RP-5 overdentures compared with RP-4 or fixed restorations is the continued bone loss in the posterior regions. The posterior bone resorbs faster than the anterior bone, and implant prostheses with posterior soft tissue support may accelerate posterior bone resorption two to three times faster than in a complete denture wearer.[73-75] By contrast, patients wearing fixed implant–supported prostheses showed no bone loss and usual occurrences of bone apposition.[76,77] Therefore the short-term benefit of decreased cost may be offset by the accelerated bone loss that is a primary consideration, especially in the younger edentulous patient. As previously discussed, all implant overdentures would benefit if they were completely implant supported, and the recommendation is to consider a RP-5 prosthesis as an interim device designed to enhance the function of the patient. These prostheses should not be considered as an end result for all patients. Instead, a regular evaluation of patients' performance paired with patient education should enable the transformation to a RP-4 restoration. In addition, reports indicate that mandibular implant overdentures may cause a combination-like syndrome, with increased looseness, subjective loss of fit, and midline fracture of the upper

denture.[78-82] Although not yet established as a cause-and-effect situation, the condition also appears to be controlled by the choice of proper occlusal scheme.[80]

A side effect of a mandibular overdenture is food impaction. The flanges of the prosthesis do not extend to the floor of the mouth in the rest position (to eliminate sore spots caused by elevation of the floor of the mouth during swallowing). However, during eating, food particles migrate and become impacted under the prosthesis during swallowing. A similar condition is found with a traditional denture. However, because a lower denture "floats" during function, the food more readily goes under and out, whereas the implant overdenture traps the food debris against the implants, bars, and attachments (Box 14-3).

OVERDENTURE MOVEMENT

The most common complications found with mandibular implant overdentures are related to a lack of understanding of retention, support, and stability of the prosthesis. When a fixed restoration is fabricated on implants, it is rigid, and cantilevers or offset loads are clearly identified. Rarely will a practitioner place a full-arch fixed restoration on three implants, especially with excessive cantilevers because of implant positioning. However, three anterior implants with a connecting bar may support a fixed overdenture system solely because of attachment design or placement. The restoring doctor thinks the overdenture needs less support, but does not realize that an overdenture that does not move during function is actually a fixed restoration. Therefore an overdenture with no prosthesis movement should be supported by implants in number, position, and design similar to fixed restorations.

Many precision attachments with varying ranges of motion are used in implant overdentures. The motion may occur in one to six directions or planes: occlusal, gingival, facial, lingual, mesial, and distal. A type 2 attachment moves in two planes, a type 4 attachment in four planes. However, the resulting overdenture movement may be completely different from the one provided by independent attachments and may vary from one to six directions depending on the position and number of attachments, even when using the same type. Therefore attachment and prosthesis movement are independent from each other and should be evaluated as such.

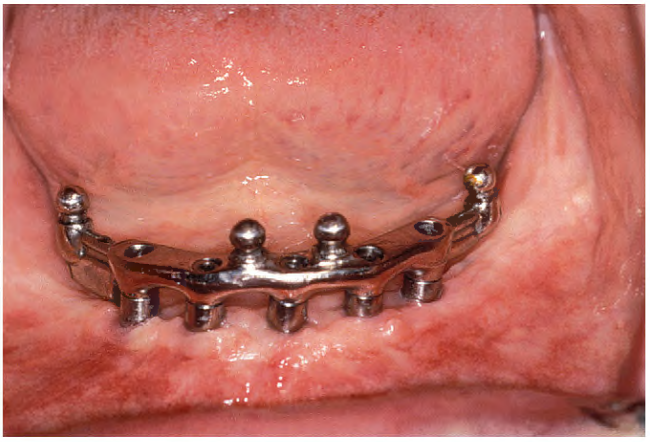

Figure 14-3 Prosthesis movement for overdentures is often different than "attachment" movement categories. In this illustration, O-rings (a Class 6 attachment movement) and Hader clip (a Class 2 attachment movement) support a rigid overdenture. The prosthesis movement is PM-0.

Classification of Prosthesis Movement

The classification system proposed by the author in 1985 evaluates the direction of movement of the implant-supported prosthesis, not the overall range of motion for the individual attachment; therefore the amount of prosthesis movement (PM) is the primary concern. An overdenture is by definition removable, but in function the prosthesis may not move. If the prosthesis does not have movement during function, it is designated PM-0 and requires implant support similar to a fixed prosthesis. A prosthesis with a hinge motion is PM-2, and a prosthesis with an apical and hinge motion is PM-3. A PM-4 allows movement in four directions, and the PM-6 has all ranges of prosthesis movement.

The dentist evaluates the prosthesis movement when seating the restoration. If the prosthesis is rigid when in place but can be removed, the prosthesis movement is labeled PM-0, regardless of the attachments used. For example, O-rings may provide motion in six different directions. But if four O-rings are placed along a complete arch bar, and the prosthesis rests on the bar, the situation may result in a PM-0 restoration (Figure 14-3). A hingelike prosthesis movement permits movement in two planes (PM-2) and most often uses a hingelike attachment. For example, the Dolder bar and clip without a spacer or Hader bar and clip are the most commonly used hingelike attachment. A Dolder bar is egg shaped in cross section, and a Hader bar is round. A clip attachment may rotate directly on the Dolder bar. A Hader bar is more flexible because round

WWW.HIGHDENT.IR

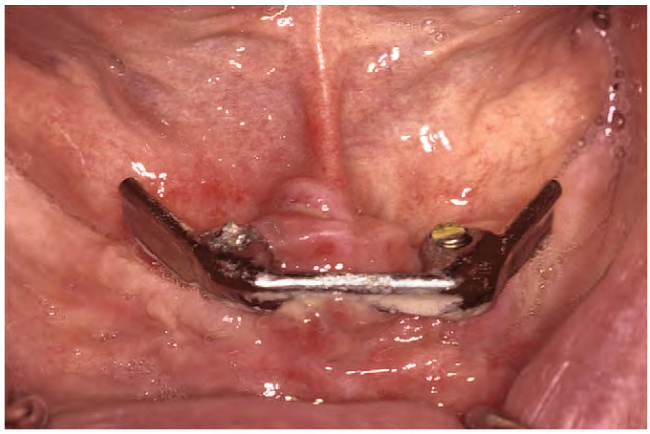

Figure 14-4 A Hader bar clip is a Class 2 attachment system. However, when the clips are placed parallel or at an angle to the desired prosthesis movement, the prosthesis is rigid. In this case, two implants are not enough to support a PM-0. Screw loosening, bone loss, and implant failure resulted.

bars flex to the power of 4 related to the distance and other bar shapes flex to the power of 3. As a result, an apron often is added to the tissue side of the Hader bar to limit metal flexure, which might contribute to unretained abutments or bar fracture. It should be noted that for these systems to function efficiently, the hinge attachment needs to be perpendicular to the axis of prosthesis rotation, so the prosthesis movement also will be in two planes (i.e., PM-2). If the Hader or Dolder bar is at an angle or parallel to the direction of desired rotation, the prosthesis is more rigid and may resemble a PM-0 system (Figure 14-4).

A cross section of the Hader bar and clip system reveals that the apron, by which the system gains strength compared with a round bar design, also limits the amplitude of rotation of the clip (and prosthesis) around the fulcrum to 20 degrees, thus transforming the prosthesis and bar into a more rigid assembly. Therefore the Hader bar and clip system may be used for a PM-2 when posterior ridge shapes are favorable and soft tissue is firm enough to limit prosthesis rotation.

A Hader bar-clip system is an ideal low-profile attachment for an RP-4 prosthesis, with PM-0. Usually, these clips are placed on the bar in different planes around the arch.

A Dolder bar and spacer is desirable when greater amplitude of movement is needed to account for poorer ridge anatomy. An attachment system that permits apical movement and a hinge motion is called a type 3 system. For example, a Dolder bar with spacer and clip is designed for three planes of movement.

A spacer can be added to the occlusal surface of the egg-shaped Dolder bar during the processing of the clip attachment. The retention clip does not engage the top of the bar when the spacer is removed. As a result, the removable prosthesis may move down toward the clip and then rotate around the bar. The bar and clip also must be perpendicular to the direction of prosthesis rotation to allow a PM-3 movement. When no clip is included to enhance prosthesis rotation, a more rigid system is created (i.e., PM-2).

A PM-4 restoration rarely is created with an overdenture system. The type 4 overdenture attachment systems allow a range of motion (i.e., mesial, distal, facial, and lingual directions), and the restoration may be removed. Magnets are the most common implant attachment system, allowing a PM-4. An advantage is that they exert practically no lateral force on the implants. However, the implants usually must be independent from each other for this range of motion to occur. If a superstructure connects the implants, the range of prosthesis motion decreases. Independent magnets provide excellent retention, but often poor stability of the prosthesis. Although great improvements in their size and retention characteristics have been achieved since their introduction into dentistry, magnets still often are plagued with long-term problems of corrosion.

An O-ring or extracoronal resilient attachment may correspond to six directions of motion. However, the implants usually need to remain independent (not connected with a bar) to permit a PM-6 range of movement. A superstructure bar limits the prosthesis movement, depending on its design. A greater interarch space is required and greater forces are applied against the support system of an O-ring because the vertical component of rotation for this attachment extends about 5 mm above the implant.

MANDIBULAR IMPLANT SITE SELECTION

Anterior retention and stability for an overdenture offer several advantages. The greatest available height of bone is located in the anterior mandible, between the mental foraminae. This region also usually presents optimal density of bone for implant support. In addition, overdentures with posterior movement (RP-5) gain better acceptance than removable restorations with anterior movement. An axiom in removable partial denture design is to gain rigid prosthetic support in the anterior region. When the prosthesis has poor anterior and good posterior support, it rocks back and forth. This rocking action applies torque to the abutments and increases stresses on the overdenture components and bone-implant interface. Therefore anterior forces should be resisted by implants or bars, whereas posterior forces may be directed on a soft tissue area such as the mandibular buccal shelf. Therefore the implant overdenture treatment options presented are designed for anterior implant placement.

The available bone in the anterior mandible is divided into five equal columns of bone serving as potential implant sites, labeled A, B, C, D, and E, starting from the patient's right side (Figure 14-5).[83,84] Regardless of

WWW.HIGHDENT.IR

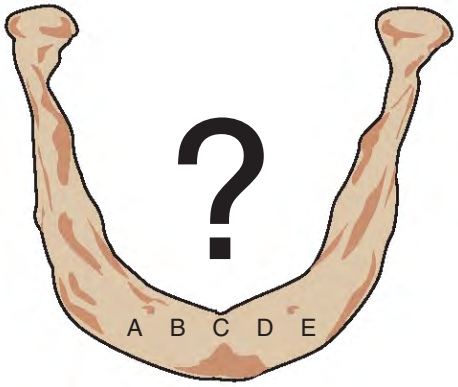

Figure 14-5 The anterior mandible is divided into five equal columns of bone between the mental foramens: A, B, C, D, and E.

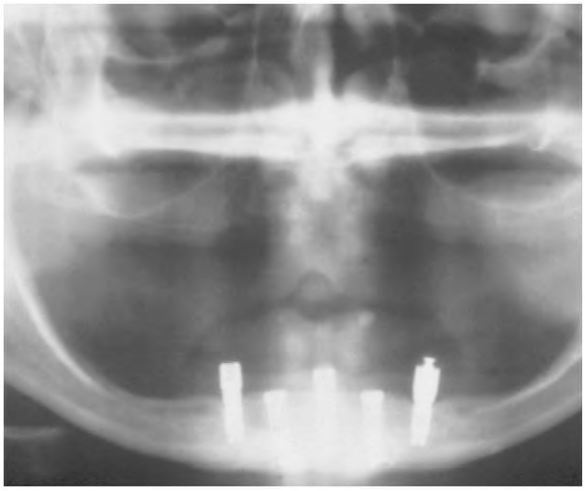

Figure 14-6 This patient wore a three-implant overdenture for several years. She then decided to improve the overdenture support, stability, and retention. The implant sites B and D could be added later because all five implant sites were planned initially.

the treatment option being executed, all five implant sites are mapped at the time of treatment planning and surgery. In this way, the patient always has the option to obtain additional implant support in the future. For example, a patient may receive adequate support for an implant overdenture with four implants. However, if the patient desires a fixed prosthesis in the future, these four implants may fall short of the new requirements. If the implant surgeon did not plan an additional implant site at the initial surgery but instead placed the four implants an equal distance apart, the additional space may not be available without removing one of the present implants. In addition, a patient may desire a completely implant-supported restoration as an RP-4 or fixed prosthesis but cannot afford the treatment all at once. Three implants in the A, C, and E positions and an overdenture may be provided now, and two implants may be added in the B and D locations later and a completely implant-supported overdenture or fixed restoration may be fabricated (Figures 14-6 and 14-7).

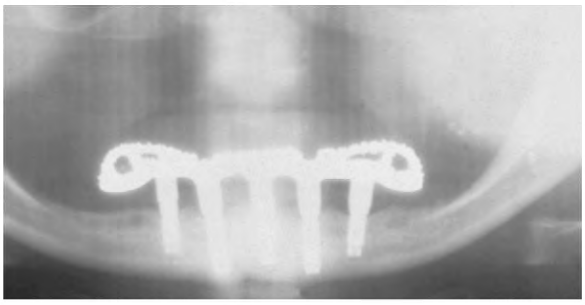

Figure 14-7 A hybrid fixed prosthesis was fabricated after the two additional implants were placed (same patient as Figure 14-6).

If an implant complication occurs, the preselected option sites permit corrective procedures. If implants were placed in the A, B, D, and E positions, and an implant fails to achieve rigid fixation, the failed implant may be removed and an additional implant placed in the C position at the same time. This saves an additional surgery and eliminates the time required for bone healing before another implant could be reinserted.

OVERDENTURE TREATMENT OPTIONS

In 1985 the author presented five organized treatment options for implant-supported mandibular overdentures in the completely edentulous patient.[12,83,84] The treatment options range from primarily soft tissue support and implant retention (RP-5) to a completely implant-supported prosthesis (RP-4) with rigid stability (Table 14-1). The options err on the side of safety to reduce the risk of failure or complications of bone loss and superstructure loosening. The initial treatment options are presented for completely edentulous patients with Division A (abundant) or B (sufficient) anterior bone, treated with Division A anterior root form implants of 4 mm or greater diameter. Modifications related to posterior ridge support and arch form also are discussed. Following these standardized conditions, anterior bone volume conditions of moderate atrophy (Division C minus height [C–h]) are presented.

The dentist evaluates the patient's existing dentures concerning support, retention, and stability. Support is related to the resistance to occlusal load. Retention describes the resistance of the prosthesis to movement away from the tissues. Stability is the lateral resistance criterion. The patient's complaints, anatomy, desires, and financial commitment determine the amount of implant support, retention, and stability required to address these conditions predictably. The amount of resistance provided in implant overdentures is related to the number and position of the implants (see Table 14-1). One should emphasize that most mandibular overdentures should be designed to eventually result in an RP-4 prosthesis, as previously discussed.

Box 14-4 Patient Selection Criteria: OD-1

- Anatomical conditions are good to excellent.
- Posterior ridge form is an inverted U shape.
- Patient's needs and desires are minimal, primarily related to lack of retention.
- Cost is the primary factor.
- Hygiene is improved.
- Arch form is tapered.
- Additional implants will be inserted within 3 years.

Overdenture Option 1

The first treatment option for mandibular overdentures (OD-1) is indicated primarily when cost is the most significant patient factor. However, the patient's desires should also be minimal, and the bone volume should be abundant (Division A or B). The posterior ridge form should be an inverted U shape, with high parallel walls for good to excellent anatomical conditions for conventional denture, support, and stability (Box 14-4). The problem associated with the existing denture relates primarily to the amount of retention. Under these conditions, two implants may be inserted in the B and D positions. The implants remain independent of each other and are not connected with a superstructure. The most common type of attachment used in OD-1 is an O-ring design, and the prosthesis movement should be as much as is practical.

Positioning of the implants in the B and D position is a much better prosthetic option in OD-1 than positioning in the A and E regions (Figure 14-8). Kennedy Class 1 patients with bilateral distal extensions and anterior missing teeth often are restored with a fixed prosthesis anteriorly and a Class 1 removable partial denture. This eliminates the unfavorable rocking leverages that exist when replacement denture teeth are anterior to the fulcrum line. If only two natural canines remain, a cross-arch tissue bar can be placed to gain a favorable distribution of forces in the anterior region.[85] Likewise, independent implants in the A and E positions allow a greater amplitude of rocking of the restoration compared with implants in the B and D regions. When using B and D implants, the anterior movement of the prosthesis is reduced, and the prosthesis even may act as a splint for the two implants during anterior biting forces, thereby decreasing some of the stress to each implant. However, most situations do not allow the prosthesis to act as a true splint because a stress relief attachment permits movement in any plane. As a result, only one implant is loaded at a time in most situations. The stability and support of the prosthesis are gained primarily from the anatomy of the mandible and prosthesis design, which is similar to a complete denture. The implant support mechanism is poor because stress relief is permitted in any plane.

The patient's primary advantage with OD-1 is cost. The existing restoration often may be adapted with an intraoral rebase and pickup procedure around the implants and attachments. Additional indications are

WWW.HIGHDENT.IR

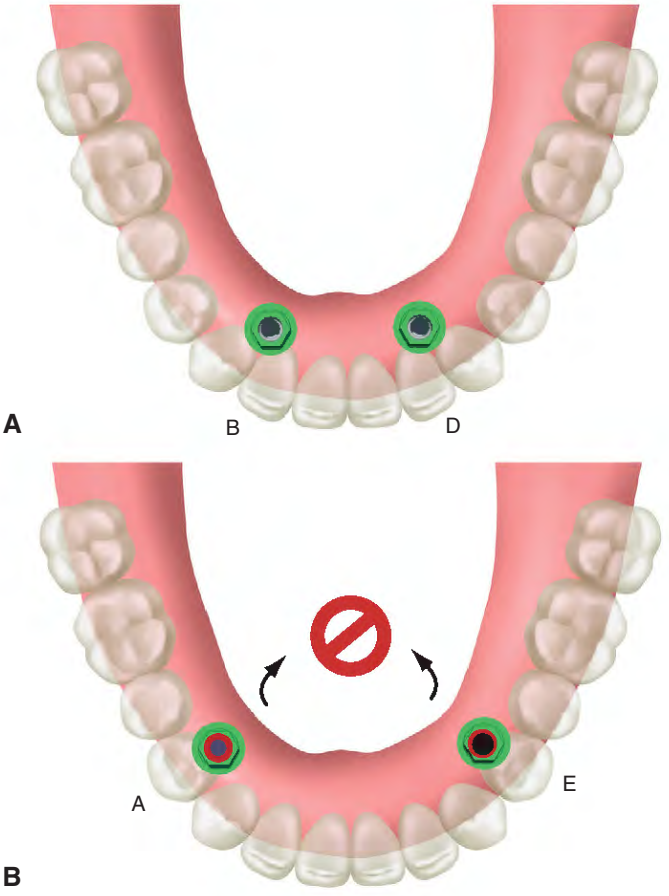

Figure 14-8 Overdenture option 1 consists of two independent implants. These are best placed in the B and D positions **(A)** to limit the forward rocking of the restoration during function. Independent implants in the A and E positions **(B)** allow a greater rocking of the restoration and place greater leverage forces against the implants.

when arch shape is considerably tapered such that a connecting bar would be cantilevered too far to the facial or would interfere with speech and mastication if too lingual. Hygiene procedures also are facilitated with independent ball attachments.

The disadvantages of the OD-1 relate to its relatively poor implant support and stability, compared with the other options (which have connecting bars), because of the independent nature of the implants. Jemt et al.[4] demonstrated a decrease in occlusal force when the bar connecting implants was removed from implant overdenture patients. In addition, bone loss in the edentulous regions of the mandible is not reduced significantly because only two anterior implants are inserted.

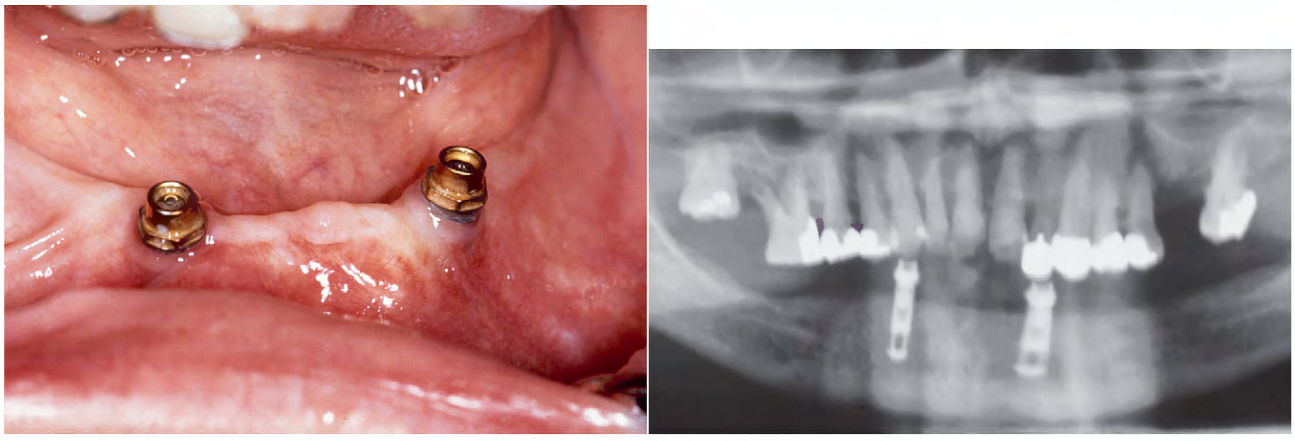
The other disadvantages of OD-1 relate to an increase in prosthetic maintenance appointments. For the restoration to be inserted and function ideally, the two implants should be parallel to each other, perpendicular to the occlusal plane, at the same horizontal height (parallel to the occlusal plane), and equal distance off the midline. If one implant is not parallel to the other, the prosthesis will wear one attachment faster because of the greater displacement during insertion and removal than the other. If the angulation difference is severe, the prosthesis may not engage one attachment at all. The implants also should be perpendicular to the occlusal plane. Because the goal is to allow the posterior regions of the overdenture to rock downward and load the soft tissue over the mandibular buccal shelves for support, the hinge rotation should be at 90 degrees to the rotation path. In addition, because only two implants sustain the occlusal load during function or parafunction, minimization of the forces to the implant components and crestal bone by placing them in the long axis of the implant body and perpendicular to the occlusal plane is ideal.

The two independent implants should be positioned at the same occlusal height, parallel to the occlusal plane. If one implant is higher than the other, the prosthesis will disengage from the lower implant during function and rotate primarily on the higher implant (Figure 14-9). This situation will accelerate the wear of the O-ring or attachment on the lower implant. In addition, because the higher implant receives the majority of the occlusal load, an increased risk of complications may occur, including abutment screw loosening, crestal bone loss, and implant failure.

The implants should be equal distance off the midline. If one implant is more distal (farther from the midline), it will serve as the primary rotation point or fulcrum when the patient occludes in the posterior segments. As such, the more medial implant attachment will wear faster, and the more distal implant will receive a greater occlusal load. As a consequence of additional maintenance risks, independent implants should be used less frequently than implants joined together with a bar. Attachments in a connection bar may be placed by the laboratory in similar horizontal, vertical, and axial planes much easier than the surgeon placing the implants.

The OD-1 is used as a treatment option when patients understand that additional implant support is beneficial, but financial constraints require a transition period of a few years before placing additional implants. The next goal in the treatment plan is to convert OD-1 patients to an RP-5 prosthesis with more support and stability before the loss of the posterior bone in the mandible behind the foraminae. As soon as the patient can afford two more implants, the implants should be placed in the A and E position, and all four ABDE implants should be connected with a bar that may be cantilevered to help reduce the posterior bone loss (OD-4). If bone height and width distal to one mental foramen are adequate, the additional implants may be positioned in one of the first molar regions. This plan will help maintain posterior bone, limit the cantilever to only one side, and greatly improve the anteroposterior distance (A-P spread) between implants and allow an RP-4 restoration.

WWW.HIGHDENT.IR



A B

Figure 14-9 **A,** When one implant is placed more anterior than the other (as shown), the more distal implant is the fulcrum when chewing in the posterior region and the more anterior implant is the fulcrum for movement when the patient incises food. This causes instability, wearing of the attachments, and loosening of the O-rings from the implant bodies. **B,** Two independent implants should be at the same height, equal distance off the midline, and parallel to each other. When the implants are positioned as in this radiograph, one implant (not two) becomes the dominant fulcrum and increases the risk of overload complications. This is especially important when force factors are higher than usual. The patient's occlusal plane also should be modified to allow a bilateral balanced occlusion on an RP-5 overdenture.

Box 14-5 Patient Selection Criteria: OD-2

- Anatomical conditions are good to excellent.
- Posterior ridge forms an inverted U shape.
- Patient's need and desires are minimal, primarily related to lack of retention.
- Patient can afford new prosthesis and connecting bar.
- Additional implants will not be inserted for more than 3 years.

Overdenture Option 2

The second treatment option for a mandibular overdenture (OD-2) is selected as the initial option more often than OD-1. The implants are positioned in locations B and D and splinted together with a superstructure bar without any distal cantilever (Figure 14-10). Reduced loading forces are exerted on two anterior implants when splinted with a bar compared with individual implants.[86-89] The bar is designed to position the attachments an equal distance off the midline, parallel to each other, at the same occlusal height, and in a similar angulation to provide added retention[27] (Box 14-5).

The two splinted implants should not be in the A and E positions (Figure 14-11). There are many reasons why two implants placed in the A and E positions should not be splinted together. Because these implants are placed just anterior to the mental foraminae, they are usually in the first premolar positions. This results in a curved arch form anterior to the implant sites and is too long a span relative to occlusal loading and flexibility of the metal bar.

The superstructure that follows the anterior curve of the arch results in an improved lingual contour of the restoration. However, the curve corresponds to an increased length and even greater flexibility of the superstructure. Because the bar is under the anterior teeth but anterior to the implants, a greater moment of force also is created. The prosthesis attachment system to the superstructure also may be compromised if clips are used for retention. The clips must be perpendicular to the path of rotation but a curved bar often places the clips closer to the implants and prevents rotation of the prosthesis. If the prosthesis rests against the sides of the curved bar, the prosthesis movement may be reduced to PM-0. This places a much greater lateral load on the implant system. Bars that course in a tangential direction do not permit friction-free rotation of the prosthesis around the fulcrum. Excess torsional loading is exerted on the implants and bar resulting in screw loosening or crestal bone loss.

The distance between A and E implants represents approximately a span of six teeth. The superstructure flexibility is related to the length. As a result, five times more flexure is observed than if the implants were in the B and D locations.[89] The increase in superstructure movement may result in loosening of the coping screws. After this occurs, the remaining attached implant receives a dramatic increase in moment of forces from the long lever arm of the superstructure. This increase in force may result in bone loss, mobility of the implant, and possible fracture of an implant component.[89] The ideal distance between the implants is in the 14- to 16-mm range or B and D positions. However, implants placed too close to each other will result in reduced prosthesis stability during function.

Another problem of joining A and E implants is the sagittal position of the superstructure. If the bar is straight and not bent to follow the arch, it occupies a lingual position relative to the arch. The lingual flange of the denture then extends as much as

WWW.HIGHDENT.IR

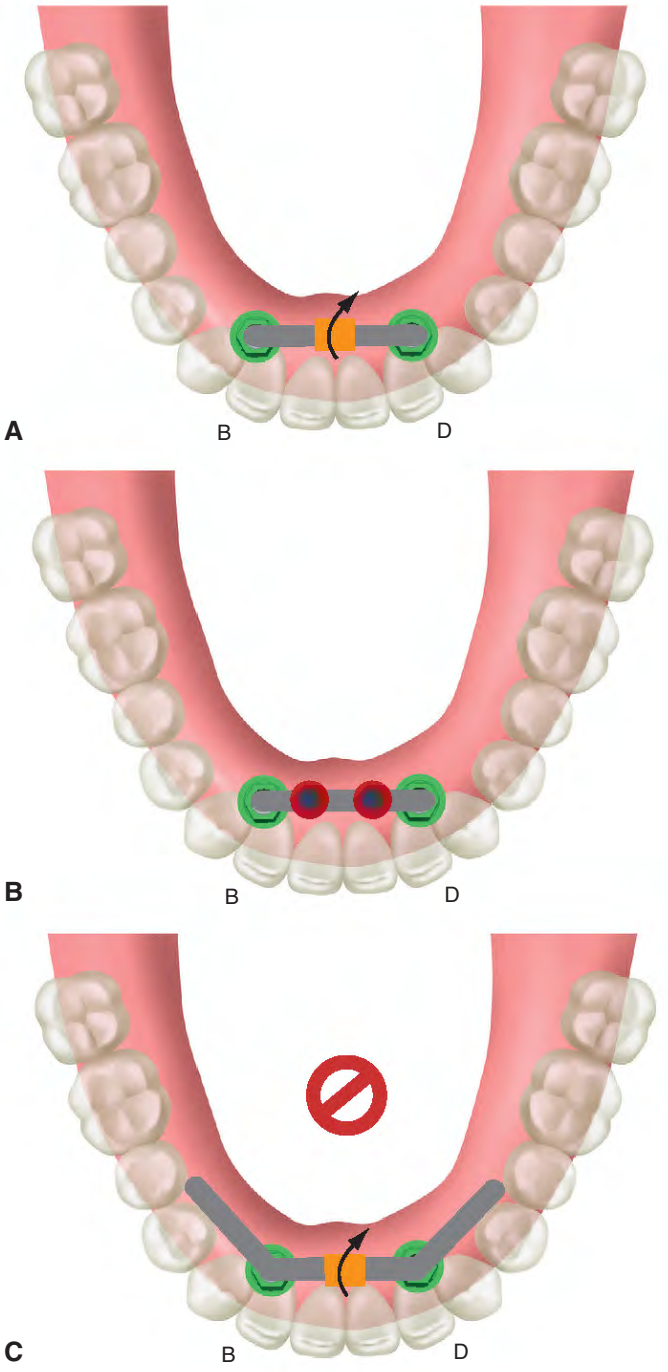


Figure 14-10 **A,** Treatment Option 2 has implants in the B and D positions and a bar joins the implants. The bar should not be cantilevered off the distal side of the implants. The prosthesis movement will be reduced and too much force on the bar and implants will increase complications. Attachments such as an O-ring **(B)** or a Hader clip **(C),** which allow movement of the prosthesis, can be added to the bar. The attachments are placed at the same height at equal distance off the midline and parallel to each other.

10 mm more lingually and 7 mm more vertically to accommodate the attachment, which is connected over the superstructure.

Because the teeth are set over or are anterior to the crest of the ridge, anterior to the superstructure bar, rotation and tipping of the restoration are more

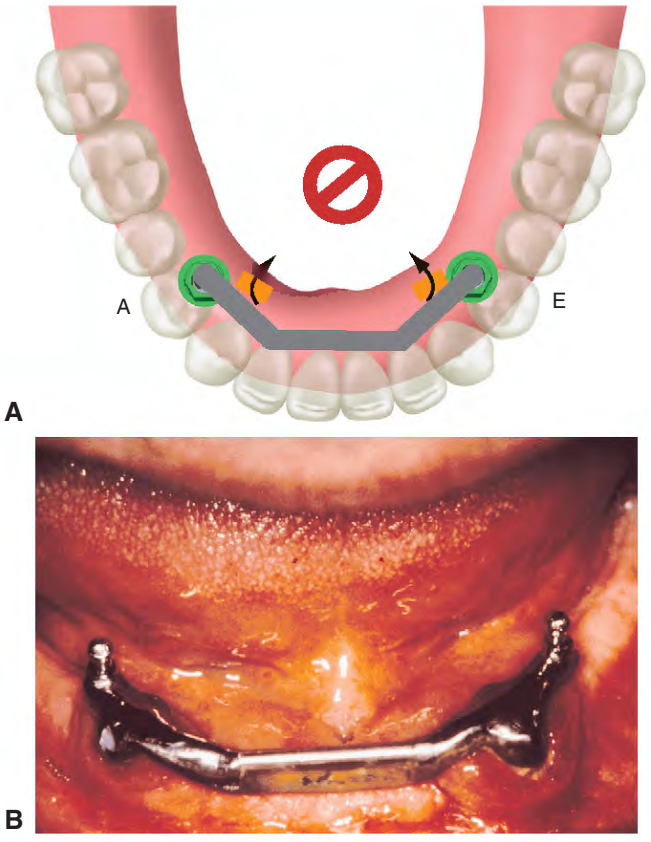

Figure 14-11 **A,** Implants in positions A and E should not be splinted. **B,** This patient had an overdenture constructed on the two first premolar teeth. The bar became uncemented in the patient's right side and then acted as a cantilever on the patient's left premolar. This situation is similar to implant positions A and E because the mental foramens are most often between the premolars or distal to the second premolar.

prevalent. The moment of force on a straight bar connecting implants in the A and E positions is twice that for implants in the B and D locations.[89]

Implants splinted in the A and E positions have greater potential load per surface area compared with implants in the B and D regions. The bite force increases toward the posterior aspects of the mouth. As a result, a greater vertical load is also present, with increased stresses when implants are placed in the A and E positions.

The A and E positions give more lateral stability to the prosthesis than the B and D positions. However, only two implants resist this lateral load. In contrast, the B and D positions increase lateral movement of the prosthesis, which is a patient disadvantage, but the positioning also decreases the lateral forces on the implants (Box 14-6). As a result of these many disadvantages, the placement of two implants in the A and E positions is strongly discouraged.

If the surgeon inadvertently inserts the implants in the A and E position, two options exist. The first is to place at least one additional implant, usually in the C position. The second is to leave the implants

WWW.HIGHDENT.IR

independent with O-ring attachments. With the second option, the anatomical ridge form should be good to excellent, and the overdenture should have excellent support and retention independent of the implants. The two implants should not be splinted to reduce complications because they are too far apart.

Two implant overdentures are not indicated in C–h or D bone and are not indicated when opposing natural teeth. The increase in crown height and the poorer posterior ridge form or the increase in bite forces place additional stresses on the implant system and increase complications. Additional implants should be used to decrease the implant and prosthetic risks. The length of the edentulous span, the position of the connecting bar, the flexure of the metal span, and the forces on the abutments create considerable risk in this treatment option. Instead, the B and D implant positions are closer to the canine positions and are much better suited for force and prosthetic guidelines.

Patient selection criteria for OD-2 treatments include the following (see Box 14-5):

- Anatomical conditions for a traditional denture are good to excellent.
- The posterior ridge form is an inverted U shape and provides good to excellent support and lateral stability.
- The patient's complaints are minimal and relate primarily to retention.
- The patient requires a new prosthesis and is willing to invest slightly more time and expense than the patient with the OD-1 option.
- When the patient is unable to insert additional implants within a short time frame (within 3 years), OD-2 is safer than an OD-1 independent implant approach. Some disadvantages of OD-2 treatments compared with OD-1 are possible tissue hyperplasia under the bar, more difficult hygiene under the bar, and a more expensive initial treatment option (because a bar and retentive elements are included).

Box 14-6 Disadvantages of A and E Splinted Implants (First Premolar to First Premolar)

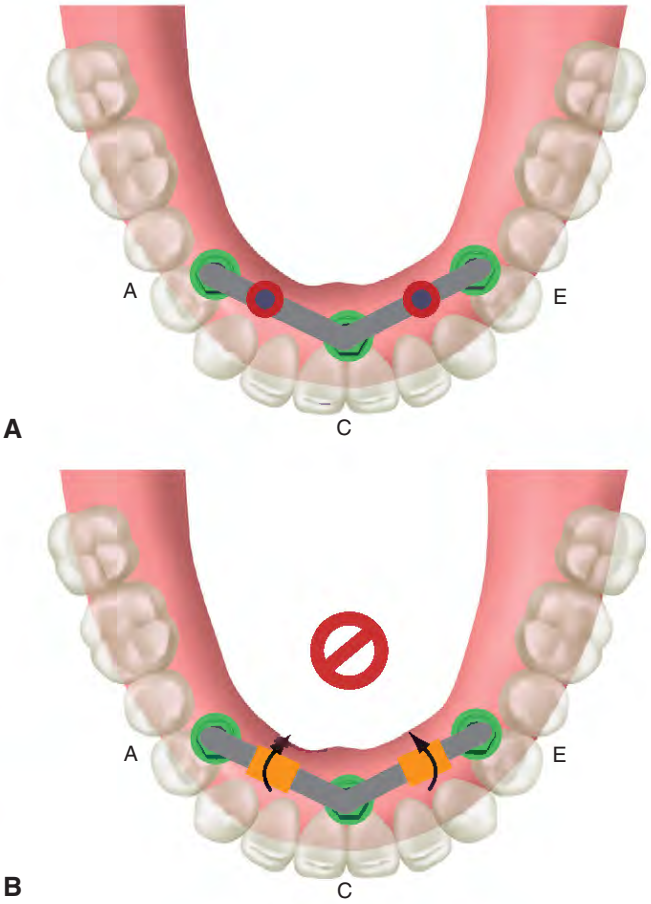
- Implants joined with straight bar are lingual to ridge.
  - Difficulty with speech
  - Anterior tipping of overdenture
  - Five times greater bar flexure than B and D positions
- Implants are joined with anterior curved bar.
  - Greater bar flexibility (nine times the B and D positions)
  - Increased screw loosening
  - Increased moment forces on anterior aspect of prosthesis
  - Attachment of curved bar may prevent prosthesis movement
- Bite force is higher than for B and D positions.
  - Greater lateral load from prosthesis to implants than B and D positions

Box 14-7 Patient Selection Criteria: OD-3

- Patient's needs and desires require improved retention, support, and stability
- Cost a moderate factor:
  - Anatomical conditions good to excellent
  - Posterior ridge forms inverted U shape

Overdenture Option 3

Three root form implants are placed in the A, C, and E positions for the third overdenture treatment option (OD-3) (Box 14-7). A superstructure bar connects the implants, but with no distal cantilever (Figure 14-12). The advantages of splinting A, C, and E implants compared with implants in the B and D positions are many (Box 14-8). The additional implant provides a sixfold reduction in superstructure flexure and limits



A

B

Figure 14-12 Overdenture option 3A corresponds to implants in the A, C, and E positions connected with a bar. The attachments should be positioned to allow movement of the distal section of the prosthesis **(A).** Two nonaligned Hader clips will not allow movement **(B).**

WWW.HIGHDENT.IR

Box 14-8 Advantages of Splinted A, C, and E Implants

- Six times less bar flexure compared with A and E positions
- Less screw loosening
  - Less metal flexure
  - Three implant abutments
- Less stress to each implant compared with A and E implants
  - Greater surface area
  - More implants
  - Greater A-P distance
- One-half moment force compared with A and E implants
- Less prosthesis movement
- One implant failure still provides adequate abutment support

A-P, Anteroposterior.

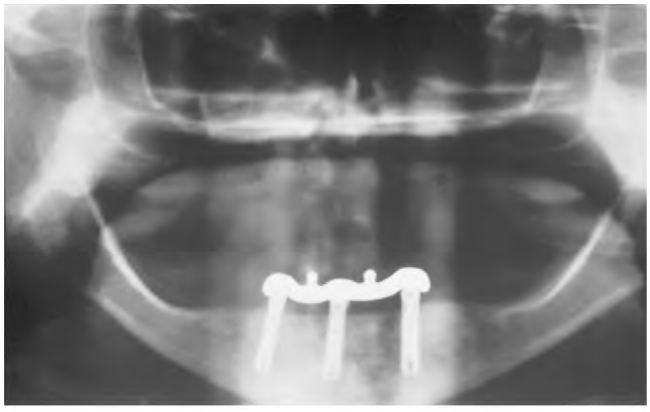


Figure 14-13 Panoramic radiograph of a mandible with Division A bone and overdenture option 3A, with implants in the A, C, and E positions.

the consequences previously discussed.[87] In addition, screw loosening occurs less frequently because three coping screws retain the superstructure rather than two. Implant reaction forces are reduced with a third implant as compared with two implants. The greater surface area of implant to bone allows better distribution of forces. The risk of abutment or coping screw loosening is reduced further because force factors are decreased. Three permucosal sites distribute stresses more efficiently and minimize crestal bone loss. Because the crestal bone is the first region of the bone to be affected, this represents a major advantage. The reduction in the maximum moment of force is twofold with a three-implant system compared with two implants in the A and E regions.[89]

The implants splinted in the A, C, and E positions should not form a straight line. The C implant is anterior to the more distal A and E implants and directly under the cingulum position of the denture teeth. The restoration benefits from direct occlusal load to the implant support in the anterior arch. When more than two implants are in the anterior mandible, a tripod support system may be established. To determine this benefit, the distal of the most posterior implants on each side are connected with a straight line. The distance from this line to the perpendicular position of the center implant is called the A-P spread.[89-91] The greater this dimension, the more biomechanically stable the implants when splinted together. The greater the A-P spread of the A, C, and E implants, the greater the biomechanical advantage of the bar to reduce stress on the implant and the better the lateral stability of the implant bar and overdenture system. Rotation of the prosthesis may also be more limited compared with OD-1 and OD-2. Therefore the third implant for OD-3 is a considerable advantage for the mandibular edentulous patient. This is usually the first treatment option for a patient with minimal complaints who is concerned primarily with retention and anterior stability when cost is a moderate factor. The posterior ridge form determines the posterior lingual flange extension of the denture, which limits lateral movement of the restoration. If the anterior and posterior ridge form is favorable (Divisions A or B), the implants are placed in the A, C, and E areas, and a wide range of attachments is available (Figure 14-13).[89]

If the posterior ridge form is poor (Division C–h), the lack of lateral stability places additional forces on the anterior implants. Implants then are best placed on the BCD position to allow greater freedom of movement of the prosthesis (Figure 14-14). The greater the stress to the system, the greater prosthesis movement/stress relief indicated. This increases the posterior movement of the restoration, but decreases the amount of stress placed on the implants and screw-retained bar.

The prosthesis movement for three implants with C–h posterior bone should be greater to minimize forces on the implants and bar retention system. If the patient with poor posterior ridge form requires more stability, more than three implants are indicated. In Division D posterior mandibles, five anterior implants are indicated to support the restoration.

When the patient can afford additional implants to those in the A, C, and E positions, the next implant placement is in the B and D positions when the posterior bone is inadequate for implants (C–h). When posterior bone permits, the two new implants are positioned with one in a molar region and the other inserted in the contralateral B or D position.

Overdenture Option 4

In the fourth mandibular overdenture option (OD-4), four implants are placed in the A, B, D, and E positions. These implants usually provide sufficient support to include a distal cantilever up to 10 mm on each side if the stress factors are low (Figure 14-15). The cantilevered superstructure is a feature of the four or more implant treatment option for three reasons: The first relates to

WWW.HIGHDENT.IR

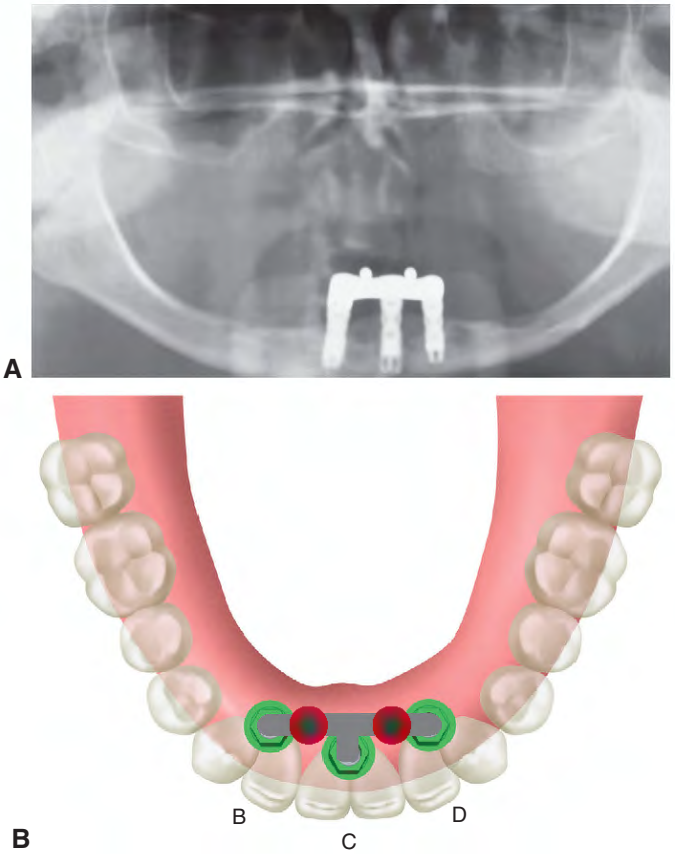

Figure 14-14 **A,** A panoramic radiograph of a Division C–h edentulous mandible. The patient should have more than three implants to protect the posterior bone loss. When the posterior ridge is poor and only three implants are placed, the implants are placed in the B, C, and D positions to decrease the risk of overload to the implants, screws, and bone and to allow the fabrication of an RP-5 prosthesis with distal movement of the prosthesis **(B).**

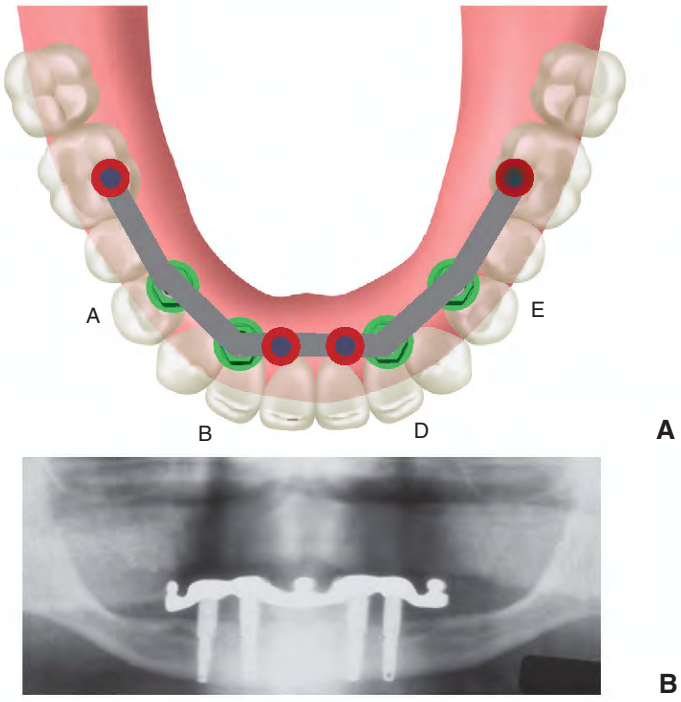

Figure 14-15 **A,** In overdenture option 4, four implants are placed in the A, B, D, and E positions. The implants provide sufficient support for a distal cantilever up to 10 mm. **B,** Panoramic radiograph of a mandibular overdenture option 4. In this option implants in the A, B, D, and E positions are connected with a cantilevered bar (up to 10 mm). The stress-breaking attachments are designed to allow some movement of the prosthesis during function.

the increase in implant support compared with OD-1 to OD-3. The second is that the biomechanical position of the splinted implants is improved in an ovoid or tapering arch form compared with OD-1 or OD-2. The third is related to the additional retention provided for the superstructure bar, which limits the risk of screw loosening and other related complications of cantilevered restorations.

In considering a distal cantilever for a mandibular overdenture bar, the implant position is the primary local determinant. Cantilevers may be compared with a class 1 lever in mechanics. The distalmost implant on each side acts as a fulcrum when occlusal forces are applied to the distal cantilever. Therefore the amount of the occlusal force is magnified by the length of the cantilever, which acts as a lever. For example, a 25-lb load to a 10-mm cantilever results in a 250-lb moment force.

This moment force is resisted by the length of the bar anterior to the fulcrum. Therefore if the two anterior implants are 10 mm from the fulcrum (distal implants), the effect of the posterior cantilever is countered. If the implants are 5 mm apart, the mechanical advantage of the lever is the 10-mm cantilever divided by the 5-mm A-P spread, which equals 2. A 25-lb distal force is magnified to 50 lb to the anterior implant and 75 lb (50 + 25 = 75) to the distal (fulcrum) implant.

The mandibular arch form may be square, tapering, or ovoid. Square arch forms limit the A-P spread between implants and may not be able to counter the effect of a distal cantilever. Therefore rarely are distal cantilevers designed for square arch forms. In a tapering arch form, the A-P spread between implants in the AE and DB positions is greater and therefore permits a longer distal cantilever. This A-P spread is often 10 mm and therefore often permits a cantilever up to 10 mm from the A and E positions. In an ovoid arch, which is most common, the A-P spread between AE and BD is usually 8 mm. Therefore the cantilever may be up to 8 mm long distally from the A and E implants.

The A-P spread is only one factor to determine the length of the cantilever. When stress factors such as occluding forces are greater, the cantilever is decreased. When the crown height is doubled, the moment forces are doubled. Therefore under ideal, low-force conditions (crown height less than 15 mm, no parafunction, older females, opposing maxillary denture), the cantilever may be up to 1.5 times the A-P spread for OD-4 overdentures.

WWW.HIGHDENT.IR

The patient's indications for this OD-4 include moderate to poor posterior anatomy that causes a lack of retention and stability, soft tissue abrasions, and difficulty with speech. The edentulous posterior mandible resorbs four times faster than the anterior mandible. In the C–h posterior mandible the external oblique and mylohyoid ridges are high and often correspond to the crest of the residual ridge. The muscle attachments therefore are at the crest of the ridge. The patient's complaints and desires are more demanding than for the previous treatment options (Box 14-9).

The OD-4 prosthesis is indicated to obtain greater stability and a more limited range of prosthesis motion. The overdenture attachments often are placed in the distal cantilevers with an O-ring attachment in the midline. The prosthesis is still RP-5, but with the least soft tissue support of all RP-5 designs. The anterior attachment must allow vertical movement for the distal aspect of the prosthesis to rotate toward the tissue. Clips, which permit rotation, are difficult to use on cantilevered superstructures. To allow movement, the clip must be placed perpendicular to the path of rotation, not along the cantilevered bar where its only function then is retention.

The patient benefits from the four implants because of greater occlusal load support and lateral prosthesis stability. The prosthesis only loads the soft tissue over the first and second molars and retromolar pad regions. Therefore the amount of occlusal force is reduced because the bar does not extend to the molar position, where the forces are greater. The amount of distal cantilever is related primarily to the force factors and to the arch form, which corresponds to the A-P spread from the center of the most anterior implants to the distal portions of the A and E implants.

The next treatment plan for the patient with a greater budget is to add an additional implant in one of the first molar positions (preferred) or the C position. Both these options increase the A-P spread to fabricate a prosthesis with enhanced implant support. The goal is to convert all patients to an RP-4 or fixed restoration (OD-5).

Box 14-9 Patient Selection Criteria: OD-4

- Moderate to severe problems with traditional dentures
- Needs or desires are demanding
- Need to decrease bulk of prosthesis
- Inability to wear traditional prostheses
- Desire to abate posterior bone loss
- Unfavorable anatomy for complete dentures
- Problems with function and stability
- Posterior sore spots

Box 14-10 Patient Selection Criteria: OD-5

- Moderate to severe problems with traditional dentures
- Needs or desires are demanding
- Need to decrease bulk of prosthesis
- Inability to wear traditional prostheses
- Desire to abate posterior bone loss
- Unfavorable anatomy for complete dentures
- Problems with function and stability
- Posterior sore spots
- Moderate to poor posterior anatomy
- Lack of retention and stability
- Soft tissue abrasion
- Speech difficulties
- More demanding patient type

Overdenture Option 5

The fifth mandibular overdenture option (OD-5) is designed for two types of patients. This is a minimum treatment option for patients with moderate to severe problems related to a traditional restoration. The needs and desires of the patient are often most demanding and may include limiting the bulk or amount of the prosthesis, major concerns regarding function or stability, posterior sore spots, and the inability to wear a mandibular denture (Box 14-10).

The second patient condition is for the treatment of continued bone loss in the posterior mandible. If no prosthetic load is on the posterior bone, the resorption process is delayed considerably and usually is reversed. Therefore even when no posterior implants are inserted, the cantilevered bar and overdenture avoid load to the residual ridge and often halt its resorption process. Recent evidence shows that completely implant-supported prostheses may increase the amount of posterior bone height, even when no posterior implants are inserted.[76-78] A better option to prevent this bone loss is the insertion of posterior implants before atrophy. This treatment option is more likely when the patient desires a fixed restoration or the arch form is square.

In the OD-5 treatment, five implants are inserted in the A, B, C, D, and E positions. The superstructure is cantilevered distally a maximum of 2.5 times the A-P spread (if all the stress factors are low) and averages 15 mm, which places it under the first molar area (Figures 14-16 and 14-17). If any stress factors are not favorable, the cantilever should be reduced. Stresses increase with the length of cantilever and should be planned carefully based on force factors and the existing anatomy.[90-98] In a study in which the failure criterion was the failure of the screw joint with arrangements of three, four, five, and six implants submitted to forces from 143 to 400 N, the transmitted forces to the prosthetic connection always exceeded the yield strength of the system. This study emphasizes the fact that the A-P spread is not the only factor to be considered for cantilever length determination.[92]

WWW.HIGHDENT.IR

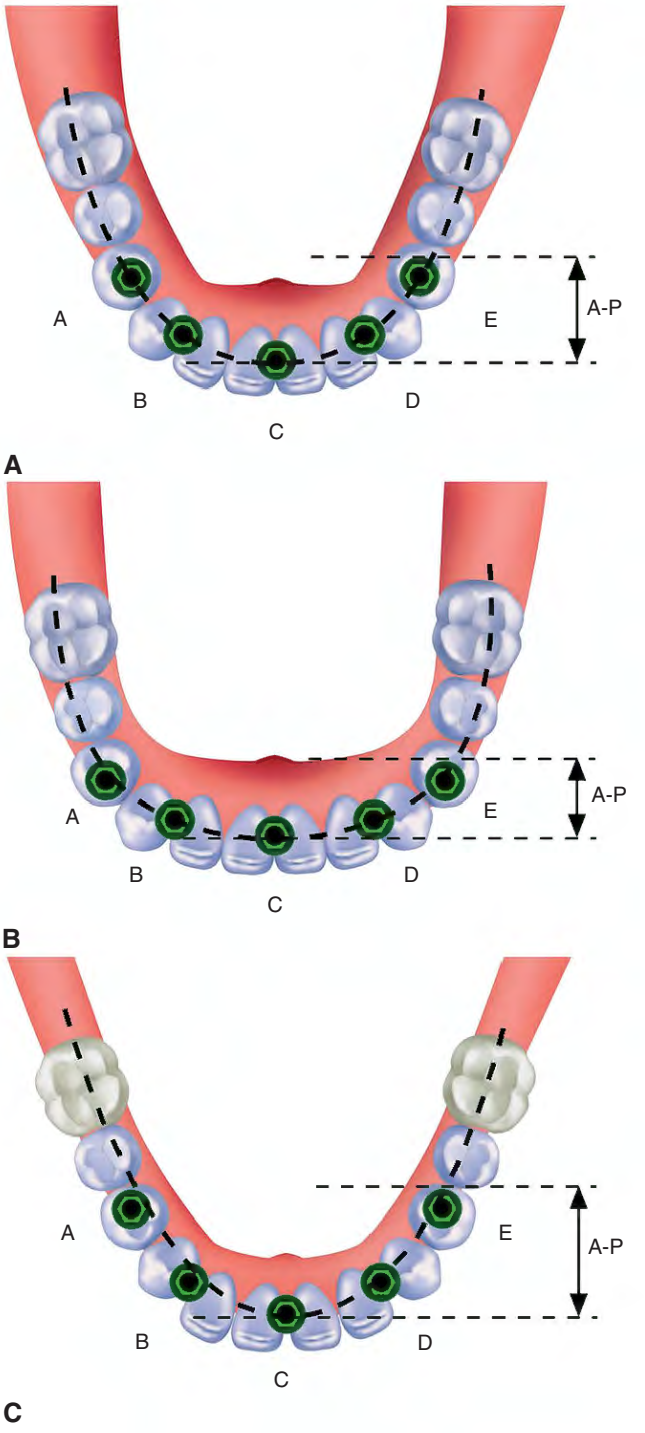

Figure 14-16 Arch shape affects the anteroposterior (A-P) distance. The ovoid arch form **(A)** often has an A-P distance of 6 to 8 mm. A square arch form **(B)** often has an A-P dimension of 2 to 5 mm. A tapered arch form **(C)** has the greatest A-P distance, larger than 8 mm.

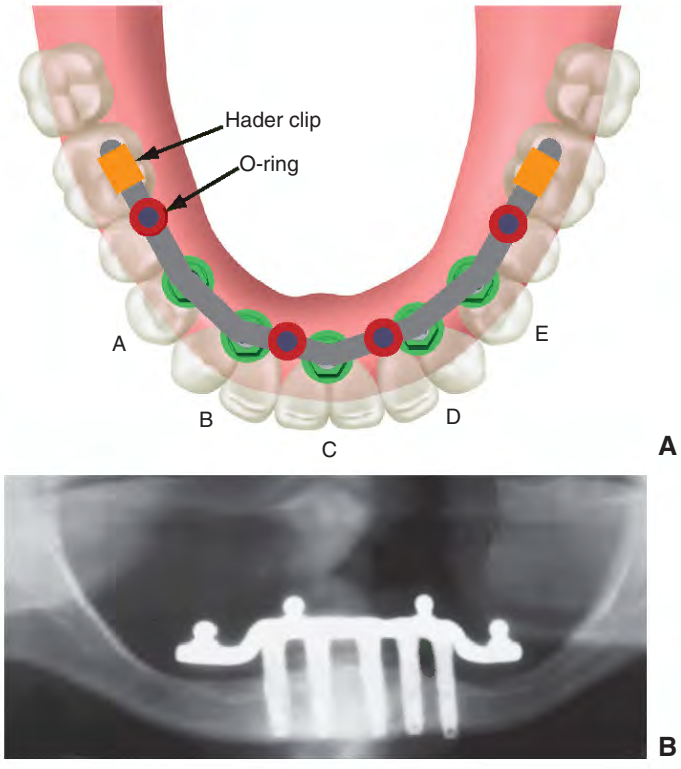

Figure 14-17 **A,** In the overdenture option 5, implants are placed in the A, B, C, D, and E positions. A bar splints the implants together and is cantilevered distally. The length of the cantilever depends on the anteroposterior distance and the force factors. **B,** A panoramic radiograph of an option 5 overdenture bar and five implants in the anterior mandible.

The Hidden Cantilever

The teeth on the final restoration usually do not extend beyond the first molar, so the last tooth does not extend beyond the bar. This helps prevent a hidden cantilever, which may extend beyond this position. The hidden cantilever is that portion of the cantilever that extends beyond the connecting bar. If the prosthesis does not rotate at the end of the bar to load the soft tissue, a hidden cantilever exists. For example, if the bar extends to the first molar but forces in the second molar of the restoration do not result in movement of the restoration down in the back and up in the front, the cantilever really is extended to the second molar position. Therefore the cantilever length is measured to the point of prosthesis movement, not to the end of the bar and attachment system. Under ideal conditions, the restoration is often an RP-4 completely implant-supported prosthesis.

When arch form or force factors do not permit an RP-4 restoration with only implants between the foramenae, placing an implant in one of the first molar positions should be considered. This increases the A-P spread and results with only one cantilever. Most often an RP-4 restoration is then acceptable with this implant position.

DIVISION C–H ANTERIOR MANDIBLES

The five treatment options proposed for mandibular implant–supported overdentures provide an organized

WWW.HIGHDENT.IR

approach to solving a patient's complaints or anatomical limitations.

The prosthesis support and range of motion should be part of the initial diagnosis. The treatment options initially proposed are designed for completely edentulous patients with Division A anterior bone in desire of an overdenture. These options are modified if the anterior bone is Division C–h. The increase in crown/implant ratio and decrease in implant surface area mandate modification of these initial options.

In the C–h anterior bone volume patient, one more implant is added to each option and OD-1 is eliminated completely. Therefore OD-2 has three implants (A, C, and E positions), OD-3 has four implants (A, B, D, and E regions), OD-4 has five implants (A, B, C, D, and E areas), and OD-5 has six implants. If six implants cannot be placed because of inadequate posterior bone, the cantilever length is reduced and a RP-5 restoration is fabricated.

DISCUSSION

The doctor and staff can explain the amount of support each treatment option can provide by comparing them with the support system of a chair. Treatment options OD-2 or OD-3 are related to a two-legged chair. The prosthesis provides some vertical support but can rock back and forth. Option OD-4 with four implants is compared with a three-legged chair. This system provides further support but can be rocked one way or the other under lateral forces. A four-legged chair provides the greatest support and is similar to OD-5, which is a stable, retentive prosthesis and RP-4 in design.

Overdenture bars may be cemented or retained with screws. Whether a cemented or screw-retained bar is used, the overdenture prosthesis retention is achieved by a similar combination of clips or O-ring attachments. Three advantages of a cemented bar are the insurance of a passive superstructure, reduced cost, and an easier bar impression technique.[25,99] Reports in the literature document similar success rates for both options, and the choice may be left to the discretion of the restoring doctor. However, stronger cements and a reduction of the cantilever length should be considered for OD-4 and OD-5 treatment plans because tensile forces may break the anterior cement seals and cause complications.[25,26]

SUMMARY

Implant overdentures borrow several principles from tooth-supported overdentures. The advantages of implant overdentures relate to the ability to place rigid, healthy abutments in the positions of choice. The number, location, superstructure design, and prosthetic range of motion can be predetermined and based on a patient's expressed needs and desires. Two implants placed just anterior to the mental foraminae rarely should be used. The overdenture should be designed to satisfy the patient's desires and anatomical limitations predictably.

The most common overdenture option used by the profession is the two-implant overdenture, with individual O-ring attachments. Yet the only benefit of this approach is a reduced initial cost. The bone loss accelerates in the posterior, and the maintenance of anterior bone is limited to the zone around each implant.

An ideal approach for the overall long-term health of the mandible is a complete implant–supported prosthesis. The bone volume is maintained in the anterior, and the posterior bone loss is significantly reduced. The stability of the prosthesis is maximal because it does not move on the connecting bar. The retention is excellent because it may have four to six attachments. The occlusal load support is on the implants, not the soft tissues.

The patient initially may not be able to afford an OD-5 option. However, an OD-3 may be converted to an OD-4 after several years and eventually to an OD-5 after several more years. If the transition from one option to another is in a short time frame (1 to 2 years), the implants may be independent and use an O-ring system short term. This reduces the fee for the transitional prosthesis because no bar is fabricated, and a rebase may be used to modify the prosthesis.

Chapter 15

The Completely Edentulous Mandible: Treatment Plans for Fixed Restorations

Carl E. Misch

Twenty million adults in the United States have completely edentulous mandibular arches.[1] Over the last 15 years, many of these patients have been treated with an implant overdenture, which is a vast improvement compared with a complete denture. Many of these same patients might have preferred a fixed prosthesis, but often for financial considerations they chose to have a removable prosthesis fabricated. Maxillary implant-supported removable prostheses may provide advantages over full-arch fixed restorations, such as upper lip support for esthetics and ease of daily maintenance of a removable prosthesis. However, unlike a maxillary denture, the labial flange of a mandibular overdenture rarely is required for esthetics. The laboratory and component costs for a hybrid fixed restoration are often similar to those for a fully implant-supported overdenture (RP-4). The chair time required to fabricate an overdenture and bar is similar to that for an implant-supported fixed prosthesis. Yet because dentures and partial dentures typically cost several times less than fixed restorations on teeth, the doctor often charges half the fee for an implant overdenture and bar compared with a fixed restoration. However, the laboratory fees, component fees, and chair time are similar for these two types of prostheses. If the fees for these two restorations were similar, many patients would opt for a fixed prosthesis (Figures 15-1 and 15-2).

COMPARING FIXED VERSUS REMOVABLE IMPLANT PROSTHESES

A fixed restoration provides the psychological advantage of acting and feeling similar to natural teeth, whereas an overdenture, even if fully implant supported, remains a removable prosthesis. In fact, a common remark heard from patients with fixed restorations is "these implant teeth are better than my own teeth," whereas comments related to implant overdentures are "these are better than my denture."

Removable implant overdentures require greater maintenance and exhibit more frequent prosthetic-related complications than fixed restorations. Walton and McEntee[2] noted that there were three times more maintenance and adjustments for removable prostheses compared with fixed restorations. Implant overdentures (IODs) often require attachments to be changed or modified every 6 months to 2 years, and denture teeth often wear, requiring a new prosthesis to be fabricated every 5 to 7 years.[2-7] In a review of literature by Goodacre et al., IODs have retention and adjustment problems 30% of the time, relines 19%, clip or attachment fracture 17%, and fracture of the prosthesis 12% of the time. Fixed prostheses need less repair and less maintenance and often last the life of the implant support. Although porcelain fractures with a fixed restoration may be costly to repair, over a lifetime, the implant-supported removable prosthesis may be more expensive.

A mandibular overdenture often traps food below its flanges, similar to a denture. Dentures are border-molded to the muscle attachment level to allow the floor of the mouth to raise during swallowing. As a consequence,

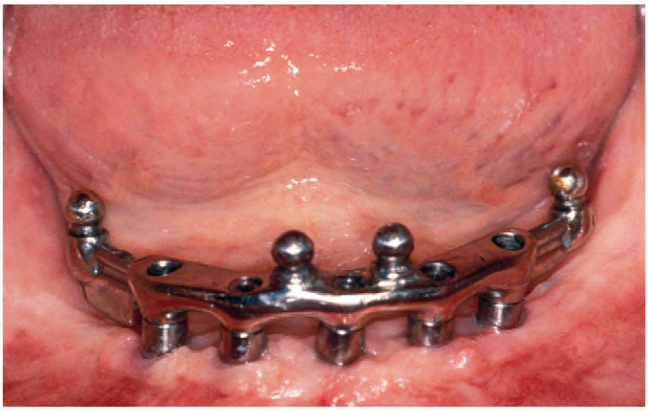

Figure 15-1 A mandibular implant overdenture may have complete implant support, retention, and stability from the implant support system (RP-4 prosthesis).

WWW.HIGHDENT.IR

Figure 15-2 A complete arch implant fixed prosthesis may be hybrid, with denture teeth and acrylic joined to a metal substructure.

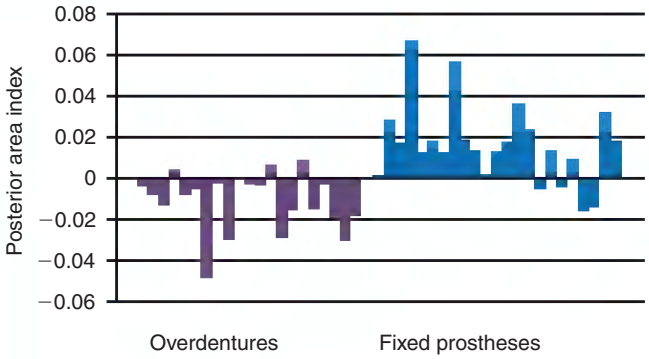

Figure 15-3 Implant overdentures with posterior soft tissue support lose bone in the posterior regions almost 75% of the time. Fixed prostheses cantilevered from anterior implants gain bone in the posterior regions more than 80% of the time (right side of graph).

Box 15-1 Advantages of a Fixed Partial Denture

- Psychological: "feels like teeth"
- Less prosthetic maintenance (e.g., attachments, relines, new overdenture)
- Less food entrapment
- Posterior mandibular bone gain

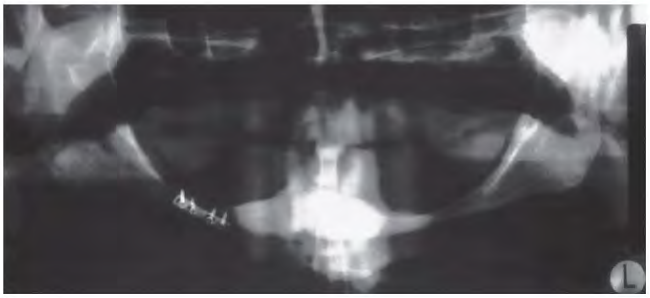

Figure 15-4 A panoramic radiograph of a severely resorbed mandible with a fracture and bone plate in the right body region. This patient has bilateral paresthesia of the lower lip.

food accumulates below the denture flange while the muscles are at rest and then is compressed under the restoration during deglutition. The contour of a fixed restoration is less prone to food entrapment (Box 15-1). The daily care for a bar implant overdenture (RP-4) is similar to that for a fixed mandibular restoration because ridge lap pontics are not required for esthetics or speech, as with some maxillary fixed prostheses.

A more recent clinical study by Wright et al. has evauated posterior mandibular bone loss in implant overdentures (RP-5) compared with cantilevered fixed prostheses from anterior implants.[8] The annual bone loss index observed in the RP-5 overdentures ranged from +0.02 to −0.05 with 14 of 20 patients losing bone in the posterior regions. On the other hand, the fixed prostheses group had a range from +0.07 to −0.015 with 18 of 22 patients gaining posterior bone area (Figure 15-3). Reddy et al. also found a similar clinical observation in 60 consecutively treated cantilevered fixed prostheses supported by five to six implants placed between the foarminae.[9] The mandibular body height was measured 5, 10, 15 and 20 mm distal to the last implant. The baseline measurements up to 4 years after function increased from 7.25 ± 0.25 mm to 8.18 ± 0.18 mm. Nearly all of the bone growth occurred during the first year of function. Therefore an important role for the presence of a complete implant-supported restoration is the maintenance and even regeneration of posterior bone in the mandible. This is especially important because posterior bone loss in this region may lead to paresthasia and even mandibular body fracture (Figure 15-4).

Too often, the dentist offers overdentures as the only option for edentulous patients, rather than including fixed treatment options. The advantages of a fixed restoration over an overdenture warrant most all edentulous patients to be given an option for a fixed prosthesis. This chapter discusses fixed treatment planning options for the completely edentulous mandibular arches.[10]

FORCE FACTORS

The amount of force transmitted to an implant-fixed prosthesis is similar to that of a completely implant-supported overdenture (RP-4). In one aspect then, the number of implants to support either prosthesis type should be similar. Mandibular overdentures may be removed at night to decrease the risk of nocturnal parafunctional overload. However, most mandibular edentulous patients also have an edentulous maxilla. Therefore if the patient is willing to remove the maxillary

WWW.HIGHDENT.IR

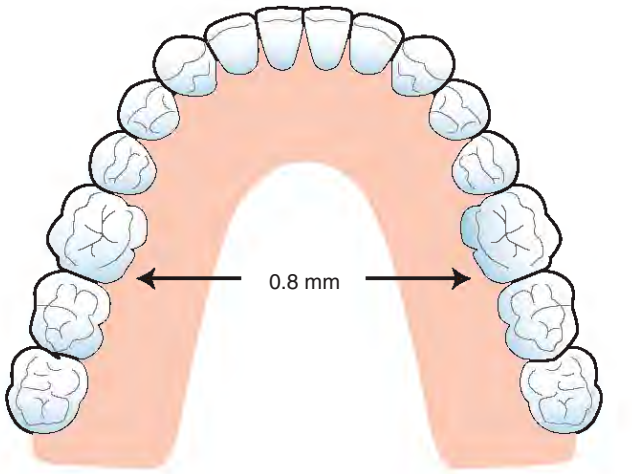

Figure 15-5 The flexure of the mandible during opening and protrusive movements occurs distal to the mental foramens. The amount of flexure depends on the amount of the bone volume and the sites in question. The medial movement from the first molar to the first molar region may be 800 µm.

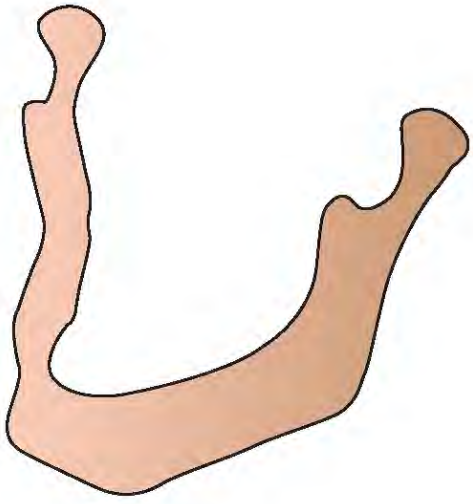

Figure 15-6 The mandible flexes toward the midline on opening or during protrusive movements as a result of the internal pterygoid muscle attachments on the ramus. The mandible also torques, with the inferior border rotating out and up and the crestal region rotating lingually. The movement is caused by the masseter muscles during forceful biting or parafunction.

denture at night, the risk of nocturnal parafunction also may be eliminated for patients with mandibular fixed prostheses. As a consequence, the number of implants required to restore a fixed prosthesis may be similar to a fully implant-supported overdenture.

When the patient has natural teeth and/or implants in the maxilla, more implants usually are indicated for the mandibular fixed prosthesis to reduce the risk of occlusal overload, or a reduction in cantilever length is necessary. Force factors such as parafunction, crown height, masticatory dynamics, and the bone density of the implanted regions also should modify the implant position, implant number, size, and design. Increased force factors contribute to uncemented restorations, screw loosening, component fracture, and crestal bone loss. As a result, the fixed prosthesis often may require an improved biomechanical position compared with an implant overdenture support system.

MANDIBULAR DYNAMICS

Medial Movement

Many reports have addressed the dimensional changes of the mandible during jaw activity as a result of masticatory muscle action.[11-19] Five different movements have been postulated.[18] Medial convergence is the one most commonly addressed.[19] The mandible between the mental foraminae is stable relative to flexure and torsion. However, distal to the foraminae, the mandible exhibits considerable movement toward the midline on opening.[15-16] This movement is caused primarily by the attachment of internal pterygoid muscles on the medial ramus of the mandible. The distortion of the mandible occurs early in the opening cycle, and the maximum changes may occur with as little as 28% opening, or about 12 mm of mandibular movement.[11] This flexure has also been observed during protrusive jaw movements.[20,21] The greater the active opening and protrusive movements, the greater the amplitude. The amount of movement varies among individuals and depends on the density and volume of bone and the location of the site in question. The amplitude of the mandibular body flexure toward the midline has been measured to be as much as 800 µm in the first molar to the first molar region to as much as 1500 µm in the ramus-to-ramus sites (Figure 15-5). In a study by Hobkirk on deformation of the mandible in subjects with fixed dental implant prostheses, medial covergence up to 41 µm was observed.[20]

Torsion

Torsion of the mandibular body distal to the foraminae has also been documented in animal and human studies.[22-26] Hylander evaluated larger members of the rhesus monkey family (macaque) and found the mandible twisted on the working side and bent in the parasagittal plane on the balancing side during the power stroke of mastication and unilateral molar biting.[25] Parasagittal bending of the human jaw during unilateral biting was confirmed by Marx,[26] who measured localized mandibular distortion in vivo in humans by using strain gauges on screws attached to cortical bone in the symphyseal and gonial regions. Hobkirk et al. confirmed the mandible of patients with implant prostheses measured up to 19 degrees of dorsoventral shear.[22] The torsion during parafunction is caused primarily by forceful contraction of the masseter muscle attachments (Figure 15-6). Therefore parafunctional bruxism and clenching may cause

WWW.HIGHDENT.IR

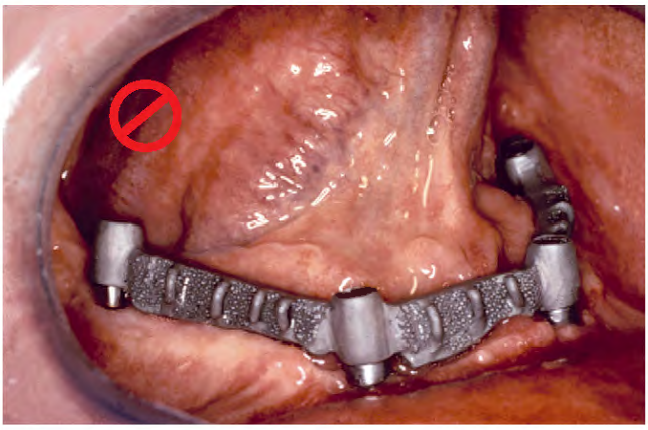

Figure 15-7 Some authors propose that the ideal implant positions to support a mandibular full-arch prosthesis are the bilateral molars and bilateral canines, splinted together with a rigid structure. These positions are not ideal because of the mandibular dynamics during opening and function.

problems in the implant support system and prosthesis when the mandibular teeth are splinted from molar to molar.

The posterior bone gain in edentulous patients restored with cantilevered prostheses from anterior implants may be a consequence of the mandibular flexure and torsion. Because the bite force may increase 300% with an implant prosthesis compared with a denture, the increased torsion may stimulate the posterior mandibular body to increase in size, as reported by Reddy et al.[9] and Wright et al.[8]

The most common position of the mental foramen is between the first and second premolar teeth; therefore when splinting teeth distal to the bilateral premolar position, mandibular dynamics should be considered.[27] A study by Miyamoto et al. identified jaw flexure as the primary cause of posterior implant loss in full-arch mandibular prostheses.[28] The more distal the rigid splint from one side to the other, the greater the risk that mandibular dynamics may influence the implants or prosthesis prognosis. In addition, the body of the mandible flexes more when the size of the bone decreases. As a result, the Division C minus height (C–h) or D mandible flexes or exhibits torsion more than the Division A mandible, all other factors being similar.

As a consequence, posterior rigid, fixated implants splinted to each other in a full-arch restoration are subject to a considerable buccolingual force on opening and during parafunction.[27-29] The difference in movement between an implant and a tooth has been addressed as a concern for dentists. The natural tooth movement ranges from 28 µm apically and 56 to 108 µm laterally. In contrast, the rigid implant has movement up to 5 µm apically and 10 to 60 µm laterally, yet the mandibular flexure and torsion may be more than 10 to 20 times the movement of a healthy tooth. Therefore the flexure and torsion of the mandibular body are more critical in the patient evaluation compared with whether an implant should be joined to the natural dentition.

Past authors have suggested four implants in the mandible with a full-arch splinted fixed restoration—two in the first molars and two in the canine regions[30] (Figure 15-7). Additional implants have been used with this full-arch splinted restorative option, with up to four other implants in the premolar and the incisor regions.[31] However, complete cross-arch splinting of posterior, molar rigid, fixated implants should be reconsidered in the mandible. The flexure of the mandible is thwarted by the prosthesis,[22,27,29,32-34] but this introduces lateral stresses to the implants. These implant positions place the molar implants, screws, and bone at increased risk because of the mandibular flexure and torsion previously addressed.

In complete mandibular subperiosteal implants, pain upon opening was noted in 25% of the patients at the suture removal appointment when a rigid bar connected molar-to-molar regions. When the connecting bar was cut into two sections between the foraminae, the pain upon opening was eliminated immediately. This clinical observation does not mean the other 75% of patients did not have flexure of the mandibular arch upon opening. The observation does demonstrate, however, that flexure may be relevant to postoperative complications. Consequences of a treatment plan with cross-arch connection of posterior mandibular implants may include bone loss around the implants, loss of implant fixation, material fracture (implant or prosthesis components), unretained restorations, and discomfort upon opening. Until clinical studies become available and state otherwise, full-arch splinted restorations joining bilateral molar implants in the mandible should not be a treatment of choice.

Implants placed in front of the foraminae and splinted together, or implants in one posterior quadrant joined to anterior implants, have not shown these complications related to the flexure or torsion of the mandible. Complete implant-supported fixed restorations can halt the posterior bone loss associated with edentulism, improve psychological health, and produce fewer prosthetic complications compared with removable restorations. Therefore all edentulous mandibular patients should be given the option of having a fixed prosthesis. There are five treatment options used to restore a complete edentulous mandible with a fixed prosthesis. These implant position options also may be considered for implant-supported overdentures.

When a mandibular overdenture is completely implant supported and retained and stabilized by a cantilevered bar, it acts similarly to a fixed prosthesis in function and bone maintenance. Therefore the five treatment options included in this chapter may be used for either a RP-4 overdenture or a fixed prosthesis (see Figures 15-1 and 15-2).

WWW.HIGHDENT.IR

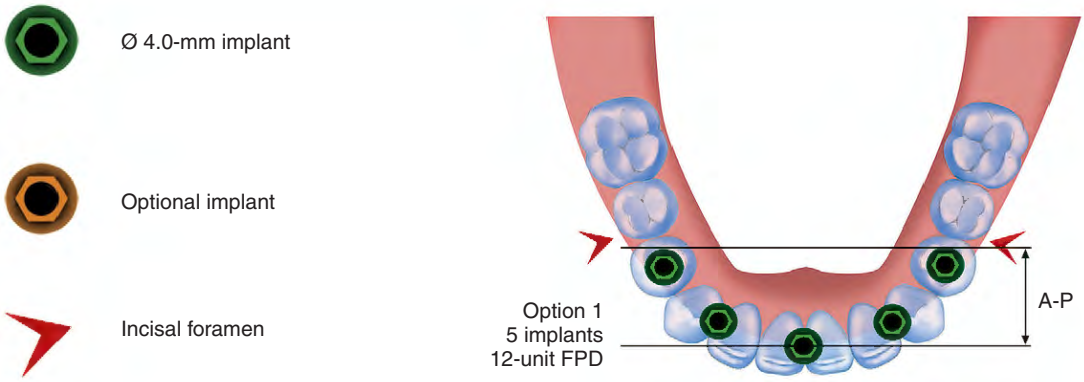

Figure 15-8 The most common number of implants between the foramens for option 1 is five. These implants provide as great an anteroposterior (A-P) distance as possible between the foraminae with sufficient interimplant spacing for treatment of complications. *FPD,* Fixed partial denture.

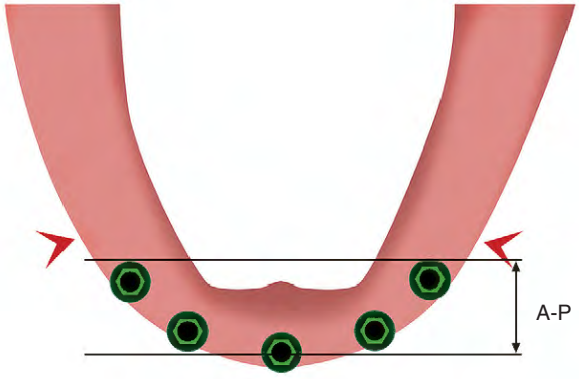

Figure 15-9 The anteroposterior (A-P) distance is determined by a line drawn from the distal portion of the distalmost implant on each side of the arch and another parallel line drawn through the center of the anteriormost implant from the cantilever.

Figure 15-10 A full-arch mandibular implant prosthesis with five implants placed between the mental foraminae and a hybrid fixed prosthesis cantilevered to the first molar region.

IMPLANT TREATMENT OPTIONS FOR FIXED RESTORATIONS

Treatment Option 1: The Brånemark Approach

The mandible does not flex or exhibit significant torsion between the mental foraminae. Therefore anterior implants may be splinted together without risk or compromise. The placement of four or six anterior root forms between the mental foraminae and a distal cantilever off each side to replace the posterior teeth was the treatment of choice for clinical reports from 1967 to 1981 with the Brånemark system[35] (Figure 15-8). This treatment approach resulted in an 80% to 90% implant survival for 5 to 12 years after the first year of loading. In a long-term, 18- to 23-year study, Attard and Zarb[36] reported an 84% success rate for prostheses and implants, respectively. The range of survival may be due to the broad application of the modality, regardless of crown height, opposing dentition, implant length, anteroposterior (A-P) position of implants, and parafunction.

The arch form and the position of the mental foraminae are important criteria when four to six implants are placed only in the anterior segment to replace the entire mandibular arch. The anterior arch form and foraminae position affects the position of the distalmost implants and the anterior arch form (square, oval, or tapering) is relative to the anteriormost implant position. The distance from the center of the most anterior implant to a line joining the distal aspect of the two most distal implants on each side is called the *A-P distance* or the *A-P spread*[37] (Figure 15-9). The greater the A-P spread, the further the distal cantilever may be extended to replace the missing posterior teeth.

The most common number of implants used today in the Brånemark treatment option is five (Figure 15-10). This number allows as great an A-P spread as six implants, with greater interimplant distance so that if bone loss occurs on one implant, the loss would not automatically affect the adjacent implant site. However, the A-P spread is only one of the force factors to be considered for the extent of the distal cantilever. As a general rule, when five anterior implants are placed in the anterior mandible between the foraminae to support a fixed prosthesis, the cantilever should not

WWW.HIGHDENT.IR

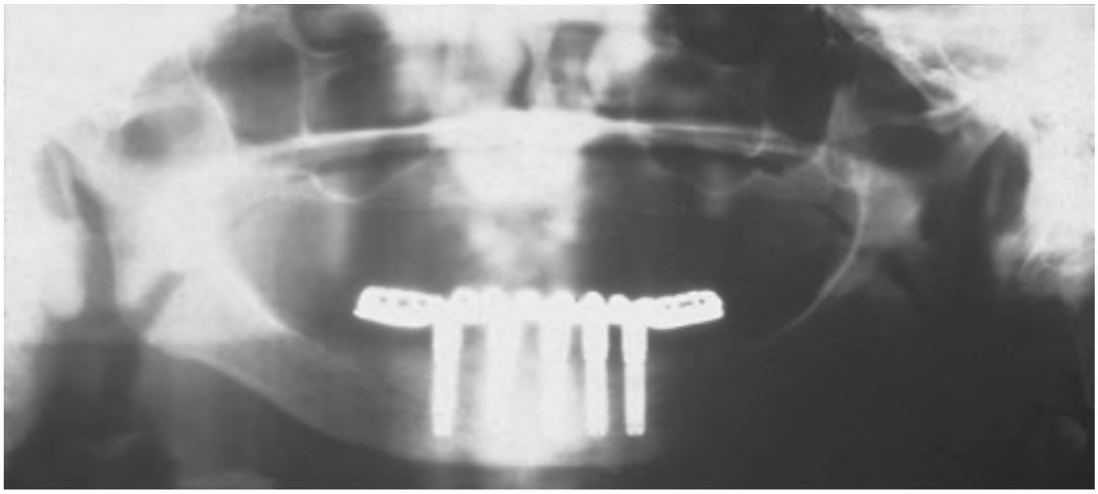

Figure 15-11 A panoramic radiograph of a hybrid full-arch fixed prosthesis cantilevered from five anterior endosteal implants positioned between the mental foraminae.

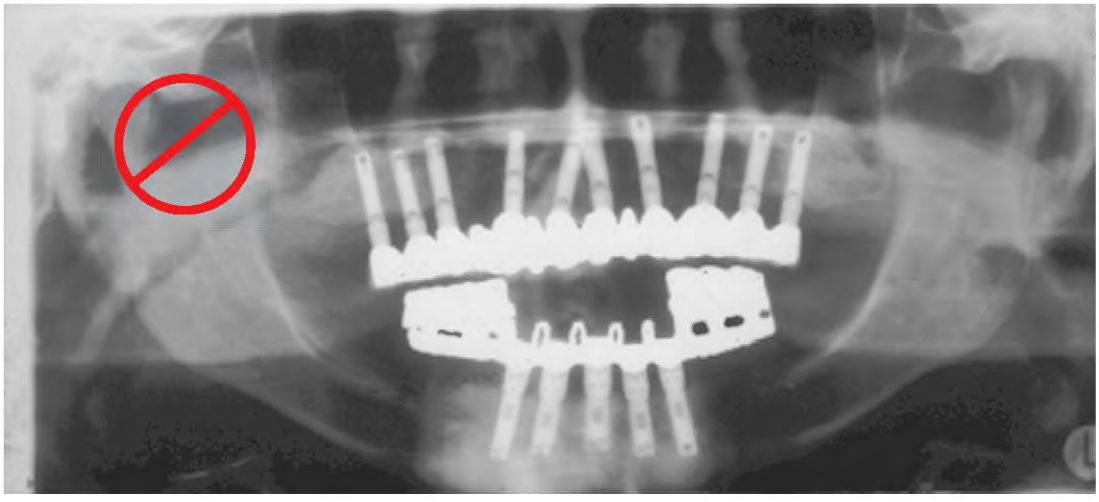

Figure 15-12 The length of the distal cantilever should be reduced when opposing an implant prosthesis or when the crown height space is more than 15 mm. A decrease in occlusal awareness causes high bite forces in implant prostheses, and crown height is a force magnifier in the presence of a cantilever. The cantilever in this radiograph should be reduced to decrease the risk of stress-related complications.

exceed 2.5 times the A-P spread, with all other stress factors being low (Figure 15-11). If the stress factors are high (e.g., parafunction, crown height, masticatory musculature dynamics, opposing arch), cantilevering of a prosthesis may be contraindicated. Therefore the length of the posterior cantilever depends on the specific force factors of the patient, of which A-P spread is only one (Figure 15-12).

Stress equals *force* divided by the *area* over which *force* is applied. The area over which the forces are applied from the prosthesis to the implants can be modified through the number, size, and design of the implants. A cantilever rarely is indicated on three implants, even with a similar A-P spread as five implants. The cantilever can be greater for five implants because of greater implant surface area and greater number of prosthetic components to decrease screw loosening. Often, narrow implants are not designed to support cantilevers, whereas wider implants can support a greater cantilever.

Treatment option 1 depends greatly on patient force factors, arch form, and the number, size, and design of the implants. As a result, the safest action is to reserve this option for patients with low force factors such as an older female wearing an upper denture, with abundant anterior bone, crown height inferior to 15 mm, with a tapered or ovoid mandibular arch, but with posterior segments of inadequate height for endosteal implant placement.

Treatment Option 2

Bidez and the University of Alabama at Birmingham, School of Engineering in the Department of Biomechanics, have evaluated dentate and edentulous mandibles and

WWW.HIGHDENT.IR

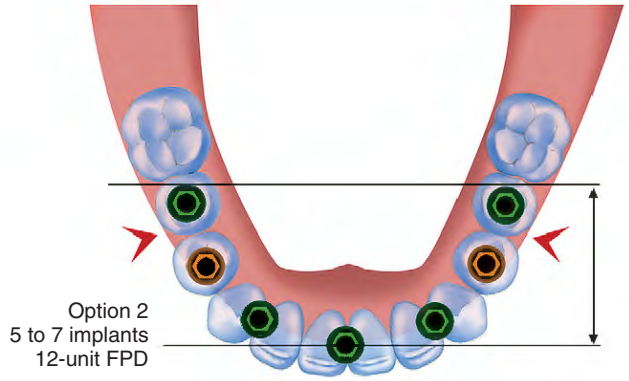

Figure 15-13 Treatment option 2 has five key implant positions: two implants placed over the mental foraminae, two implants in the canine positions, and one implant in the midline. Secondary implants may be positioned in the first premolar sites. *FPD,* Fixed partial denture.

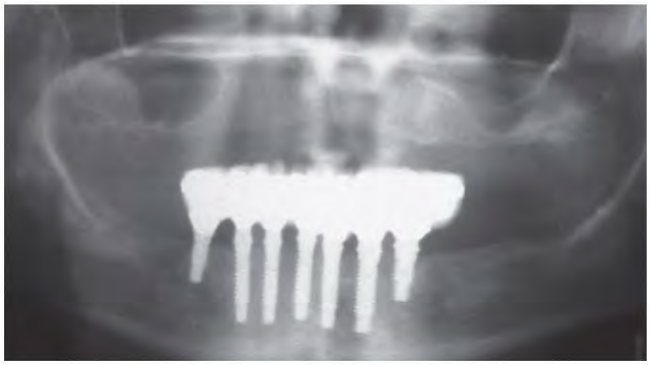

Figure 15-14 A panoramic radiograph of a full-arch fixed restoration with seven implants placed following treatment option 2: two implants over the foraminae, two implants in the first premolar sites, two implants in the canine positions, and one implant in the midline.

developed a bone strain model of flexure and torsion. As a consequence, a number of implant site options have become available.

A slight variation of the ad modum Brånemark protocol is to place additional implants above the mental foraminae, because the mandible flexes distal to the foramen (Figure 15-13). An implant above one or both foraminae presents several advantages. First, the number of implants may be increased to as many as seven (which increases implant surface area). Second, the A-P spread for implant placement is greatly increased, even when the total implant number is five. This implant position reduces the Class 1 lever forces generated from the distal cantilever. Third, the length of the cantilever is reduced dramatically because the distalmost implant is placed one tooth more distal (Figures 15-14 and 15-15).

A prerequisite for treatment option 2 is the presence of available bone in height and width over the foraminae. Because the foramen usually is located 12 mm above the inferior border of the mandible, available bone height is reduced in this location. When available, the foramen often requires implants of reduced height

Figure 15-15 An intraoral view of the full arch fixed prosthesis from Figure 15-14. A cantilever to the first molar site is reduced, because implants are positioned over the mental foraminae.

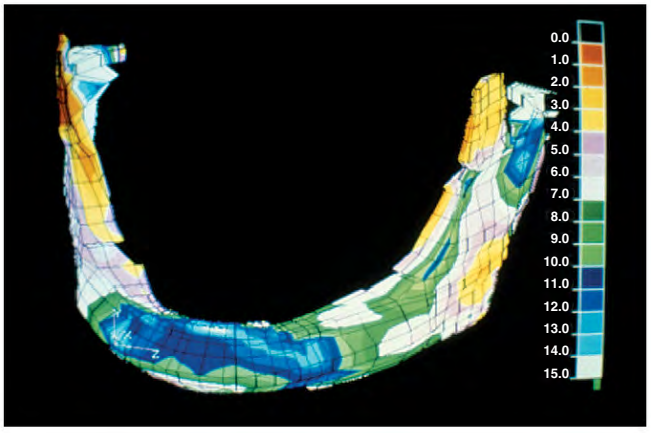

Figure 15-16 Studies at the Engineering school at the University of Alabama at Birmingham used a dentate and edentulous model to evaluate the bone strain conditions during flexure and torsion. A number of implant site options have become available as a consequence. *(Courtesy M.W. Bidez.)*

compared with the anterior implants. The most distal implant bears the greatest load when loads are placed on the cantilever (acts as fulcrum); therefore the greatest forces are generated on the shortest implants. A minimum recommended implant height of 9 mm and a greater diameter or an enhanced surface area design are recommended to compensate for the reduced length.

The key implant positions in this option are the second premolar positions, the canine positions, and the central incisor or midline position. The two optional implant sites are the first premolar sites.

Treatment Option 3

The Bidez strain model of an edentulous mandible indicated implants in one posterior section may be splinted to anterior implants without compromise (Figure 15-16). The author has evaluated full-arch fixed prostheses on implants with one posterior segment connected to the anterior region over the last decade

WWW.HIGHDENT.IR

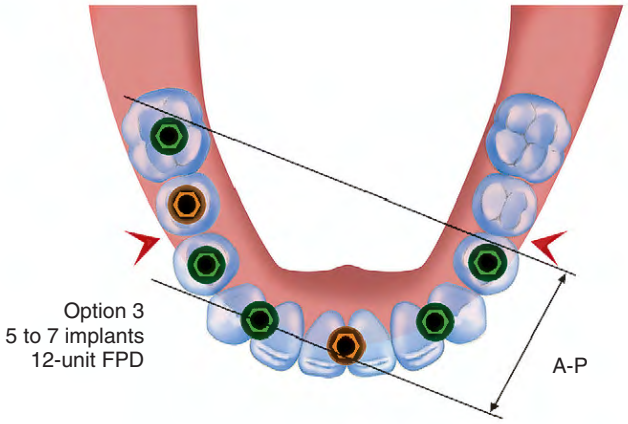

Figure 15-17 Treatment option 3 has key implant positions in one first molar site, bilateral first premolar positions, and two canine sites. Secondary implants may be used in the bilateral second premolar and midline position. The anteroposterior (A-P) distance is measured from the two distal most implants to the anteriormost implant from the cantilever. *FPD,* Fixed partial denture.

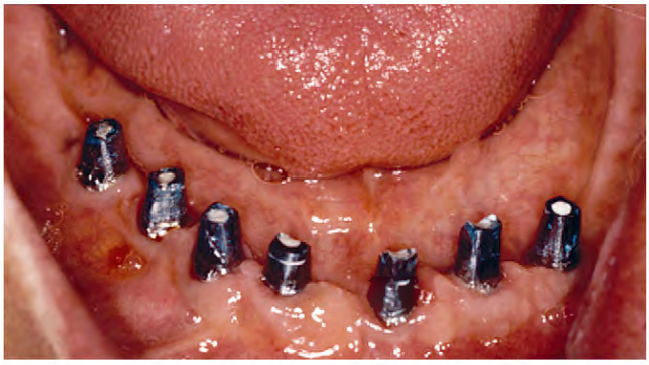

Figure 15-18 Five of the seven mandibular implants are positioned between the mental foramens, and two are placed on the patient's right side. The placement increases the anteroposterior distance and eliminates the prosthetic cantilever on the patient's left side.

and has found no additional complications experienced during this time frame compared with those with independent segments. Therefore another treatment plan option to support a fixed mandibular prosthesis consists of additional implants in the first molar or second premolar position, connected to four or five implants between the mental foraminae. Hence a total of five to seven implants usually are placed in this option.

The key implant positions for treatment option 3 are the first molar (on one side only), the bilateral premolar positions, and the bilateral canine sites. The secondary implant positions include the second premolar position on the same side as the molar implant and the central incisor (midline) position (Figure 15-17). On occasion, an additional site may include the position over the mental foramen on the side of the cantilever. A one-piece casting can be fabricated, and one cantilever to the opposite side of the molar implant would replace those posterior teeth. Although mandibular movement occurs, it has not been observed to cause complications.

Figure 15-19 A mandibular restoration in situ.

Figure 15-20 An intraoral view of the final maxillary and mandibular fixed implant-supported prostheses.

Treatment option 3 is a better option than anterior implants with bilateral cantilevers for several reasons. When one or two implants are placed distal to the foraminae on one side and are joined to anterior implants between the foraminae, a considerable biomechanical advantage is gained. Although the number of implants may be the same as option 1 or 2, the A-P spread is 1.5 to 2 times greater, because on one side the distal aspect of the last implant now corresponds to the distal aspect of the first molar (see Figure 15-17). In addition, only one cantilever is present, rather than bilateral cantilevers. When force factors are greater, six to seven implants may be used for this option. Five implants between the foraminae and one or two implants distal on one side compose the usual placement (Figures 15-18 to 15-21). Over the last 10 years, the author has fabricated more than 25 prostheses with five to seven implants in these locations. To date, no prosthesis has been replaced and no implants have failed. This approach is superior to treatment option 2 with bilateral cantilevers because the A-P spread is dramatically increased, more implants may be used if desired, and only one side has a cantilever. However, this option requires available

bone in at least one posterior region of the mandible (Figures 15-22 to 15-25).

Treatment Option 4

Treatment plan options for fixed full-arch prostheses also may include bilateral posterior implants as long as they are not splinted together in one prosthesis. This option is selected when force factors are great or the bone density is poor. Poor bone quality most often is observed in the posterior maxilla, but on occasion it is also found in the mandible. This option is also used when the body of the mandible is Division C–h and subperiosteal or disk-design implants are used for posterior implant support. Several options for fixed

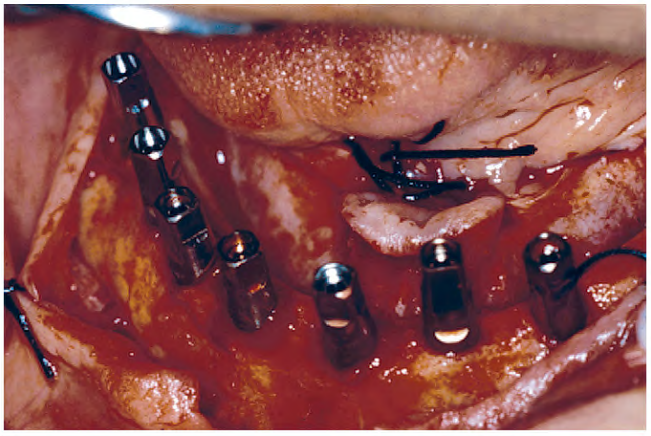

Figure 15-23 Two implants are positioned behind the foramen on the patient's right side, and one implant is added over the foramen on the patient's left side. The anteroposterior distance is increased more than four times compared with option 1, and the prosthetic cantilever has been decreased on the patient's left side.

restorations are available when bilateral posterior implants are included.

In treatment option 4, implants are placed in all three segments of the mandible (Figure 15-26). Key

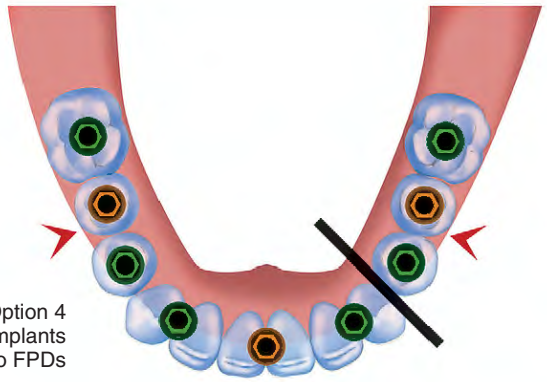

Figure 15-26 Treatment option 4 has implants in both molar sites. Other key positions include the two first premolar positions and the two canine sites. Secondary implants may also be positioned into second premolar locations and the midline. *FPD*, Fixed partial denture.

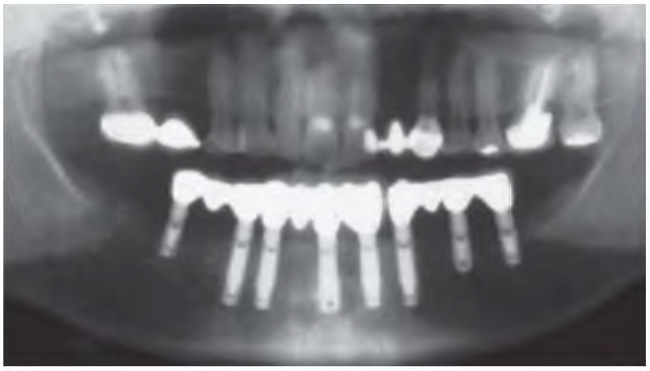

Figure 15-28 A panoramic radiograph of a full-arch fixed implant prosthesis in the mandible, with option 4 implant support. The prosthesis is separated in two sections between the first premolar and canine sites.

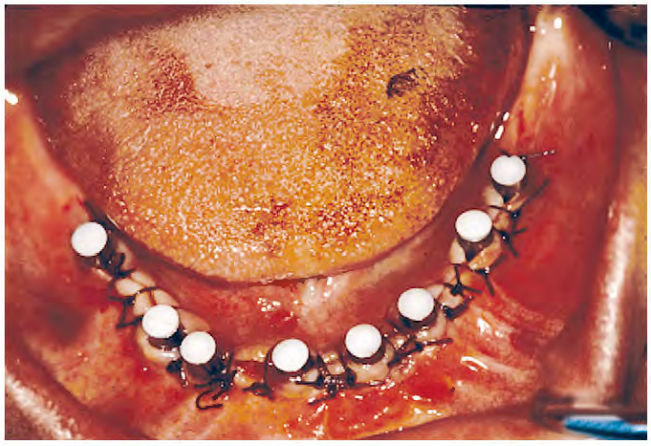

Figure 15-27 Eight endosteal implants at stage 2 uncovery with both posterior quadrants of sufficient bone height and width for endosteal implants.

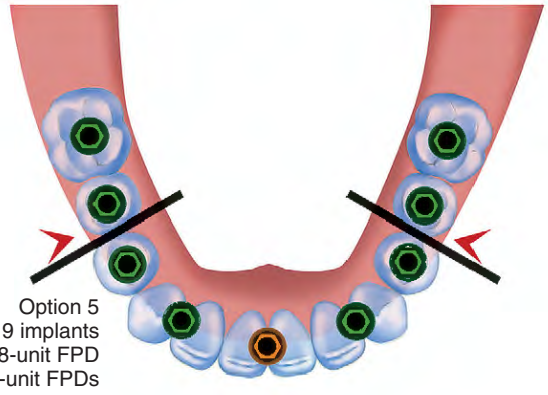

Figure 15-29 Treatment option 5 is designed to support three independent prostheses. The key implant positions are usually first molar sites, second premolar sites, first premolar sites, and canine positions. The posterior restorations are usually separated between two premolar sites. This option provides maximum flexure and torsion to the mandibular body during function and parafunction. *FPD*, Fixed partial denture.

implant positions for this treatment option include the two first molars, two first premolars and two canine sites. Secondary implants may be added in the second premolars and/or the incisor (midline) position. All implants in the anterior and one posterior side are splinted together for a nine-unit, fixed prosthesis. The other posterior segment is restored independently with an independent three-unit, fixed prosthesis supported by implants in the first premolar and first molar region as the key positions. The secondary sites are the second premolar positions (Figures 15-27 and 15-28). Three implants are used most often for the smaller segment to compensate for force factors and the alignment of the implants almost in a straight line. At least six implants typically are used in this option. Additional implants—as many as nine—may be inserted when force factors are greater.

The primary advantage of this treatment option is the elimination of cantilevers. As a result, risks of uncemented restorations and occlusal overload are reduced. Another advantage is that the prosthesis has two segments rather than one. Because no cantilever is present, weaker cements can be used to install the prosthesis. If the prosthesis requires repair, the affected segment may be removed more easily because only the segment requiring repair needs to be removed. Disadvantages include the need for abundant bone in both mandibular posterior regions and the additional costs incurred for one to four additional implants. The restoration should exhibit posterior disclusion in excursions to limit lateral loads, especially to the prosthesis supported by fewer implants.

Treatment Option 5

Another modification for the completely edentulous mandible is to fabricate three independent prostheses rather than one or two (Figure 15-29). The anterior region of the mandible may have four to five implants. The key implants are in the two first molar sites, the two first premolar, and two canine regions. Secondary positions are the two second premolar and central

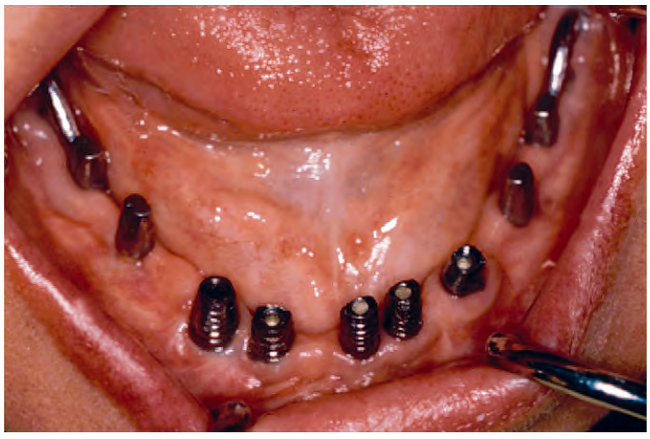

Figure 15-30 An intraoral view of five root form implants positioned between the mental foraminae. The posterior quadrants have a subperiosteal implant. This female patient desired maxillary and mandibular fixed prostheses, but declined an iliac crest bone graft to the posterior mandible.

Figure 15-31 The anterior fixed prosthesis is independent of the posterior restorations. This allows maximum flexure of the mandible. This fifth option is more indicated for Division C–h bone volume mandibles than Division A mandibles.

incisor (midline) sites. With this setup, the posterior restorations extend from first molar to first premolar and an anterior restoration replaces the six anterior teeth. However, these six implant sites are usually best used in treatment option 4. Therefore, when option 5 is indicated, it usually has two implants in first molars, second premolars, first premolars, and both canine positions. These eight implants may also have a secondary implant in the midline. The fixed anterior prosthesis extends from first premolar to first premolar. The posterior restorations are two independent implant prostheses, each with two units.

The advantages of this option are smaller segments for individual restorations in case one should fracture or become uncemented. In addition, if greater mandibular body movement is expected because of parafunction or a decrease in size of the body of the mandible, the independent restorations allow the most flexibility and torsion of the mandible. The primary disadvantage is

Figure 15-32 An intraoral view of the mandibular restorations. Two independent posterior restorations are supported by subperiosteal implants between the mental foraminae.

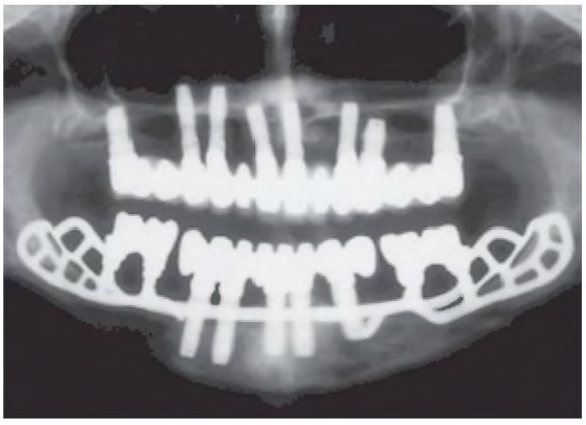

Figure 15-33 A panoramic radiograph of the final restorations and implants. The three independent mandibular prostheses permit flexure of the posterior mandible.

the greater number of implants required. In addition, the available bone needs are greatest with this treatment option. Rarely are more than nine implants required to replace the lower teeth, regardless of the bone density or force factors present. Option 5 is the treatment of choice when force factors are severe, but it is rarely used.

The most common scenario for option 5 is when the posterior mandible is C–h bone volume and a circumferential subperiosteal or disk-design implant is used as the second premolar and first molar implant abutment supports. The decrease in the bone volume of the posterior mandible increases the flexure and torsion. As a result, three independent prostheses are warranted (Figures 15-30 to 15-33).

LONG-TERM TREATMENT PLANNING

There is overwhelming evidence and agreement that a two-implant overdenture (RP-5) is a better option than a traditional denture, but the overdenture should not be considered a lifetime device. The posterior mandibular

WWW.HIGHDENT.IR

resorbs four times faster than the anterior mandible. An anterior implant-supported overdenture may accelerate posterior bone loss, because the bite force increases and the patient more likely is able to wear the mandibular prosthesis. When the doctor and patient consider a "lifetime strategy of treatment" rather than a 1-year treatment plan, the plan is then treated as a lifetime approach and both doctor and patient can benefit.

A mandibular overdenture may be upgraded from an RP-5 prosthesis to a completely implant-supported device (RP-4) and then to a fixed prosthesis (FP-3). If the cost involved to insert two or three implants can be invested every 5 years, within 4 to 20 years every patient may have a fixed restoration, provided available bone and force factors are compatible. As a result, the goal of the dentist should be to establish a lifetime strategy of health, with the patient's scheduled prosthesis upgrade. For example, if implants are placed in the canine positions at step 1 for an overdenture, the dentist may plan the placement of implants into the left first molar and right first premolar positions at step 2. At step 3, implants can be added to the left first premolar position to reach a goal of an RP-4 or FP-3 restoration.

SUMMARY

Many completely edentulous patients desire a fixed restoration rather than a removable prosthesis. Costs for a fixed implant prosthesis often have been a deterrent, but should be more similar to a completely implant-supported overdenture. The number and position of implants should be related to the amount of stress transmitted to the bone during occlusion and parafunction and the density of the bone. Other considerations include mandibular flexure and torsion. Five treatment options generally are available for this fixed complete mandibular implant-supported restoration. The primary advantage of treatment option 1 with five anterior implants is cost. Disadvantages include overload situations resulting from bilateral cantilevers. Treatment option 2 is improved, but bilateral cantilevers (which are shorter than option 1) are still a concern. Treatment option 3 is superior to the previous option but requires posterior bone in one quadrant to place endosteal, subperiosteal, or disk-design implants. The most ideal treatments are options 4 or 5 because they lack cantilevers and the dentist fabricates two or three separate restorations. These treatment options also accommodate the stronger mandibular bone dynamics without affecting the restoration. However, bone must be present or obtained through grafting for endosteal implants, or a circumferential subperiosteal or disk-design implant must be used for support in both posterior quadrants. In addition, the latter options increase costs because more implants are used for support of the fixed restoration.

Chapter 16

Single-Tooth Replacement: Treatment Options

Carl E. Misch

Seventy percent of the dentate population in the United States is missing at least one tooth. Single-tooth replacement will most likely comprise a larger percentage of prosthetic dentistry in the future, compared with past generations. In 1960 the average American over age 55 years had just seven original teeth. Today the average 65 year old has 18 original teeth; however, baby boomers (those born between 1946 and 1964) can expect to have at least 24 original teeth when they reach 65 years of age. The first adult teeth lost today are usually between the ages of 35 and 54 years. Almost 30% of the 50 to 59 year olds examined in a U.S. national survey exhibited either single or multiple posterior edentulous spaces bordered by natural teeth.[1] This segment of the population has the most disposable income and is the least dependent on insurance companies to pay for dental care. Treatment to replace single teeth in the posterior regions represents nearly 7% of the annual dental care reimbursement from insurance companies and totals more than 3.2 billion U.S. dollars each year.[2,3]

POSTERIOR MISSING TOOTH

The first molars are the first permanent teeth to erupt in the mouth and often play a pivotal role in the maintenance of the arch form and proper occlusal schemes. These teeth are often the first to decay, and the adult patient often has had one or more crowns fabricated to restore the integrity of the tooth and replace previous large restorations. Longevity reports of crowns have yielded very disparate results, with the mean life span at failure reported to be 10.3 years. The primary cause of failure of the crown is endodontic therapy, porcelain or tooth fracture (or both), or uncemented restoration. The tooth is at risk for extraction as a result of these complications and is a leading cause of single posterior tooth loss in the adult[1-9] (Figure 16-1).

POSTERIOR SINGLE-TOOTH REPLACEMENT OPTIONS

Evidence-based medicine is the conscientious, explicit, and judicious use of the best evidence in making decisions about the care of individual patients (Cochrane Center, Oxford, England).[10] Over the years, researchers have observed that external clinical evidence would both invalidate previously accepted treatment and allow replacement with new modalities that are more efficacious and safe.[10] An evidence-based approach may be applied to the replacement of a posterior single tooth.

Five alternative treatment options exist for the replacement of a posterior single missing tooth (Box 16-1). The interocclusal space must be assessed carefully, regardless of the treatment selected. Patients with insufficient vertical space may be contraindicated for any prosthesis without the prior correction of the occlusal plane and maxillomandibular relationships.

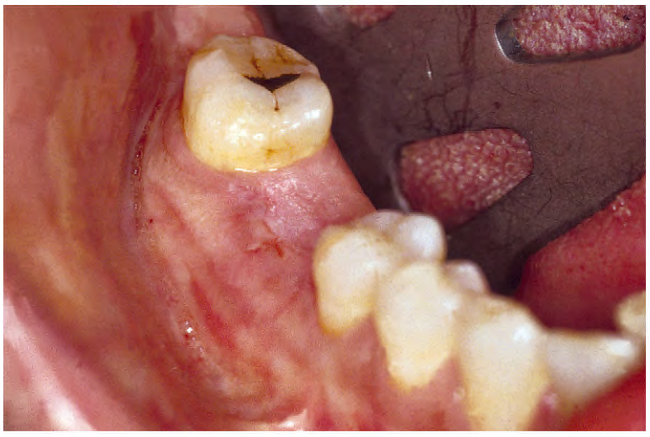

Figure 16-1 A mandibular first molar is often the first tooth lost in a permanent dentition.

WWW.HIGHDENT.IR

Box 16-1 Alternative Options: Single-Tooth Replacement

1. Removable partial denture (RPD)
2. Resin-bonded prosthesis
3. Space maintainer
4. Fixed partial denture (FPD)
5. Implant prosthesis

Box 16-2 Advantages of Removable Partial Dentures

1. Hygiene
2. Soft tissue replacement in esthetic areas
3. Maxillary lip support in gross defects
4. Minimum tooth preparation
5. Reduced cost

Removable Prosthesis

One option to replace a single missing tooth is a removable partial denture (RPD). A common axiom in restorative dentistry is to use a fixed prosthesis whenever possible.[8] RPDs are usually indicated to replace spans of three or more posterior teeth or a missing canine and two or more adjacent teeth. Rarely does a patient consent to a RPD as an acceptable definitive substitute for one posterior single tooth.

The advantages of the removable restoration for multiple tooth loss include the following: ease of daily care of the adjacent teeth, the ability to have a soft tissue replacement around the missing tooth in esthetic zones with gross defects, maxillary lip support in gross defects, minimal preparation of the abutment teeth, and reduced cost (Box 16-2). However, no reported advantages exist for an RPD replacing one posterior tooth.

Removable prostheses do not maintain bone. The maxillary posterior teeth are often in the esthetic zone (especially the maxillary premolars), and bone loss may compromise the esthetic result. Function is not improved with a removable prosthesis replacing one or two teeth, so esthetics and the fear of other teeth shifting in the arch are the two primary reasons for the patient to consent to wearing the restoration. Because of its bulk and the need for cross arch stabilization, an RPD promotes more food debris and plaque accumulation on the adjacent teeth than any other treatment option (Box 16-3). No clinical reports are available to assess the longevity survival rate, complications, or survival of adjacent teeth for a single-tooth RPD in the posterior regions of the mouth. From an evidence-based approach, this procedure is not indicated.

Recently, Shugars et al.[3] and Aquilino et al.[11] have reported on survival rates of teeth adjacent to treated and untreated posterior-bounded edentulous spaces. When RPDs were used to replace teeth, the survival of the posterior teeth adjacent to the edentulous space were poorer than with any other treatment option, with ranges from 17% to 44% abutment tooth loss at 4.2 to 13.5 years.[3,11-14] Patients electing not to wear the RPD may enjoy greater survival of the adjacent teeth than those wearing the removable prosthesis.

Box 16-3 Disadvantages of Single-Tooth Removable Partial Dentures

1. Bulk—need cross arch stabilization
2. Food debris, plaque
3. Movement
   a. Speech
   b. Function
4. No clinical studies
5. Bone loss
6. Highest loss of abutment teeth (up to 44% within 10 years)

Box 16-4 Advantages of Resin-Bonded Fixed Partial Dentures

1. Minimal preparation of teeth
2. Good on young patients (no need to crown, no risk of encroachment on pulp)
3. Good alternative when skeletal growth is not complete

Box 16-5 Disadvantages of Posterior Resin-Bonded Fixed Partial Dentures

1. High debond rates (50% within 3 years)
2. Inconvenience to patient and doctor
3. Risk of decay on abutment teeth

Resin-Bonded Fixed Partial Denture

A second option to restore a single missing tooth bordered by posterior natural teeth is a resin-bonded fixed partial prosthesis. The primary advantages of this restoration are the minimal preparation of the adjacent teeth and reduced cost (Box 16-4).

Failure rates reported in the literature are greatly disparate, but the majority of reports indicate a failure rate of at least 30% within 10 years and as high as 54% within 11 months.[6,15-17] It also appears that earlier perforated designs exhibited lower survival rates (Box 16-5).

The majority of resin-bonded fixed partial denture (FPD) failure occurs from cement failure, with different

WWW.HIGHDENT.IR

regions of the mouth exhibiting various retention rates. The highest survival rates occur in the maxillary anterior, followed by mandibular anterior, maxillary posterior, and mandibular posterior teeth respectively.[18] Therefore posterior tooth replacement is not as successful, compared with an anterior resin-bonded restoration. Debonding most often occurs during function; because eating is often a social experience, this may cause the patient embarrassment and insecurity. The selection of this option is usually driven by economics and the desire to maintain as much tooth structure as possible on the abutment teeth. This option is usually more accepted by the patient than the RPD, but it must be considered as a transitional restoration because of its high debonding rate.

Maintenance of the Posterior Space

A third treatment option to restore missing posterior teeth is to not replace the tooth but instead to maintain the missing space. A common doctrine has been to replace a missing tooth to prevent complications such as tipping, extrusion, increased plaque retention, caries, periodontal disease, and collapse of the integrity of the arch[8,14] (Figure 16-2). However, clinical studies evaluating the consequences of adjacent tooth loss indicate the loss of one or two teeth adjacent to a long-term edentulous space may range from 25% to less than 8% at 8 to 12 years.[3,13,14] For example, Aquilino et al.[11] reported an 18% 10-year tooth loss rate of adjacent teeth to a posterior missing tooth. The location of a missing posterior tooth often influences the prosthodontic treatment plan. In general, when third molars are missing, the author suggests not replacing a second mandibular molar[19] (Box 16-6). The mandibular second molar is not in the esthetic zone of the patient. Ninety percent of the masticatory efficiency is generated anterior to the mesial half of the mandibular first molar, so function is rarely a primary reason to replace the second molar. A 10% greater occlusal force is measured on the second molar compared with the first. This tooth is more likely to exhibit working or nonworking interfaces during mandibular excursions. The crown height space decreases as it proceeds posteriorly and represents a limited access for implant placement, component, and prosthesis screw, especially when opposing a natural dentition. As a result of the increased forces, occlusal interferences, limited abutment height, reduced retention, and cement surface area, a greater incidence of porcelain fracture, uncemented restorations, or both exists. In addition, the course of the mandibular canal anterior to the midfirst molar corresponds to the level of the mental foramen. However, in the region of the second molar, its course becomes highly variable with an elevated risk of paresthesia and neurovascular bundle damage during implant surgery and insertion. The bone quality in the second mandibular molar region is often inferior to other regions of the mandible, with increased risk of bone loss or implant failure.[20] The submandibular fossa topography mandates greater implant body angulation, with increased stresses at the crestal region of the implant, thereby increasing the risk of bone loss. Cheek biting is more common in this region because of the proximity of the buccinator muscle. The mandible exhibits increased flexure and torsion during opening

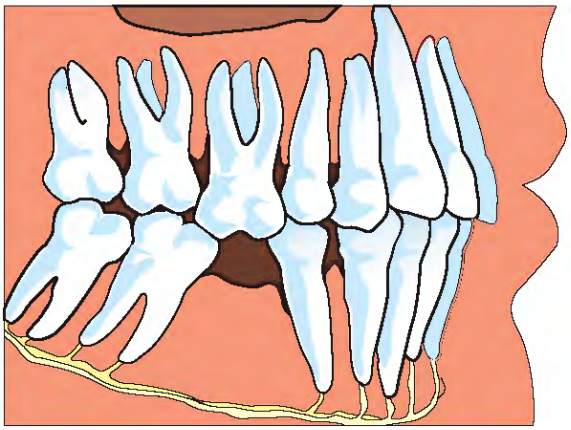

Figure 16-2 As many as 82 reasons exist for replacing a mandibular first molar after extraction. The most common reasons are tipping of adjacent teeth, extrusion of the opposing teeth, and increased plaque retention on the surrounding teeth.

Box 16-6 Disadvantages of Replacing a Mandibular Second Molar

1. Not in esthetic zone
2. Extruded maxillary second molar not esthetic or occlusal consequence
3. Less than 5% of total chewing efficiency
4. A 10% higher bite force (↑ bone loss risk, porcelain fracture risk, and abutment screw–loosening risk)
5. More often exhibits occlusal interferences during excursions
6. Higher and less predictable location of mandibular canal in that site
7. Less dense bone
8. Submandibular fossa depth greater; angulation of bone to occlusal plane greater
9. Limited to unfavorable crown height space for cement retention (increased risk of uncementation)
10. Limited access for occlusal screw placement
11. Limited access for correct implant body placement
12. Crossbite position—implant placed more buccal than maxillary tooth
13. Hygiene access more difficult
14. Cheek biting more common
15. More incision line opening after surgery
16. Greater mandibular flexure
17. Greater cost to patient
18. Mandibular third molar (when present) moves forward; intratooth space limited

WWW.HIGHDENT.IR

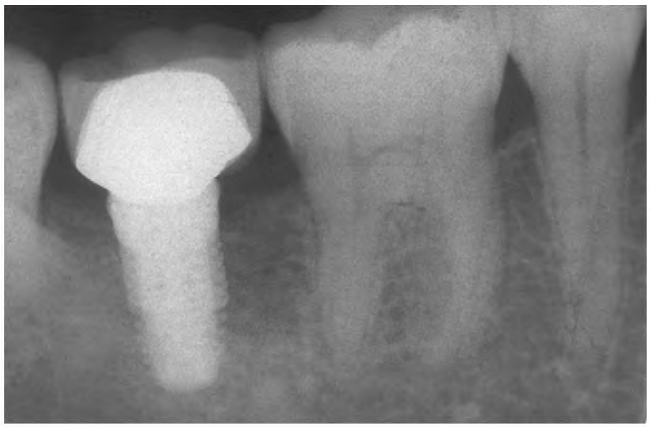

Figure 16-3 The second mandibular molar is usually replaced when the third molar is present and will remain in function.

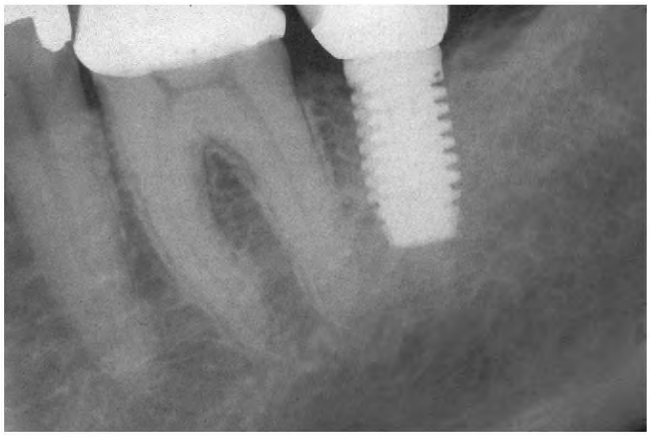

Figure 16-4 Some patients desire a second molar replacement despite the lack of need. When existing conditions are favorable, little disadvantage exists to placing an implant in this region. Most often a bicuspid-sized tooth and one implant are used in this region for restoration.

or heavy biting on one side at this second molar site, and masticatory dynamics are less favorable. Finally, the cost of an implant and/or fixed prosthesis to replace the second molar often does not warrant the benefits achieved. As a consequence, the mandibular second molar is often not replaced when the third molar and second molar are the only posterior mandibular teeth missing.

The primary disadvantage of electing not to replace a mandibular second molar tooth is the potential extrusion and loss of the maxillary second molar, or a loss of proper interproximal contact with the adjacent tooth, with increased risk of caries, periodontal disease, or both. If extrusion of the maxillary second molar is a concern for the patient or doctor, then a crown on the mandibular first molar may include an occlusal contact with the mesial marginal ridge of the maxillary second molar, or the maxillary second molar may be bonded to the maxillary first molar.

The mandibular second molar is usually replaced when the third molar is present and will remain in function (Figure 16-3). In addition, some patients desire an intact dentition and wish to have the tooth replaced (Figure 16-4). If the bone is abundant and no paresthesia risk is apparent, then the second molar may be replaced. However, this is usually the exception rather than the rule of treatment.

Another indication for not replacing a single missing posterior tooth is a small intratooth space. The existing occlusion may prevent the tipping of adjacent teeth and the extrusion of the opposing teeth. This condition is most often observed with a missing mandibular second premolar when a third molar is present. When the amount of intratooth space should be closed, orthodontics or overcontoured crowns on adjacent teeth may correct the condition.

Fixed Partial Denture

The treatment most commonly used for the replacement of a posterior single tooth is the three-unit fixed restoration. In 1990 more than 4 million FPDs were placed in the United States.[21] This type of restoration can be fabricated within 1 to 2 weeks and satisfies the criteria of normal contour, comfort, function, esthetics, speech, and health. Because of these benefits, the FPD has been the treatment of choice for the last 6 decades.[22,23] Few bone and soft tissue considerations exist in the missing tooth site. Every dentist is familiar with the procedure, and it is widely accepted by the profession, patients, and dental insurance companies (Box 16-7).

A three-unit FPD presents survival limitations to the restoration and to the abutment teeth.[7] In an evaluation of 42 reports since 1970, Creugers et al.[23] calculated a 74% survival rate for FPDs for 15 years. Walton et al.[24] and Schwartz et al.[25] reported mean life spans (50%) of 9.6 and 10.3 years, respectively. Scurria et al.[26] performed a metaanalysis of several reports at 10 to 15 years and found 30% to 50% failure within these time frames. However, reports are very inconsistent with as little as 3% loss over 23 years to 20% loss over 3 years.[4,5,23-26]

Box 16-7 Advantages of Fixed Partial Dentures

1. Most common treatment (doctor friendly)
2. Time (two appointments, 1 to 2 weeks apart)
3. Restores function, esthetics, and intraarch health
4. Few bone and soft tissue considerations
5. Proven long-term survival
6. Cost—dental insurance covers procedure (reduced patient cost)
7. Less than 6-mm mesiodistal space
8. Potential abutments have clinical mobility; will benefit from being splinted
9. Increases patient compliance and reduces fear
10. Few consequences if failure

Box 16-8 Disadvantages of Fixed Partial Dentures

1. Mean life span often 10 to 15 years
2. Caries and endodontic failure of abutment teeth most common complication
3. Increased plaque retention of pontic increases caries and periodontal disease risk
4. Damage to healthy teeth
5. Failure of prosthesis related to loss of abutment teeth (8% to 18% within 10 years)
6. Fracture (porcelain, tooth)
7. Esthetics (anterior regions)
8. Uncemented restoration

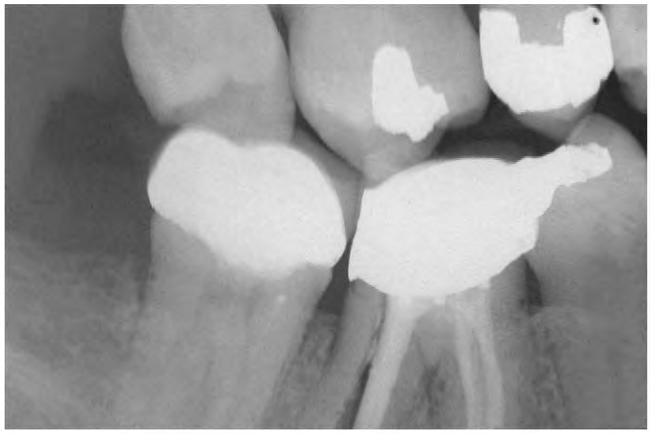

Figure 16-5 The most common cause of single-tooth loss is endodontic failure or fracture after endodontic therapy.

When a tooth is prepared for a crown, a 5.7% risk of irreversible pulpal injury and subsequent need for endodontic treatment exists.[27] In addition, the crown margin next to the pontic is more at risk of decay and the need for endodontics as a result. Caries and endodontic failure of the abutment teeth are the most common causes of prostheses failure.[22,24,26] Researchers have observed that abutment teeth for an FPD fail from endodontic complications more often than those with vital pulps.[28-30] Caries on the crown primarily occurs on the margin next to the pontic. A low percentage of patients floss on a regular basis, and those using a floss threader are even fewer.[30] As a result, the pontic acts as a large overhang next to the crown and a reservoir for plaque. Up to 15% of abutment teeth for a fixed restoration require endodontic therapy, compared with 3% of nonabutment teeth with crown preparations[31] (Box 16-8). The long-term periodontal health of the abutment teeth may also be at greater risk, including bone loss.

Unfavorable outcomes of FPD failure include not only the need to replace the failed prosthesis but also the loss of an abutment and the need for additional pontics and abutment teeth in the replacement bridge. Because

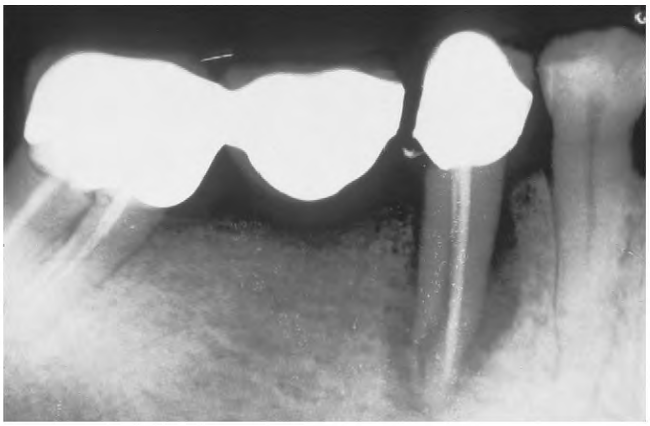

Figure 16-6 The most common reason for fixed partial denture (FPD) failure is caries on an abutment tooth resulting from increased plaque retention next to the pontic. Endodontic failure, fracture, and uncemented restorations often lead to abutment tooth loss.

Box 16-9 Contraindications for Use of Fixed Partial Dentures

1. Poor abutment teeth support
2. Inadequate hard or soft tissue (or both) in esthetic regions (pontic contour)
3. Patient will not allow preparation of adjacent teeth (patient desire)
4. Young patients with large pulp horns in clinical crowns

15% of FPD abutment teeth require endodontics, and root canal therapy is 90% successful at the 8-year mark, many abutment teeth may be lost (Figure 16-5).

The abutment teeth of an FPD may be lost at rates up to 30% for 8 to 14 years.[3,13,14] Recent reports indicate 8% to 18% of the abutment teeth holding an FPD are lost within 10 years (Figure 16-6). This is most disturbing, because 80% of abutments have no previous decay or are minimally restored before the fabrication of the FPD.[6] Some contraindications for a posterior fixed partial prosthesis are included in Box 16-9.

Single-Tooth Implants

The fifth treatment option to replace a posterior single missing tooth is a single-tooth implant. For years patients were advised to set their desires aside and accept the limitations of an FPD. However, many feel the most natural method to replace a tooth is to use an implant, rather than preparing adjacent teeth and joining them together with a prosthesis. The primary reasons for suggesting the FPD were its clinical ease and reduced treatment time. However, if this concept were expanded, then extractions would replace endodontics and dentures could even replace orthodontics. The primary reason to suggest or perform a treatment should not only be

WWW.HIGHDENT.IR

related to treatment time or difficulty to perform the procedure but also should reflect the best possible long-term solution for each individual (Figure 16-7).

Before 1990 few long-term studies focusing on single-tooth implant replacement with osteointegrated implants in any region of the mouth had been published. Early reports indicated single-tooth implant results were less predictable than they have become in the last 10 years. For example, in 1990, Jemt et al.[32] reported a 9% implant failure within 3 years of prosthesis completion on 23 implants with screw-retained restorations (21 in the maxilla, two in the mandible). In 1992, Andersson et al.[33] published a preliminary report of a prospective study of 37 implants restored with cemented single-tooth crowns in 34 patients. A 3-year follow-up included this "developmental group" and an additional 23 patients with 28 crowns. The cumulative success rate recorded was 93.7%, with 89% of the developmental group in function 3 to 4 years.[33]

From 1993 to the present time, single-tooth implants have become the most predictable method of tooth replacement. More refereed reports exist in the literature than for any other method of tooth replacement. Most all 5-year reports demonstrate a higher survival rate than for any other method of tooth replacement. For example, in 1993, Schmitt and Zarb[34] reported no failures for 40 implants placed in 32 patients (28 in the maxilla, 12 in the mandible, with 27 in the anterior region and 13 in the posterior). After a period of up to 6.6 years, all implants were in function. In 1994, Ekfeldt et al.[35] reported a 4- to 7-year retrospective study of 77 patients who received 93 implants. The restorations were cemented or screw retained. Two implants were lost, both within the first year of function. In the same year, Cordioli et al.[36] evaluated 67 endosteal implants for single-tooth replacement over a 5-year period and observed an implant loss of 5.6%. In 1995, Haas et al.[37] also reported on 76 single-tooth implants observed for 6 years with a 2.6% implant loss.

A series of reports in 1991, 1994, and 1996 reported on a multicenter prospective study consisting of 92 patients who received 107 implants with a cumulative survival rate of 97.2% at 3 and 5 years.[38-40] The mean marginal bone loss (measured from the first thread, which is 2 mm below the crestal bone) did not exceed 1.0 mm. Plaque and gingival indices were indicative of soft tissue health. The most frequent complication was loosening of the abutment fixation screw, and this complication was significantly reduced after the first year.

Becker et al.[41,42] reported more than 90% success in a study over 4 years and 282 molar implants. Simon[43] observed 70 molar implants over a period ranging from 6 months to 10 years, with a 97.1% success rate. Levin et al.[44] reported in 2006 on single-molar replacement with implants over a longer period, with a 93.6% success rate.

A multicenter prospective clinical study was initiated with the Maestro Dental Implant System from BioHorizons in 1996.[45] Thirty-eight implants were placed in the posterior regions of the jaws: 15 in the maxilla and 23 in the mandible. These included six second molars (four maxillary and two mandibular), 22 first molars (six maxillary and 16 mandibular), seven second premolars (three maxillary and four mandibular), and three first premolars (two maxillary and one mandibular). All crowns were cement retained. The implant survival rate was 100% at the 5-year follow-up. The mean bone loss from implant insertion to uncovering was 0.4 mm from the original crest of the ridge, the additional mean bone loss over the first 1 year of loading averaged less than 0.3 mm, and no bone loss over the following year was observed. No incidence of abutment screw loosening or fracture of any components was observed in this study. In 2000, Misch et al.[46] reported on 30 single-tooth implants with this same implant system in the posterior maxilla, with 100% survival rate over a 5-year period. In 2006, Misch et al.[47] found the 100% survival rate for single-tooth implants was maintained for as long as 10 years.[47]

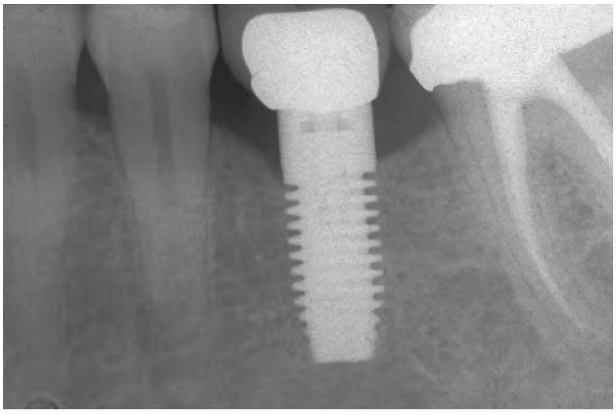

Figure 16-7 A single-tooth implant is usually the best treatment option to replace a posterior missing tooth.

A 10-year report by Priest[6] indicated the posterior single-tooth implant was more than 97% successful. Perhaps of more significance, no adjacent teeth loss from endodontic failure or caries occurred, and only one tooth required endodontic therapy after implant insertion. This report clearly identifies that the adjacent teeth are least at risk when the missing tooth is replaced with an implant.

Although posterior single-tooth replacement is a relatively new treatment alternative, more articles have been published than for any other treatment alternative. If early reports are excluded, then survival rates reported range from a low of 94.6% to a high of 100% for 1 to 10 years. A review of the literature by Goodacre et al.[48] from 1981 to 2003 found single-tooth replacement with an implant had the highest implant prosthesis survival rate and averaged 97% survival. The most common complication reported was abutment screw loosening, which did not cause the prosthesis or implant to fail.

WWW.HIGHDENT.IR

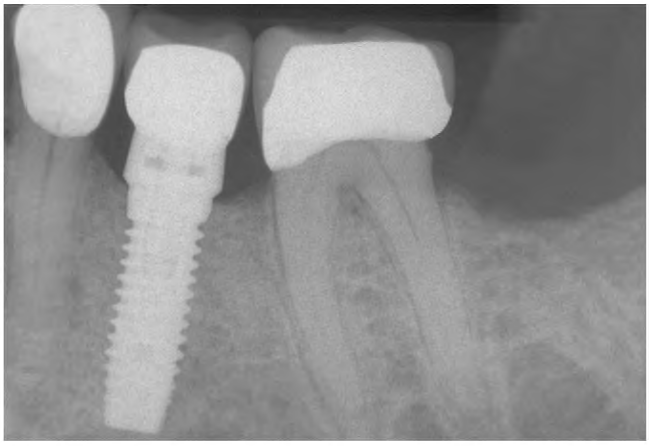

Figure 16-8 Because a single-tooth implant has the highest success rate of all the treatment options to replace a single-tooth, it is the treatment of choice, even when the adjacent teeth need crowns. (NOTE: A tooth with a crown has a 3% incidence of endodontic treatment versus a 15% risk for a tooth serving as an abutment of a fixed prosthesis.)

The single-tooth implant exhibits the highest survival rates of the five treatment options presented for single-tooth replacement. In addition, the adjacent teeth have the highest survival rate and the lowest complication rate, which is a considerable advantage (Figure 16-8). On the other hand, the longevity of the implant crown has not been adequately determined, because these reports do not extend as long as those of other treatment options. However, 10-year data clearly indicate an implant and its associated crown has greater survival than an FPD.

Despite some limitations and obvious clinical challenges, the posterior single-tooth implant represents a highly desirable and justified treatment option. In addition, cost comparison studies conclude that the implant restoration demonstrates a more favorable cost-effectiveness ratio.[6,48-49] When adjacent teeth are healthy or are able to be restored, or when the patient refuses their preparation for the fabrication of a traditional three-unit fixed partial restoration, a posterior single-tooth implant is an excellent solution. As a consequence of not preparing the adjacent teeth for crowns, many additional advantages are incurred. These advantages include the decreased risk of caries and endodontics treatment on the abutment teeth, the improved ability to clean the proximal surfaces of the adjacent teeth (which decreases the risk of decay and periodontal disease), a decreased risk of cold or root contact sensitivity with a brush or scaler on the abutment teeth, improved esthetics, maintenance of bone in the edentulous site, psychological advantages (especially with congenitally missing teeth or the loss of a tooth after a crown restoration), and the decreased risk of abutment tooth loss from endodontic failure or caries (Box 16-10). These advantages are so significant to the health and periodontal condition of the adjacent teeth and maintenance of the arch form that the single-tooth implant has become the treatment of choice in most situations.

Box 16-10 Advantages of Single-Tooth Implants

1. Adjacent teeth do not require splinted restorations
   a. Less risk of caries
   b. Less risk of endodontics
   c. Less risk of porcelain fracture
   d. Less risk of uncemented restoration
   e. Less fracture of tooth
2. Psychological need of patient addressed: patient does not desire two adjacent teeth (often virgin) prepared and splinted to restore missing tooth
3. Improved hygiene conditions
   a. Less decay risk
   b. Floss versus floss threader
   c. Less pontic "overhang"
4. Decreased cold or contact sensitivity
   a. Prepared teeth more temperature sensitive
   b. Cementum of tooth removed by tooth preparation; toothbrush or scaler sensitive
5. Improved esthetics: natural tooth versus crown esthetics
6. Maintains bone in site: 30% decreasing width within 3 years after extraction
7. Decreases adjacent tooth loss: 30% versus 0.05% risk at 10 years

The consequences of early failure may be greater for a single-tooth implant compared with a three-unit fixed prosthesis. Although surgical success is very high, the implant failure almost always results in bone loss. As a result, if the patient elects to repeat the procedure, then bone grafting may be required. This most often is at the expense of the doctor, because most patients believe early implant failure, at least in part, is the doctor's responsibility. Bone grafting is not as predictable as implant surgery; therefore if a graft is required (especially in height), then the procedure may not be successful. However, contrary to failure of a fixed prosthesis, implant failure does not compromise the adjacent teeth and does not increase the risk of their loss.

CONTRAINDICATIONS AND LIMITATIONS OF POSTERIOR SINGLE-TOOTH IMPLANTS

Local contraindications that are unique to posterior single-tooth implants (Table 16-1) and favor an FPD include inadequate bone volume, inadequate intratooth space, and observable mobility of the adjacent teeth. Grafting may modify inadequate bone volume, either in height or width. Bone grafting for additional height when the adjacent teeth have lost bone is not as predictable as implant insertion and healing, regardless of the technique used. Therefore an FPD may still be the treatment of choice.

WWW.HIGHDENT.IR

Table 16-1 Contraindications for a Posterior Single-Tooth Implant versus Indications for a Posterior Three-Unit FPD

LOCAL CONTRAINDICATIONS FOR A POSTERIOR SINGLE-TOOTH IMPLANT	INDICATIONS FOR A POSTERIOR THREE-UNIT FPD
Inadequate bone volume Faciopalatal <5 mm Mesiodistal <6.5 mm for a >3.5-mm-diameter implant	Indequate bone volume Inadequate intratooth space <6.5 mm (may also use two unsplinted crowns) Lack of intratooth bone height
Moderate to advanced mobility of two to four adjacent teeth	Adjacent teeth are mobile
Limited time for patient treatment	Reduced time of treatment

FPD, Fixed partial denture.

The mesiodistal posterior space should be at least 6.5 mm or greater. Smaller intratooth spaces should be restored with an FPD or two adjacent crowns that are overcontoured. Flossing is easier between unsplinted crowns than for a fixed prosthesis, and the cost is reduced. If the space is out of the esthetic zone, then the clinician may consider not replacing the tooth, if the adjacent teeth are not at risk of tipping or extrusion because of the occlusal relationship of the opposing teeth.

When the adjacent teeth have observable secondary mobility but all other periodontal indices are within normal limits, a three-unit fixed restoration is superior to the other treatment options. When the adjacent teeth have moderate to severe mobility, the occlusal adjustment of an implant crown may be difficult to perform, because it is the only rigid component in a span of three to five teeth. Posterior healthy teeth move vertically 28 µm and exhibit lateral movement of less than 75 µm. A heavy bite force occlusal adjustment allows the teeth to move within their physiologic range before the implant crown contacts in occlusion. However, when the surrounding teeth are mobile, an equilibration of force is not possible, because the implant crown will come into contact before the conclusion of the adjacent natural tooth movement. As a result, the implant bears the load of all the mobile teeth and therefore may be contraindicated when surrounded by teeth with advanced clinical mobility.

On rare occasions the length of time needed to replace the missing tooth constitutes the primary deterrent of the treatment. An FPD can be fabricated in less than 1 week and allows for the placement of a fixed transitional prosthesis.

To summarize, the primary indications for the selection of a three-unit FPD correspond to the limitations of single-implant tooth replacements: (1) limited time frame, (2) lack of available bone height with poor prognosis or impossibility to augment, (3) inadequate intratooth space, and (4) advanced clinical mobility of adjacent teeth.

Transitional Restorations

Few indications exist for a removable prosthesis as a definitive treatment when replacing a single posterior tooth. However, it is often used as a transitional restoration in esthetic regions during implant healing. A removable transitional restoration may load the soft tissue over a bone graft and compromise the result and volume of the augmentation. Less likely, the RPD may also cause bone loss, or perhaps even implant failure from the early loading around the implant during Stage I healing. The RPD transitional may also depress the interdental papillae of the adjacent teeth, resulting in an esthetic compromise. As a result, a resin-bonded fixed restoration may be fabricated when replacing teeth in the esthetic zone to provide an improved functional transitional prosthesis and protect the region. This is most often the primary option when bone grafting is necessary before or in conjunction with implant placement because of the bone graft's extreme vulnerability to movement and the extended healing time required.

Both a removable and a resin-bonded fixed prosthesis may be fabricated for the transitional restoration. The removable restoration (i.e., Essix appliance or flipper) is worn immediately after surgery to protect the suture line during the initial healing. Once the sutures are removed, the resin-bonded restoration (without tooth preparation) may be delivered. Because both resin-bonded and removable restorations are fabricated, the patient can insert the removable restoration if the bonded restoration becomes uncemented; this will eliminate the esthetic embarrassment until rebonding can be performed. However, this approach increases the overall cost of treatment. The posterior resin-bonded prosthesis may not be indicated in the case of short clinical crowns or unfavorable occlusal relationships.

An absence of transitional posterior tooth replacement is the most frequent situation during bone augmentation and implant healing in a nonesthetic region, such as the mandibular posterior aspect of the mouth. Although

*Average measurements of maxillary teeth.

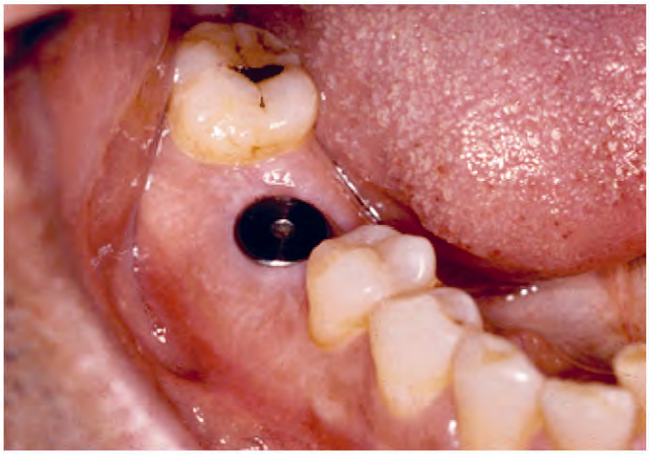

Figure 16-9 The most common option for tooth replacement during the initial healing period of the implant is no replacement.

the occlusion and adjacent teeth may change during the 4-month healing period, rarely is this a cause of further restoration in the region (Figure 16-9).

IMPLANT BODY SELECTION

The implant body for a posterior single-tooth implant should include specific features to reduce complications. The most common problem associated with a single tooth is abutment screw loosening.[35,38-42,47-55] Crest module and abutment connection designs that decrease forces to the abutment screw are therefore indicated. The implant must have an antirotational feature (i.e., external or internal hex). The greater the height or depth of the antirotational feature, the less force transmitted to the abutment screw. Accuracy of component fit and abutment screw design, as well as the number of threads, are other critical features.[56-58]

The implant body should be made of titanium alloy to reduce the risk of long-term fracture because it is four times more resistant to fracture than grade 1 titanium and twice as strong as grade 3 titanium. A threaded implant provides greater functional surface area than a cylinder, and a tapered implant provides less surface area than a parallel walled implant body. When implant bodies are internal hex designs, the dimension of the implant in the posterior regions should be at least 4 mm or more in diameter to increase the outer body wall thickness and reduce the risk of long-term body fracture.

The ideal diameter of a single-tooth implant is dependent on the mesiodistal dimension of the missing tooth and the buccolingual dimension of the implant site (Table 16-2). An angular defect may develop around the abutment-body connection measuring 1.0 to 1.4 mm in width. As a result, when the implant is placed closer than this dimension to an adjacent tooth, the vertical, angular defect dimension may cause bone loss on the tooth. When the implant has facial bone thickness less than 1.4 mm, bone loss may result and implant failures occur more frequently.[59] The horizontal bone loss around the implant will cause an increase in probing depths or an increased risk of soft tissue shrinkage. These may affect the bacterial flora or cervical esthetics of the soft tissue drape. This may be why gingival recession around wide-diameter implants have been noted to be greater than with a standard diameter.[60,61] As a consequence, the ideal implant diameter is 1.5 to 2.0 mm from an adjacent tooth and 1.5 mm from the lateral width of the ridge. Therefore the ideal implant diameter in the intratooth posterior region should be at least 3 mm less than the mesiodistal dimension of the missing tooth (from cement-enamel junction [CEJ] to CEJ) and 3 mm narrower than the buccolingual dimension of bone. As general rule, the molar implant should be larger in diameter than a premolar implant (Figure 16-10).

PREMOLAR IMPLANT REPLACEMENT

The most ideal posterior tooth to replace with an implant is the first premolar in either arch (Figure 16-11). When used as an abutment for a three-unit FPD, the canine is at an increased risk of material fracture or uncementation (because of the lateral forces applied) and is often more difficult to restore to its original appearance than are other anterior or posterior teeth.

WWW.HIGHDENT.IR

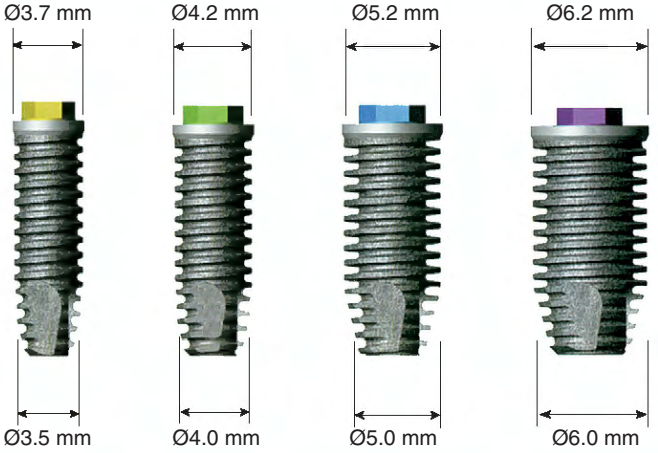

Figure 16-10 The single-tooth implant in the posterior region should range from 3.5 to 6 mm in diameter, 9 to 15 mm in length, be made of titanium alloy (for strength), and have a antirotational crest module design (i.e., external or internal hex).

Figure 16-12 The maxillary premolar implant should be positioned just lingual of the buccal cusp, similar to an implant in the anterior regions of the mouth, when the cervical region is within the esthetic zone. This position allows the facial emergence of the crown to be esthetic, yet it does not require a ridge lap or overcontouring.

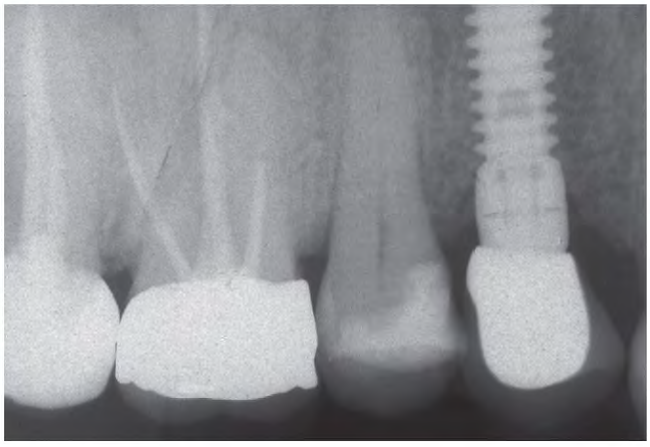

Figure 16-11 A missing first premolar (in either arch) is often indicated as an implant prosthesis, because a FPD with a canine abutment is more at risk and the vertical column of bone is usually in front of the maxillary sinus or mandibular mental foramen.

The vertical available bone is usually greater in the first premolar locations than in any other posterior tooth positions. In the maxilla, it is almost always anterior or below the maxillary sinus (or both), and the mandibular first premolar is almost always anterior to the mental foramen and associated mandibular neurovascular complex. The bone trajectory for implant insertion is more favorable in the mandibular first premolar than for any other tooth in the arch.

The maxillary premolars are often in the esthetic zone of patients with a high smile line. The need for bone grafting before maxillary first premolar implant placement is very common, because the extraction process of the thin buccal root often causes facial bone loss. Implant placement without bone grafting may result with a recessed emergence profile, which in the past was corrected with a facial ridge lap to the crown. However, the ridge lap contour does not allow proper hygiene or probing of the facial sulcular region of the crown and should not be used.

To ensure a proper esthetic result and to avoid the need for a crown with a ridge lap, the implant body is often positioned similar to an anterior implant, under the buccal cusp. The slight buccal implant placement improves the cervical emergence profile of the maxillary premolar crown (Figure 16-12). The natural premolar tooth root is 4.2 mm in diameter on average at a distance of 2 mm below the CEJ. As a consequence, the most common implant diameter is about 4 mm at the crest module. This also provides approximately 1.5 mm of bone on the proximal surfaces adjacent to the natural teeth when the mesiodistal space is 7 mm or greater. However, when the mesiodistal dimension is only 6.5 mm, a 3.5-mm implant is suggested.

The maxillary canine root is often angled 11 degrees distally and presents a distal curve 32% of the time, which may extend over the shorter root of the maxillary first premolar. The implant body is often longer than the natural tooth root. The surgeon may inadvertently place the implant parallel to the second premolar and, consequently, into the natural canine root. This may not only result in endodontic therapy of the canine but also may cause root fracture and loss of the tooth. Therefore in the maxillary first premolar region, care must be taken to evaluate the canine angulation and vertical height limitation. The first premolar implant may need to be placed parallel to the canine root, and a shorter implant than is considered ideal may be required. A tapered implant body at the apical one third may also be of benefit (Figure 16-13).

The second premolar apices may be located over the mandibular neurovascular canal or maxillary sinus. This results in a reduced height of bone, compared with the anterior region of the jaws. As a result a shorter implant is a common consequence in this region.

WWW.HIGHDENT.IR

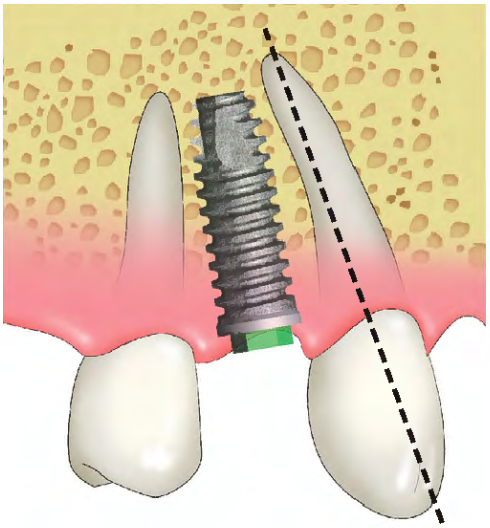

Figure 16-13 The maxillary first premolar implant often is angled distally to remain parallel to the maxillary canine root. A shorter implant or a tapered implant also may be of benefit.

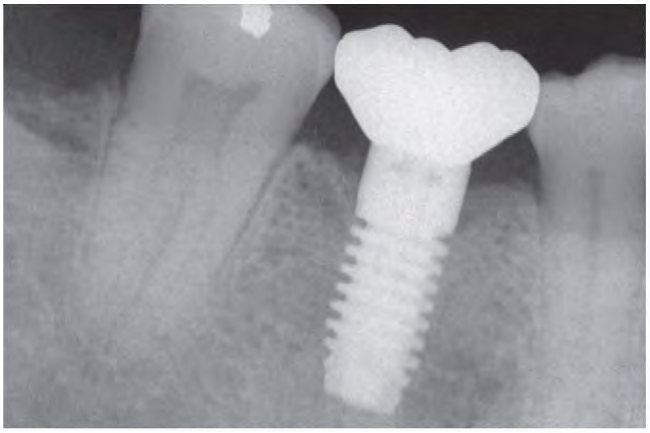

Figure 16-15 A 5-mm-diameter implant used to replace a mandibular first molar reduces the cantilever length on the marginal ridge, reduces stress to the abutment screw, and decreases the risk of crestal bone loss.

FIRST-MOLAR IMPLANT REPLACEMENT

The first molar is one of the teeth most frequently lost in a posterior segment. Its mesiodistal dimension usually ranges from 8 to 12 mm, depending on the original tooth size and the amount of mesial drift of the second molar before implant placement. When one 4-mm-diameter implant is placed to support a crown with a mesiodistal dimension of 12 mm, this may create a 4- to 5-mm cantilever on the marginal ridges of the crown (Figure 16-14). The magnified occlusal forces (especially important in parafunction) may cause bone loss, which may complicate home care, increase abutment screw loosening, and increase abutment or implant failure because of overload.[61,62] Sullivan[62] reported a 14% implant fracture rate for single molars fabricated on standard-diameter Nobel Biocare implants and concluded that this is not a viable treatment. Rangert et al.[63] reported overload-induced bone resorption appeared to precede implant fracture in a significant number of single-molar implant restorations. When possible, a larger-diameter implant should be inserted to enhance the mechanical properties of the implant system through increased surface area, stronger resistance to component fracture, increased abutment stability, and enhanced emergence profile for the crown[64-67] (Figure 16-15).

When the mesiodistal dimension of the missing tooth is 8 to 12 mm, with a buccolingual width greater than 7 mm, a 5- to 6-mm-diameter implant body is suggested (Figure 16-16). Langer et al.[64] also recommended the use of wide-diameter implants in bone of poor quality

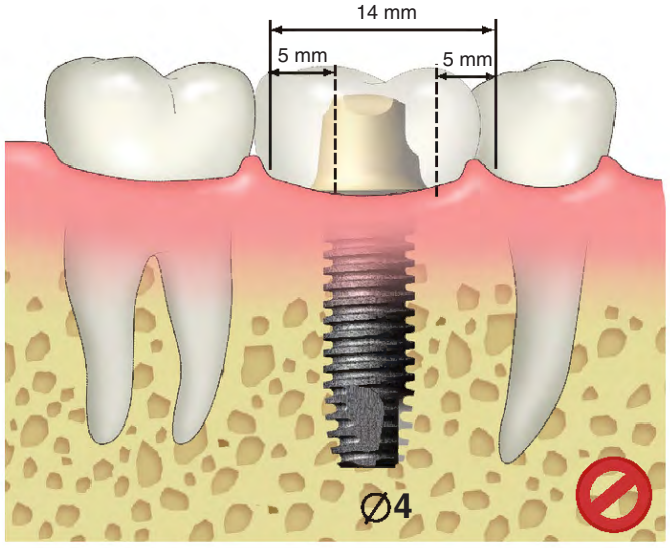

Figure 16-14 When one 4- or 5-mm-diameter implant is placed to replace a molar 14 mm in the mesiodistal dimension, as much as a 5-mm cantilever is created on both proximal aspects.

WWW.HIGHDENT.IR

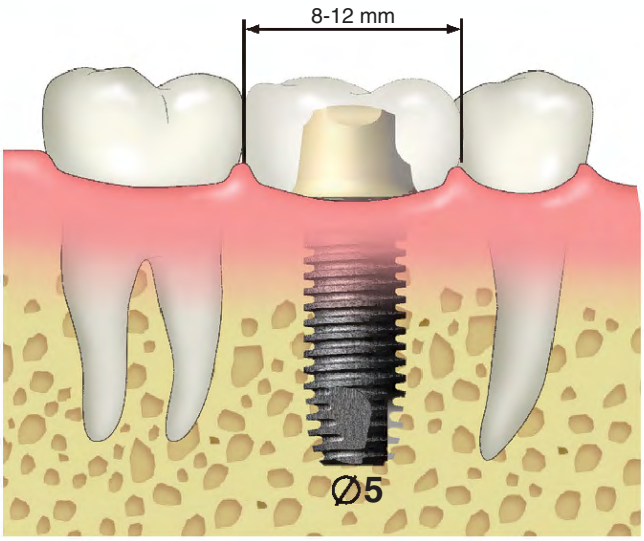

Figure 16-16 When the mesiodistal space is 8 to 12 mm and the buccolingual dimension permits, a larger-diameter implant is better suited to replace the missing tooth. The larger-diameter implant enhances the mechanical properties of the implant system (increased surface area, greater resistance to fracture, less screw loosening) and improves the emergence profile of the final restoration.

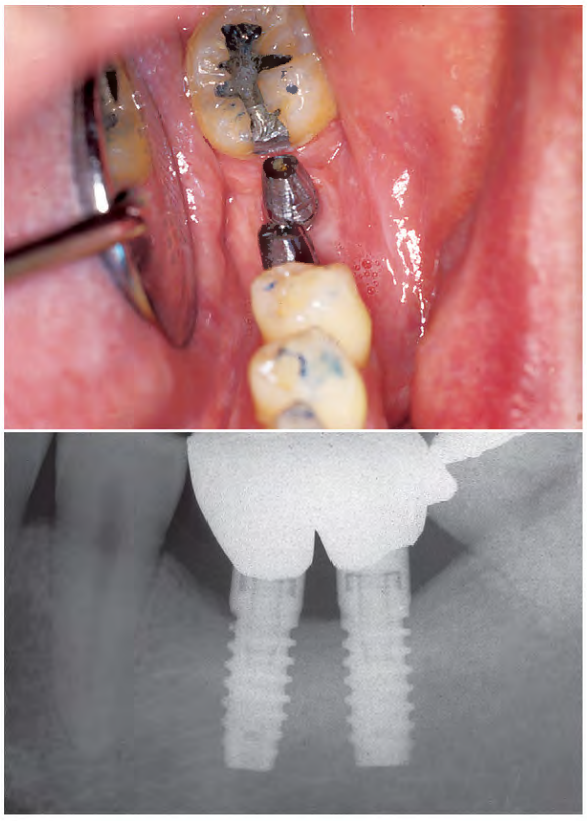

Figure 16-17 **A,** The mesiodistal space in the posterior first molar region is 14 mm. Two 4-mm-diameter implants were selected for the support of the prosthesis. **B,** A periapical radiograph of the two implants splinted together to restore the first molar site after 3 years in function.

or for the immediate replacement of failed implants. The larger-diameter implant does not require as long an implant, which is also a benefit because of the reduced posterior vertical bone height due to anatomical limitations and landmarks present, such as the maxillary sinus or mandibular canal.[51,64,68]

When the mesiodistal dimension is 14 mm or greater, two 4-mm-diameter implants should be considered to restore the region. When two implants replace the molar region, the mesiodistal offset loads to the prosthesis can be eliminated. The total surface area of support is greater for the two implants compared with the surface area provided by one larger-diameter implant. In addition, the two regular-size implants provide more stress reduction than just one larger-diameter implant, which in turn reduces the incidence of abutment screw loosening. In 1996, Bahat et al.[51] reported on the results of various implant numbers and size selection. The overall failure rate was 1.2%, with the two 5-mm implants having 100% success. In the same year, Balshi et al.[52,53] compared the use of one implant and two implants to replace a single molar. The 3-year cumulative success rate was 99%. Prosthesis mobility and screw loosening were the most common complications for the one-implant group (48%); this complication rate was reduced to 8% in the two-implant group. An in vitro study compared screw loosening of one wide-diameter versus two standard-diameter implants. Bakaeen et al.[69] also concluded that the one wide-diameter implant had greater screw loosening. In a finite element analysis of three different implant-supported molar crown design, Geramy and Morgano[70] showed a 50% decrease in mesiodistal and buccolingual stress between a 5-mm- and standard-diameter implants. The double implant design had the least stress of all. Therefore whenever possible, two implants should be used to replace a larger single-molar space to reduce cantilever loads and abutment screw loosening (Figure 16-17).

When the posterior space is 14 mm or greater, the largest implant diameter for the two implants may be calculated by subtracting 6 mm (1.5 mm from each tooth for soft tissue and surgical risk, and 3 mm between the implants) from the intratooth distance and dividing by 2, for a total of 5 mm for each implant (Figure 16-18).

$$\frac{16\,\text{mm} - 6\,\text{mm}}{2} = 5\,\text{mm}$$

The diameter is the crest module dimension, which is often 0.35 mm greater than the implant body dimension (i.e., Nobel Biocare, SteriOss, 3-I, LifeCore). The two implants should be 3 mm apart, because crestal bone loss around each implant may occur. The width of the crestal defect is usually less than 1.5 mm. Therefore the two adjacent implants 3 mm or more apart will not convert the angular defect to a horizontal defect that may increase sulcus depths and cause a loss of papilla

WWW.HIGHDENT.IR

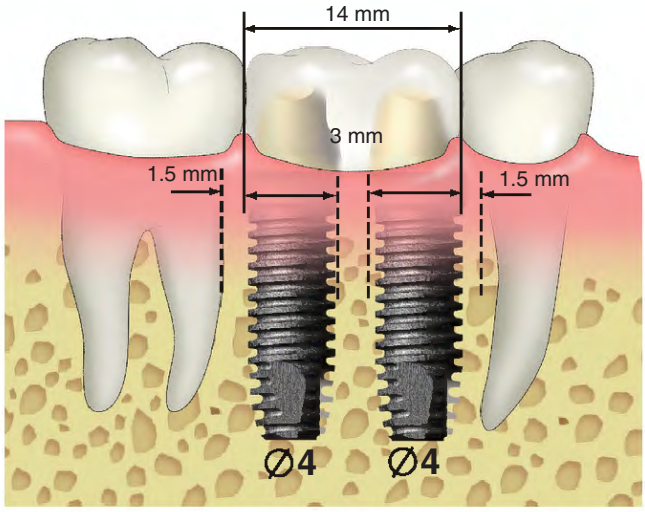

Figure 16-18 When the mesiodistal space between two teeth is 14 mm or greater, two implants should be used to restore the site. The implants are positioned at least 1.5 mm from each tooth and about 3 mm from each other.

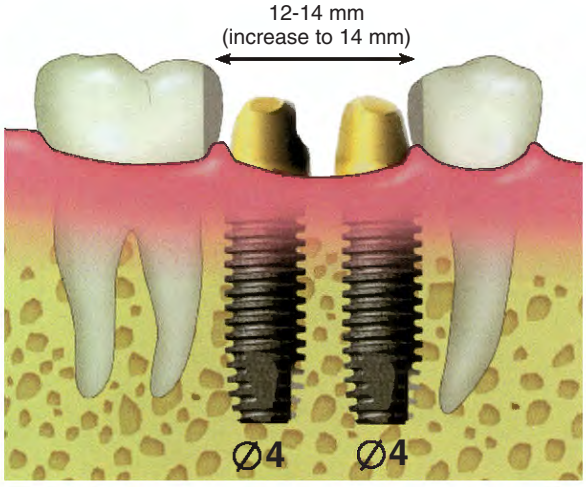

Figure 16-19 An enamoplasty can be used to increase the mesiodistal space slightly, especially on a tipped distal tooth. The minimum of 14 mm of mesiodistal space is measured from one cement-enamel junction (CEJ) to the other, not from one proximal contact to the other. When the interproximal contact is directly above the CEJ, further enamoplasty is not indicated because it will not increase the space required for the implants.

height.[71] When possible, two regular-size or one regular- and one larger-diameter implant are suggested when replacing molars. The natural molars have 200% more root surface area compared with premolars; therefore the implant support in a molar region should be greater than in the premolar position.

When the mesiodistal space is 12 to 14 mm, the treatment plan of choice is less obvious. A 5-mm-diameter implant may result in cantilevers up to 5 mm on each marginal ridge of the crown. However, two implants present a greater surgical, prosthetic, and hygiene risk. The primary goal is to obtain at least 14 mm of space,

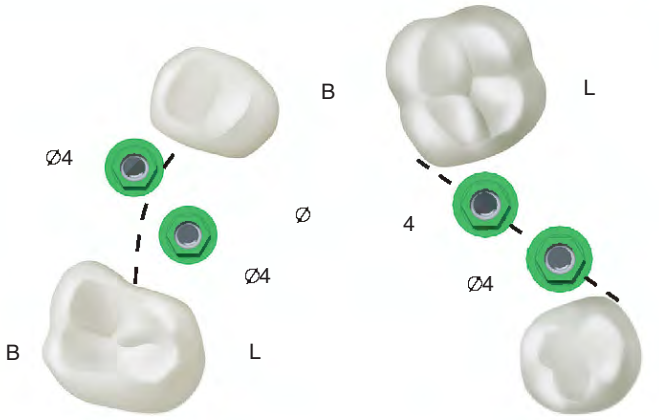

Figure 16-20 When the site is wide enough, up to 1 mm of additional mesiodistal space may be obtained when the implants are placed on a diagonal rather than aligned midcrestal. In the mandible the distal implant is positioned more buccally, and the mesial implant is placed more lingually. A floss threader has better access from the buccal for hygiene between the splinted crowns. In the maxilla the mesial implant is more buccal because it is often within the esthetic high-smile zone. The distal implant is positioned more palatal. Home care is not compromised because a palatal approach to the intraimplant space in the maxilla is more practical.

instead of 12 to 14 mm. Additional space may be gained in several ways:

- Enamoplasty of the adjacent teeth's proximal contours may be performed to increase the mesiodistal dimension of the missing tooth. It is not unusual that the distal natural tooth has tipped toward the edentulous space. An enamoplasty may be even more effective in these cases to increase space (Figure 16-19).
- Orthodontics may be the treatment of choice to upright a tilted second molar or increase the intratooth space. One anterior implant may be placed and an orthodontic spring incorporated in the transitional crown. The spring pushes the distal tooth more distal; after orthodontic movement, the second implant may be inserted with less risk and improved hygiene between each implant. Another option is to orthodontically reduce the space and place only one implant and crown.
- The implants may not be centered in the crestal width of bone. Instead, one implant is placed buccal and the other on a diagonal toward the lingual (Figure 16-20). The diagonal dimension increases the mesiodistal space by 0.5 to 1.0 mm. When implants are placed in such a way, consideration is given to oral hygiene and occlusion. In the mandible, the most anterior implant is placed to the lingual aspect of the midcrest, and the more distal implant is placed to the facial aspect to facilitate access of a floss threader from the vestibule into the intraimplant space. The occlusal contacts are also slightly modified on the buccal aspect of the mesial implant to occlude over the central fossa (Figure 16-21). In the maxilla, the anterior implant is placed to the buccal aspect and

WWW.HIGHDENT.IR

Figure 16-21 The mandibular first molar site is restored with two implants splinted together. The mesial implant is placed more lingual, and the distal implant is placed more buccal.

Table 16-3 Single-Molar Replacement Options

MESIODISTAL DIMENSION (mm)	IMPLANT DIAMETER
7	4 mm
8 to 12	5 mm
12 to 14	Gain additional space, then place 2 × 4 mm
≥14	For 14 mm, 2 × 4 mm For 15 mm, 1 × 5 mm, 1 × 4 mm For 16 mm, 2 × 5 mm

the distal implant to the palatal region, to improve the esthetics of the more visible half of the tooth. The distal occlusal contact is placed over the lingual cusp, and the mesial occlusal contact is located in the central fossa position. The cervical esthetics of the maxillary molar is compromised on the distal half of the tooth to the benefit of greater intratooth distance and easier access for home care. This maxillary implant placement requires the intraimplant furcation to be approached from the palate, rather than the buccal approach as in the mandible (Table 16-3).

ESTHETIC MAXILLARY ANTERIOR TOOTH REPLACEMENT

Contrary to missing posterior teeth, nearly all patients have an emotional response regarding a maxillary anterior missing tooth. No question exists regarding the need to replace the tooth, and financial considerations are less important. When posterior teeth are extracted, little resistance to the preparation of adjacent teeth may be given to the dentist. However, when anterior, normal-looking teeth must be prepared to serve as FPD abutments, the patient is more anxious and often looks for an alternative. In the patient's perspective, anterior FPD restorations are never as esthetic as natural teeth. In part, this is because patients are able to distinguish between good and poor esthetic results. Because patients are only able to notice the restorations that are not natural in appearance, they think anterior FPDs are not esthetic. In younger patients with congenitally missing maxillary lateral incisors or with trauma to the maxillary central incisor (which resulted in its failure, often after endodontic therapy), the parents are eager to provide the best possible replacement option. They often perceive this option to be a single-tooth implant. As a consequence of these psychological factors, a common site for a single-tooth implant in a restorative practice is the maxillary central or lateral incisor.

In 1994 the number of implants used in the United States averaged fewer than two per patient. This was a consequence of most dentists using implant treatments for a single-tooth implant,[72] small-span FPDs with two implants, and two implant overdentures. From 1990 to 1999, a threefold increase occurred in the number of single-tooth implants placed by a practitioner, as well as an increase in the overall implant market.[73] Single-tooth implants are now one of the most common implant procedures performed in the United States. In the nonesthetic posterior region, the single-tooth implant is one of the simplest procedures in implant surgery and prosthetics. However, the maxillary central incisor single-tooth replacement is often the most difficult procedure to perform in all of implant dentistry.

The highly esthetic zone of the premaxilla often requires both hard (bone and teeth) and soft tissue restoration. The soft tissue drape is often the most difficult aspect of treatment. As a consequence, maxillary anterior single-tooth replacement is often a challenge, regardless of the experience and skill of the dentist.

The most common causes of maxillary anterior single-tooth loss are included in Box 16-11. Endodontic failure is less likely in the maxillary anterior region compared with posterior teeth, but the cause of pulp necrosis may more often lead to root resorption, compared with the posterior regions.

ALTERNATE TREATMENT OPTIONS FOR ANTERIOR SINGLE-TOOTH REPLACEMENT

The treatment plan for a single missing tooth in the maxillary anterior region is more complex than in other regions of the mouth. The alternatives to restore a single, maxillary anterior missing tooth are listed in Box 16-12.

Factors that contribute to the selection of a specific treatment option include the expected longevity of the device, the most common complications, and the successful treatment of the complications. An evidence-based evaluation of alternative options for single-tooth replacement is warranted.

Fixed Partial Denture

The three-unit fixed restoration can be fabricated in shorter time, is more predictable in the short term, and often satisfies the criteria of normal contour, comfort, function, esthetics, speech, and health. However, 7- to 9-year survival estimates for a three-unit FPD are often less than 75%, with disparate longevity studies reporting failures ranging from only 3% over 23 years to 20% over 3 years.[6,8,26,11] In a study of 42 reports since 1970, Creugers et al.[23] calculated an estimated survival rate for FPDs under ideal conditions of 74% at 15 years. Scurria et al.[26] performed a meta-analysis of FPDs at 10 and 15 years and found a 30% and 50% failure rate.

The most common complications associated with FPD failure include caries, endodontic complications (including fractures), and uncemented restorations (leading to decay).[5,9,24] When a tooth is prepared for an FPD abutment, a 15% risk of endodontic treatment exists, compared with a 3% to 5% risk for a single crown.[7,27] This may be related to the additional tooth preparation for parallelism of the abutments, the repreparation of teeth after prosthesis failure, or the increased risk of decay on the abutment teeth. The success rate of endodontic treatment at 8 years is 90% in a review of the literature.[74-76] A 10% endodontic failure increases the risk of tooth loss and is the most common cause of single-tooth loss at 8 to 10 years.[6] Endodontically treated teeth are also at increased risk of fracture, which is the second most common cause of single-tooth loss.[6] The increased plaque retention of an FPD pontic increases the risk of caries and periodontial disease that may lead to the loss of an abutment tooth.[5,7,9,24] Fracture of porcelain with an FPD is also a contributing complication at increased risk compared with a single crown (16% versus 2%). In addition, esthetic failures are more frequent in the anterior than in the posterior regions of mouth (see Box 16-8). Goodacre et al.[7] determined the incidence of complications associated with FPDs to be 27%, with an average length of service of about 8 years, compared with a complication incidence of 11% at 6 years for a single crown.

An unfavorable outcome or FPD failure may not only require the replacement of the failed prosthesis but also may include the replacement of an abutment tooth. The abutment tooth of an FPD is extracted 8% to 12% of the time within 10 years and as often as 30% within 14 years. This is particularly disturbing, because the abutment teeth maybe unrestored or have minimum restoration before the FPD almost 80% of the time.[77] In this respect, a single-tooth implant places the adjacent teeth at a lesser long-term risk compared with a fixed prosthesis.

In light of the present technology, the primary reasons for suggesting an FPD are its clinical ease and reduced time and cost. If this concept was expanded, then extractions would replace endodontics and RPDs would replace FPDs. Dentures could even replace orthodontics, because the denture teeth are almost always straight. The primary reason to suggest or perform a treatment is often not related to the cost, time, or difficulty to perform the procedure; instead it lays in the best possible long-term solution for each individual patient. However, considerations exist for the maxillary anterior missing tooth that favor an FPD over other treatment options (see Box 16-7).

Advantages of a Fixed Partial Denture

Patient Compliance and Patient Fear

Patients with desires for an ideal result often must be willing to follow through with many steps of treatment in conjunction with an implant restoration. Orthodontics to improve the adjacent teeth position, bone height, or soft tissue may be necessary. Soft tissue surgeries, bone graft surgery, implant surgery, and several prosthetic steps most likely are required during an extended treatment and healing process. If the patient is unwilling to comply with these many steps emotionally, financially, and physically, then the result is often less than ideal and falls short of what the patient envisioned. An FPD may have less compromise of treatment in conditions of inadequate bone, soft tissue, or space considerations.

The fear of surgery may be a deterrent for treatment. Repeated surgeries for soft tissue, bone grafting, implant insertion, and uncovery may be too much for some patients to handle. As a result, nonsurgical procedures may be warranted. The patient's desires, compliance,

WWW.HIGHDENT.IR

or fears may be a contraindication to the implant procedures just as much as other factors.

Time of Treatment

Limitations of treatment are also related to the time of treatment. The time required for a rigidly fixated implant to heal and be restored is approximately 3 to 6 months, when adequate bone volume is present. If bone grafting and soft tissue rehabilation are required, then the treatment may extend more than 1 year. In contrast, a traditional three-unit fixed prosthesis often may be completed in less than 3 weeks.

In some carefully selected cases, grafting with immediate implant placement may be performed simultaneously and shorten the length of treatment. However, this is limited to extraction sites compatible with the requirements of the technique, such as a nonsalvageable tooth as a result of endodontic failure, fracture, extensive root caries, or some type of root resorption. This technique is not recommended in cases of an active inflammatory process or periodontal disease in which the pathogenic flora would impair the healing of the site.

Consequence of Failure

The consequences of bone graft, implant, or prosthetic short-term failure are greater for a single-tooth implant, compared with a three-unit fixed prosthesis.[78] The implant failure may result in bone loss (especially when it occurs in the anterior regions) and is not only limited to the implant site but also may include the support system of the adjacent teeth. This consequence of failure is, in general, not limited to only the hard tissues, because any vertical bone loss is usually associated with a soft tissue recession with devastating effects on the esthetics of the entire edentulous site and adjacent teeth. As a result, bone grafting may be required not only before implant placement but also after a bone graft or implant failure. Additional soft tissue reconstruction is also often needed in the process.

These additional procedures are most often at the expense of the doctor, because the patient believes the early implant failure, at least in part, is the doctor's responsibility. One single-tooth implant failure can eliminate the profits of more than five successful restorations, depending on the time and techniques required to bone graft and replace the failed implant. These potential complications affect the overall overhead of the implant crown procedure and the cost to the patient for a maxillary anterior single-tooth implant.

The most common contraindication for a traditional fixed prosthesis and indication for a single-tooth implant in the anterior regions of the mouth is the patient's desire. Typically, an anterior tooth is damaged by decay or trauma and is restored with a full crown. The tooth later requires endodontic therapy. Subsequent endodontic failure leads to an apicoectomy. A vertical fracture is discovered, and the tooth is extracted. Because this whole cascade of events started with an anterior single crown, the patient may not accept a three-unit conventional FPD. In addition, patients are more concerned regarding the appearance of anterior teeth and wish to keep adjacent teeth intact. Their point of view is that a single-tooth replacement is superior to and more esthetic than a three-tooth replacement.

Patient desires always affect the treatment options. The expected end results must be clearly explained along with risks and limitations. Care is taken to discuss the soft tissue drape, especially when a high lip line is present during smiling. When the patient's expectations are very high, all conditions before implant restoration must be ideal. Bone volume, location, implant position, angulation, size and depth, as well as soft tissue health, contour, and color all must be ideal to obtain the ideal result. In addition, crown contour, color, and all restorative aspects are to be considered.

Cost to Patient

The laboratory fee to the doctor for three crowns is usually $400 to $500. The implant body, abutment, analog, and final crown fee usually is more expensive. The scheduled operating room time for setup, preparation, impression, temporization, and insertion for a three-unit prosthesis is less than 2 hours. The time allotted for an implant setup, surgery, transitional restoration, uncovery, abutment selection, preparation, impression, transitional Stage II restoration, and crown insertion for an anterior single-tooth implant and crown is often longer. The training to perform a three-unit fixed prosthesis is acquired in dental school; the training for an anterior single-tooth implant is acquired in continuing education programs after graduation or through several trial-and-error experiences. The equipment to prepare and deliver an FPD is present in any general dentist office. The electric motor, hand pieces, and inventory to place a single-tooth implant are additional expenses, which all in turn affect the cost of the procedure. In addition, the financial consequences of a bone graft or implant short-term failure are greater than a traditional restoration. Initially an anterior single-tooth implant and crown most often cost more than a traditional three-unit fixed prosthesis.

Although the initial cost of treatment may be higher for an implant single crown, in a study evaluating the cumulative expense to the patient for replacement of an FPD over a 30-year period, Priest and Priest[79] showed that despite an initial higher cost for the implant option, the implant becomes a better alternative economically after the break-even point at 7 years. From a practice management point of view, Bragger et al.[49] also concluded that implant reconstruction was a better financial option in the long term.

Adjacent Tooth Mobility

When an anterior tooth is lost because of periodontal disease, the longer clinical crown on an implant abutment is not the only concern. Ideally, the adjacent teeth of the anterior implant site should exhibit minimum mobility.

WWW.HIGHDENT.IR

Figure 16-22 An orthodontist moved the lateral incisors together to replace the central incisors. The lateral incisor edentulous sites are too narrow for independent implants and crowns. Two three-unit fixed partial dentures (FPDs) would increase the central incisor crowns and decrease the canine crowns to provide improved size for the lateral incisor pontics.

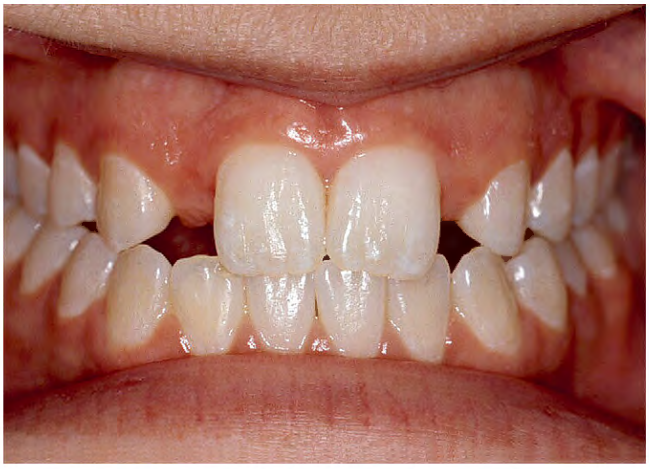

Figure 16-23 Inadequate bone in height, width, or intratooth space is a contraindication to an implant. A cantilevered fixed partial denture (FPD) from the canine position should be considered when the lateral incisor space is less than 5 mm.

However, this may not be the case because of a history of past periodontal disease. As a consequence, the slightly mobile adjacent teeth move out of occlusion during excursions, and the load of several teeth may be exerted solely on the rigid implant crown. When the adjacent teeth are mobile at a class 2 Miller index, the rigid implant most likely will bear the brunt of all occlusal load in centric occlusion and all mandibular excursions to this site. Therefore single-tooth implants surrounded by anterior mobile teeth are not indicated, unless the occlusion on the implant crown can be relieved to distribute occlusal forces to the natural teeth.

In cases of moderate to severe parafunction, movement of the adjacent teeth is a considerable risk. Natural tooth longevity is not related to mobility if all other periodontal indices are normal. Therefore a traditional FPD may be the treatment of choice under conditions of mobile adjacent teeth to the implant site. Splinting additional teeth to decrease the abutment mobility may be in order, especially if the adjacent teeth already require a restoration.

Unfavorable Tooth Size and Position

On occasion, the maxillary anterior central incisors may be misplaced, angled, rotated, or smaller than ideal (Figure 16-22). An FPD replacing a lateral incisor may improve the position and size of the central incisor. The canine may be made slightly narrower to make the lateral incisor similar in size to the contralateral incisor, because only the mesial half of a canine is visible when the rest of the anterior dentition is in view. Under these conditions, a conventional three-unit fixed prosthesis to replace the anterior missing tooth has several cosmetic advantages. This is especially noted when the lateral edentulous sites are smaller than 5 mm in width.

Contraindications for a Fixed Partial Denture

Contraindications for an FPD include poor abutment teeth support, inadequate bone and soft tissue in the edentulous site for proper pontic contour, anterior diastemae that the patient desires to maintain, adjacent teeth the patient will not allow to be prepared, or a young patient with large pulp horns in the clinical crowns (see Box 16-9).

Cantilevered Fixed Partial Denture

A cantilevered FPD has a worse prognosis than a traditional FPD.[8] The genesis of failure is usually an uncemented restoration, because it transfers tensile and shear forces to cements, and cements are more than 10 to 20 times weaker with this load type. However, a cantilever may be indicated in the anterior region (where forces are less) when the cantilever is short, when limited occlusion on the pontic exists, and when limited mesiodistal space exists.

When a missing lateral incisor space is less than 5 mm, consideration is given to a cantilevered restoration, most often using only the canine for abutment support because of its larger surface area and unique root shape (Figure 16-23). If needed, the canine crown may also be restored to a narrower mesiodistal dimension—to distribute more size to the lateral incisor pontic in order to make the anterior restoration more harmonious to the contralateral side.[4] As such, the cantilever FPD may eliminate the risks of implant placement in minimum intratooth space and eliminate the need for orthodontic treatment to gain additional space.

Removable Partial Denture

A transitional option to replace the single maxillary anterior tooth is an RPD. A common axiom in restorative dentistry is to use a fixed prosthesis whenever possible.[8] No short- or long-term clinical studies exist in the literature for single anterior tooth replacement with an RPD. The term *flipper* is often associated with this

WWW.HIGHDENT.IR

Figure 16-24 **A,** A resin-bonded restoration replacing a lateral incisor. **B,** The lingual support structure is bonded to the adjacent teeth, without preparation of the enamel. Therefore the restoration is retained below the occlusal contacts.

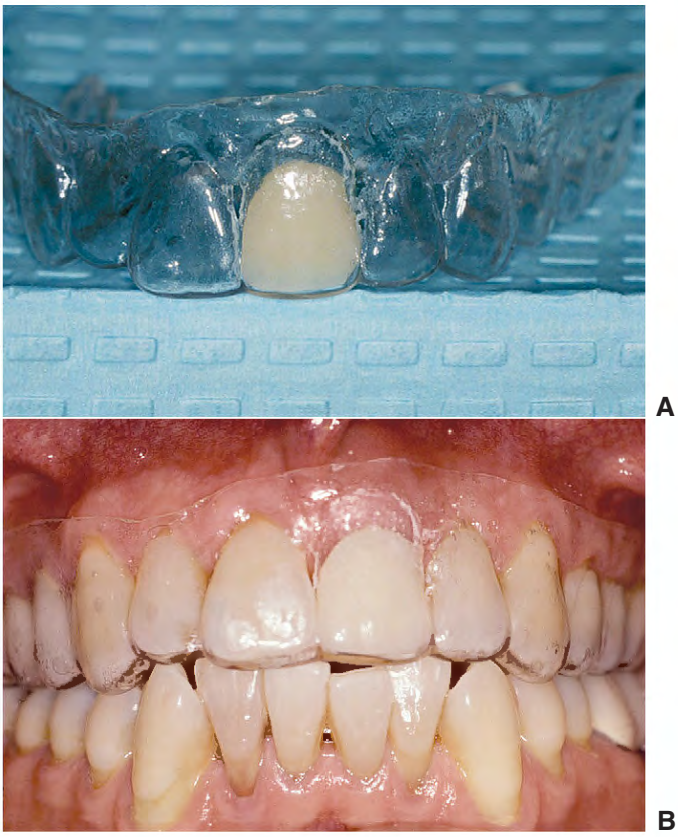

Figure 16-25 **A,** An Essix transitional restoration often is fabricated as the initial temporary device. If the patient is unhappy with the appearance, then a resin-bonded restoration is fabricated. **B,** The Essix appliance in place. If the resin-bonded restoration becomes unretained because of the reduced surface area design, then the Essix transitional restoration may be used until the patient returns to the office.

device and conveys the instability of the restoration during both speech and function. The usual indication for the removable option is economics. Rarely does a patient desire or accept a removable partial prosthesis as a definitive substitute for a single maxillary anterior tooth. However, this device represents the easiest interim treatment modality during submerged implant healing.

Loading of a bone graft with an RPD during initial healing will increase the risk of micromovement and decrease the success rate of a bone augmentation. Therefore if a bone augmentation is indicated and an RPD is used, it should have a cast framework with occlusal rests to prevent rotation and loading of the soft tissue during function.

Resin-Bonded Restoration

A resin-bonded restoration has a higher survival rate in the maxillary anterior region than any other location in the mouth. Despite this, a 30% uncementation rate is often reported.[15,18] Because the debonding is related to function, and eating is often a social event, the risk of embarrassment is high. Ideally, dental "emergencies" should be restricted to pain, rather than recementing a definitive restoration.

The primary indication for a resin-bonded prosthesis is as a transitional restoration during bone grafting and soft tissue grafts before implant placement. Soft tissue–borne interim prostheses impair bone graft healing. As such, a resin-bonded transitional restoration with two modifications may be used. First, no enamel preparation exists on the abutment teeth for occlusal clearance, and the metal substructure design is extended in areas of enamel that are gingival to the occlusal contact zones (Figure 16-24). As a result, the abutment teeth do not require restoration after treatment. However, this approach decreases retention of the device. The second modification of treatment is a modified Essix appliance (acrylic removable overlay prosthesis), or an acrylic RPD (flipper) is fabricated (Figure 16-25). The patient carries the RPD in case the resin-bonded restoration fails; as a result, cosmetic emergency appointments are eliminated. The secondary RPD is only intended to reduce cosmetic inconveniences to the patient. The bonded restoration may then be reinserted during regular scheduled office hours.

WWW.HIGHDENT.IR

Box 16-13 Contraindications for Resin-Retained Fixed Partial Dentures

1. Thin enamel on abutment teeth
2. Mobile abutment or abutments
3. Vertical overlap
4. Bruxism
5. Anterior diastemata
6. Short clinical crown
7. Poor occlusal relationship

Several limitations exist for a resin-bonded restoration. Thin enamel of adjacent teeth may result in a darkening or graying of teeth once the prosthesis is in place. Mobile teeth (even slight mobility differences in the abutments) often cause the debond rate to increase. A deep vertical overbite places considerable force on the prosthesis, especially in the presence of parafunction. Bruxism, in general, places this restoration at greater risk than a traditional prosthesis. The resin-bonded bridge may also be contraindicated in the case of wide interproximal spaces, short clinical crowns, and unfavorable occlusal relationships (Box 16-13).

Single-Tooth Implant

Maxillary single-tooth replacement is one of the most challenging restorations in dentistry. However, in light of all the advantages of single-implant longevity, bone maintenance, reduced abutment teeth complications, and increased survival of abutment teeth, single-tooth implants have become the treatment of choice.

Literature Review

Before 1990 few long-term studies of anterior single-tooth implant replacement with osteointegrated implants were conducted.[32] In 1996, Malevez et al.[61] presented a retrospective study of 75 patients treated with 84 screw-shaped implants (71% of the implants were in the anterior region), with a cumulative failure rate of 2.4% at 5 years. In 1997, Gomez-Roman et al.[54] published a 5-year report on 696 implants in 376 patients. Of the 696 implants, 42% were maxillary single-tooth implants, with a 96% overall success rate.

In 2005, Misch et al.[80] reported on 276 anterior maxillary single implants to restore missing teeth from agenesia. In 255 adolescent patients, the implants were monitored for a range of 2 to 16 years, with a 98.6% implant and prosthesis survival rate. In the same year, Wennstrom et al.[81] reported on a 5-year prospective study with 45 single-tooth implants, with a 97.7% implant survival rate with minimal bone loss. In 2006, Zarone et al.[82] reported on lateral maxillary agenesis replacement with 34 implants, with a 97% survival rate at 39 months.

More clinical studies have been conducted for a maxillary anterior single-tooth replacement with an implant than any other treatment option. Retrospective reports are available as with other modalities; however, of more importance is the fact that many prospective clinical studies confirm the data of previous reports.

The maxillary anterior single-tooth implant has the highest success rate compared with any other treatment option to replace missing teeth with an implant restoration (i.e., overdentures, short-span FPD, full-arch FPD, or single-tooth implant).[48,79-84] In a systematic review of single-implant restorations in all regions of the mouth, Creugers et al.[83] reported a cumulative rate of 97% success at 4 years, with 83% reporting uncomplicated maintenance. Lindhe et al.[84] published a meta-analysis of implants with nine studies on single implants, with a total of 570 single crowns with a follow-up range of 1 to 8 years and a 97.5% survival rate. A review of the literature by Goodacre et al.[48] found single-tooth implant studies had the highest survival rate of any prosthesis type and averaged 97%.

More recently, a trend toward single-stage and immediate-extraction implants has emerged. This appears especially attractive in the maxillary anterior region, where the soft tissue drape is ideal before the extraction and patients are more anxious to have a fixed replacement. In a prospective study of 102 single-tooth implants in the anterior maxilla, Kemppainen et al.[85] reported a 99% success rate using one-stage and two-stage implants. Other studies have recommended one stage and immediate load with some success in specific situations.[86-88]

As important as implant versus prosthesis survival rates is the fact that the adjacent teeth prognosis is improved with single-tooth implants compared with any other option. In a 10-year report, Priest[6] indicated adjacent teeth next to implants have less decay, endodontic risk, less sensitivity, less plaque retention, and less evidence of adjacent tooth loss over 10 years. Studies by Krenmair et al.[89] and Misch et al.[80] also resulted in a similar conclusion. As such, the maxillary anterior single-tooth implant has become the treatment of choice when bone and space parameters are sufficient or may be created.

Limiting Factors Influencing Treatment

One of the most common procedures performed in implant dentistry is a single-tooth replacement. Although implant success rates are high in the maxillary regions, high patient expectations, high esthetic requirements, and sensitive soft and hard tissue management compound the complexity of the anterior teeth restoration. A single maxillary central crown on a natural tooth is often a very difficult challenge for the restoring dentist. This

WWW.HIGHDENT.IR

Box 16-14 Maxillary Anterior Single-Tooth Replacement Influencing Factors of Treatment

1. Patient compliance and patient fear
2. Patient desires
3. Treatment time
4. Consequence of failure—potential damage to adjacent teeth
5. Cost
6. Patient's age
7. Esthetics
8. Adjacent tooth mobility
9. Crown height and occlusal relationship
10. Mesiodistal space at crown and bone level
11. Available bone height
12. Available bone width (buccolingual)
13. Soft tissue drape type—surrounding gingival tissues
14. Transitional prosthesis

challenge is significantly compounded when an implant serves as the prosthetic support. As a consequence, implants to replace a maxillary anterior single tooth remain one of the more difficult treatments to perform in implant dentistry.[90,91]

The limiting factors that may influence the treatment plan for maxillary anterior single-tooth replacement should be included in the presurgery preprosthetic evaluation. They are either related to the patient in general or are specific soft and hard tissue considerations for the area of treatment. The first five considerations (addressed earlier in the chapter) and other concerns are listed in Box 16-14.

Age Limitations

The minimum age of the implant patient is more often a concern for maxillary anterior tooth replacement, especially for congenitally missing teeth. Fixed partial dentures to replace teeth in children increase the risk of pulp necrosis of the adjacent teeth, because of the size of the pulp horns. Resin-bonded prostheses often become unretained in the younger patient. If bone is available, then the dentist wants to place the implant before bone loss in the near future. However, growth and development in the region may be affected by the implant, because it may act as an ankylosed tooth.

Researchers have documented that implants do not erupt along with adjacent teeth or become secondarily displaced in space as do ankylosed teeth during growth of the jaws.[92,93] As a result, many implants placed in adolescents with residual growth may be in infraposition after 10 years.[94,95] A new crown may correct the esthetic problem, but the bone position creates a greater soft tissue pocket around the implant, which may lead to shrinkage, peri-implant conditions, or both (Figure 16-26). In an 8-year study of single maxillary incisor implants in adolescents, Thilander et al.[96] concluded that a fixed chronological age is not an adequate guideline because of a slight continuous eruption of the adjacent teeth after adolescence. Instead, proper orthodontic treatment must be performed before implant placement to achieve proper space, avoid tooth intrusion movement, establish good incisor stability, and ensure proper stabilization (using a retainer) to avoid relapse.

The growth of the maxilla occurs in three distinct planes: (1) transverse (width), (2) sagittal (length), and (3) vertical. The transverse growth of the anterior maxilla is completed before adolescence, and the intercanine distance changes very little after age 10. The sagittal growth is the result of growth at the suture and bone apposition in the maxillary tuberosity region. The most variable growth of concern is the sagittal growth, because the premaxilla may advance downward and forward or primarily downward. As much as 25% of this displacement is lost as the result of resorption at the anterior region that can lead to facial bone resorption of the maxillary implants placed before completion of growth. This growth is a result of passive displacement, which comprises one third of the growth at age 7, whereas the additional two thirds of growth occurs later because of enlargement. However, this enlargement has been shown to be extremely variable among individuals.[97] This is the region where the growth should be completed before implant placement. Multiple implants should not be splinted across the midline in the adolescent when cessation of growth and development is undetermined.

Additionally during this growth, teeth shift mesially. The posterior segment (canine to molar) moves an average of 5 mm mesially between the ages of 10 and 21, and the anterior segment moves an average of 2.5 mm. Therefore an implant placed too early in the growth period could impede the mesial shift, thus resulting in an asymmetrical arch.

Figure 16-26 An implant and crown in a developing child will become "submerged," similar to an ankylosed deciduous tooth. The implant captures the bone in time and space. The soft tissue may recede and create a peri-implant pocket next to the implant.

WWW.HIGHDENT.IR

The vertical growth of the maxilla occurs via displacement and drift by growth of the orbits, nasal cavity, maxillary sinuses, and by deposition of bone on the palatal and alveolar surfaces. The vertical growth continues well after transverse and sagittal growth. The maxillary incisors have been shown to move approximately 6 mm downward and 2.5 mm facial between the ages of 9 and 25.[98] The eruption velocity is approximately 1.5 mm per year during active growth and 0.1 to 0.2 mm per year up to the age of 18. Clinical reports have shown that implants in the anterior maxilla at the age of 7 may be located up to 10 mm apically compared with the neighboring teeth 9 years later, and solitary implants placed at the age of 12 will be in infraocclusion 5 to 7 mm 4 years later.[99]

As a general rule, the lateral incisor may be inserted at a younger age than a central incisor or canine. It is less obvious to the eye when lateral incisors are at different height positions, compared with central incisors. It is not unusual for a lateral incisor to be shorter than the adjacent teeth, whereas a shorter central incisor becomes a more obvious esthetic problem when growth and development brings the adjacent natural tooth more incisal.

Over the last decade, Misch et al.[80] have created four guidelines for implants placed in younger patients. The first guideline is the chronological age of the patient. The chronological age of growth cessation for girls ranges from 9 to 15 years and 11 to 17 years for boys. It is logical to wait until skeletal and dental growth have been completed. As a general rule, implant insertion in the anterior maxilla is delayed for female patients until at least 15 years and male patients until 18 years of age. However, this guideline is too variable to be used alone; ideally, age is related to the patient's biological age more than his or her chronological age.[97]

Other biological factors indicative of completed growth should be assessed before implant insertion. The second criterion for implant insertion relative to children is endocrine changes. The female patient should be able to menstruate, and the male patient should have body hair, voice changes, and most often need to shave (if his father shaves daily).

The size of the child is also very relevant for implant insertion and is the third criterion. The prospective implant patient should have greater height than their same-sex parent. The size of the patient is more important than the age of the patient.

The fourth criterion for implant insertion is that the patient has not grown in the last 6-month period. Thilander et al.[96] has noted that if no statural growth has occurred in the last 6 months, then growth and development of the jaws is near completion. This criterion is easier to observe than cephalograms or hand-wrist films with a 2-year evaluation period. Some authors have suggested lateral cephalograms of 2 consecutive years of no changes. Although it is difficult to superimpose radiographs taken over several years, this criteria is the best indication that the pubertal growth spurt is finished and the majority of facial growth is finished.

The two criteria that make the implant site most at risk are (1) a male patient and (2) a central incisor. When a male patient has a delayed growth spurt, a 4-inch change in height may be observed, whereas a female patient may grow 1 to 2 inches. The central incisor position will be most noticeable, even if slight changes occur, whereas it is common for one lateral incisor to be shorter than the contralateral side.

If all four criteria are fulfilled (i.e., minimum age, endocrine changes, recent stature growth, 2-year lateral cephalometric radiographs with no changes) it is very likely the patient has completed their maxillary anterior jaw growth, and the implant may be inserted with little risk or compromise.

Challenging Esthetics

The esthetics of a maxillary anterior single crown on a natural tooth is often one of the most difficult challenges in restorative dentistry. The challenge to fabricate a natural-looking crown on an implant abutment is even greater. The implant is often 5 mm or less in diameter and round in cross section. A natural maxillary anterior crown cervix region is 4.5 to 7.0 mm in mesiodistal cross section and is never completely round.[99] In fact, the natural central incisor and canine teeth are often larger in their faciopalatal dimension at the CEJ than the mesiodistal dimension[100] (Table 16-4; Figure 16-27). Implants replicating the exact radicular cross section of a tooth would not be practical because it would be much more difficult to surgically prepare the bone and insert the implants. In addition, because the bone is lost first in faciopalatal width, the greater width of implants in this dimension would require even greater augmentation than presently advocated. As a result, the cervical esthetics of a single-implant crown must accommodate a round-diameter implant and balance

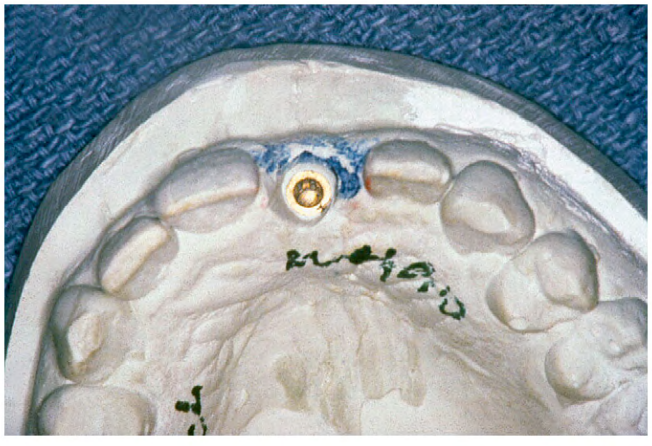

Figure 16-27 Cross sections of teeth are not round and are often larger in the faciopalatal dimension. The cervical emergence profile of a crown on a round implant platform needs to be created prosthetically.

WWW.HIGHDENT.IR

Table 16-4 Maxillary Anterior Teeth Dimension

TYPE AND NUMBER OF TEETH	MESIODISTAL CROWN (mm)	MESIODISTAL CERVIX (mm)	MESIODISTAL CEMENT-ENAMEL JUNCTION (–2 mm)	FACIOLINGUAL CROWN (mm)	FACIOLINGUAL CERVIX (mm)
Central incisor	8.6	6.4	5.5	7.1	6.4
Lateral incisor	6.6	4.7	4.3	6.2	5.8
Cuspid	7.6	5.6	4.6	8.1	7.6

hygiene and esthetic parameters. Additional prosthetic steps and components with varied emergence profiles or customized tooth-colored abutments are often required to render the illusion of a crown on a natural abutment.

The laboratory technician for a maxillary anterior implant crown should have specific training. Often a soft tissue model is required to transfer the soft tissue clinical condition to the laboratory. The soft tissue emergence from the bone and through the soft tissue drape is customized for each case. Rarely are these unique techniques required for implant restorations needed for a crown on a natural tooth. As a consequence, the learning curve for the restoring dentist and laboratory technician is more extended on implant crowns in the esthetic zone, and an increased risk of esthetic failures and redoing the restoration exists.

Crown Height Space

The interocclusal space should be assessed carefully. Patients with Angle's Class II Division II skeletal patterns, an inadequate maxillomandibular relationship, or a severe deficiency in the vertical dimension are poor candidates for many treatment options; therefore they are contraindicated for dental implants without prior corrections. In fact, limited vertical space complicates all options to replace a maxillary anterior tooth. Removable partial dentures often fracture because the occlusal aspects in a deep overbite do not permit proper thickness of the acrylic base. The FPD abutment tooth preparation is often inadequate to allow clearance for proper casting thickness. An implant abutment is usually too short for proper retention of the crown. This may mean orthognathic surgery, orthodontic therapy, or both is required before any tooth replacement.

Mesiodistal Space

An adequate mesiodistal space is necessary for an esthetic outcome of an implant restoration and the interproximal soft tissue of the adjacent teeth (Figure 16-28). A traditional two-piece implant should be at least 1.5 mm from an adjacent tooth. When the implant is closer than this to an adjacent tooth, any bone loss related to the microgap, the biological width, or stress will cause the implant and adjacent tooth to lose bone. This may compromise interproximal esthetics and sulcular health of the implant and natural tooth.[101,102] The smallest-diameter implant body offered by most commercial companies is 3.2 mm. However, the crest module of these two-piece implants is usually 3.5 mm or more. Therefore the mesiodistal edentulous space for a two-piece implant should be 6.5 mm or greater. The average maxillary lateral incisor is 6.6 mm in width, but patients with congenitally missing teeth often have contralateral anterior teeth narrower than typical. Therefore under these conditions, even orthodontic therapy to increase the intratooth space is inadequate for a single-tooth replacement. In addition, when the lateral incisor is missing, the root of the adjacent teeth may be angled toward the edentulous site, further decreasing the intratooth bone dimension for implant placement. Orthodontic treatment to reposition the roots out of the edentulous root space may not be accepted by the patient and therefore contraindicate the implant surgery. As a consequence, under these conditions a cantilevered FPD may be the treatment of choice.

One-piece dental implants may be fabricated in 2.5-mm to 3.0-mm diameters to accommodate a reduced mesiodistal dimension criterion.[103-105] These implant

Figure 16-28 Adequate mesiodistal space is required for an acceptable esthetic restoration. This implant is unable to be restored with an esthetic result.

WWW.HIGHDENT.IR

Figure 16-29 The bone in the implant site should be ideal, because it influences the soft tissue drape, implant size, implant position, and esthetic results. This central incisor site required significant augmentation of hard and soft tissue before implant placement.

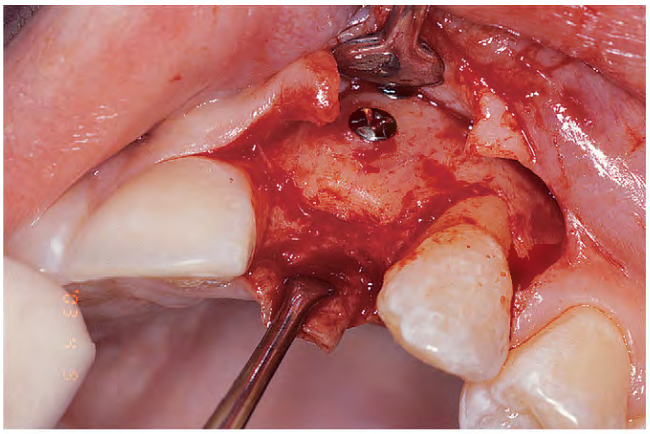

Figure 16-30 After bone augmentation the midosseous crest is too high, and osteoplasty before implant insertion is indicated.

designs do not have a microgap, and the vertical defect is narrower than most two-piece implant systems. As such, they may be placed as close as 1 mm from an adjacent tooth and therefore can accommodate a 5-mm mesiodistal missing tooth space (see Chapter 35).

Bone Height

The available bone for implant insertion in esthetic regions should be closely evaluated because it will greatly influence the soft tissue drape, implant size, implant position (angulation and depth), and ultimately the final esthetic outcome. An ideal hard tissue topography is a prerequisite to an optimal, esthetic implant restoration (Figure 16-29). Not only is available bone volume necessary but also the position of the osseous crest is specific. The ideal midcrestal position of the edentulous site should be 2 mm below the facial CEJ of the adjacent teeth. On occasion, the bone crest may be above this position when a bone graft was performed (Figure 16-30). Ideally, the interproximal bone should be scalloped 3 mm more incisal than the midcrestal position.

The position of the interproximal crest of bone is an important anatomical consideration, especially for the development of the interproximal soft tissue height. Becker et al. found the range of interproximal bone height above the midfacial scallop was from less than 2.1 mm to more than 4.1 mm and classified the interproximal bone height as flat for 2.1 mm, scalloped for 2.8 mm, and pronounced scalloped for 4.1 mm above the midcrestal bone level.[105a] The flat anatomy ideally corresponds to a square tooth shape, the scalloped to a ovoid tooth shape, and the pronounced scalloped to a triangular-shaped tooth. However, these relationships do not always exist. When a flat interdental-to-crest dimension is found on triangular teeth, the interproximal space will usually not be filled with soft tissue, because the dimension of the interproximal contact to the bone will be greater than 5 mm.

Often the osseous crest may be more apical than ideal, in both the implant site and the adjacent tooth roots. Under these conditions, ideal crown contour, soft tissue emergence, and interproximal tissue conditions are less likely. Bone and soft tissue changes after maxillary anterior tooth loss are rather rapid and of considerable consequence. As a result, many maxillary anterior edentulous sites require at least some bone and/or soft tissue modification before, in conjunction with, or at implant uncovery. Under ideal conditions, the implant body should not be inserted until the bone and soft tissue are within normal limits.

A careful evaluation of the three-dimensional soft and hard tissue complex in the edentulous space and the adjacent teeth is necessary before committing to a specific treatment modality. The crestal height of bone is one of the more important considerations for an implant in the esthetic zone. Overall bone height in an apical direction is not a problem in the anterior regions, it is often deficient at the crest of the ridge and greatly affects the position of the implant in relation to the adjacent teeth and the related soft tissue configuration. Bone grafting for height adjacent to a tooth is more difficult and less predictable than grafting for width or in extraction sockets. It is a clinical challenge when a single-tooth site has inadequate bone height at the crest and the adjacent roots also have lost bone, because it is not predictable to grow bone on a natural tooth root. Therefore growing bone height both in the edentulous site and growing bone on the roots of the adjacent teeth is not predictable.

To grow crestal bone height on the adjacent roots, in relation to the ideal crest of the ridge, orthodontic extrusion of the teeth may be considered. However, in cases of significant crestal bone height loss, endodontic therapy and a crown on the affected tooth is often indicated after treatment. After the bone on the adjacent teeth is at an ideal height, the edentulous site may be augmented with increased success.

WWW.HIGHDENT.IR

Figure 16-31 The cause of maxillary anterior tooth loss most often is associated with facial bone loss.

Box 16-15 Local Contraindications for the Anterior Single-Tooth Implant

1. Inadequate bone volume
   a. Faciopalatal (<5.5 mm)
   b. Mesiodistal (<6 mm for a 3.2-mm implant to allow 1.5 to 2 mm from adjacent roots; varies in function of tooth replaced)
   c. Height (<9 mm)
2. Inadequate crown height
3. Mobility of two to four adjacent teeth >+1

Faciopalatal Width

Most of the conditions that lead to single-tooth loss result in the loss of some or all of the facial bone in the region of the missing tooth (Figure 16-31). In addition, a 25% decrease in faciopalatal width occurs within the first year of tooth loss and rapidly evolves into a 30% to 40% decrease within 3 years. As a result, even an intact alveolus 6 to 8 mm wide is often adequate in width after 1 year for a root form implant in a central incisor position. After 3 years it almost never presents adequate available bone for the properly sized implant. The bone width loss is primarily from the facial region, because the labial plate is very thin compared with the palatal plate, and facial undercuts are often found over the roots of the teeth (Figure 16-32). A bone graft is necessary to restore the proper anatomy of the ridge and avoid a compromised implant position more palatal and apical. The final crown under these compromised conditions appears longer than the adjacent teeth, and the prosthetic "solution" often compromises long-term daily maintenance of the facial sulcular region. Therefore the majority of edentulous maxillary central incisor single-tooth sites require bone grafting for ideal cervical esthetics and hygiene.[106-107]

The amount of available bone width (faciopalatal) should be at least 2.0 mm greater than the implant diameter at implant insertion and ideally more than 3 mm greater in width; a 3.5-mm implant requires at least 5.5 mm of bone width (Box 16-15). Bone augmentation in width is very predictable. In many instances it is performed before implant placement but may be performed at the time of implant insertion, especially when no dehiscence of implant is visible. The implant diameter measurement is made at the crest module of the implant; 3.75-mm diameter implant bodies are 4.1 mm at the crest module. Therefore in these situations, the mesiodistal limitation is 7.1 mm, and the faciolingual width limitation is 6.1 mm.

Soft Tissue Drape

The position and architecture of the interdental papillae are noted before developing the implant treatment plan. The soft tissue in the region of the edentulous site should ideally have the same color and form as the adjacent teeth. When a tooth is lost, the thin interseptal bone disappears and the bone remodels in a sloping fashion from the palatal to the more apical facial bony plate. As a result, the interdental papillae are often depressed compared with their level between healthy adjacent teeth (Figure 16-33). The papilla height is also affected as a result of the lack of interproximal contact with the missing tooth. The use of a soft tissue removable prosthesis often accelerates the collapse of the soft tissue and its apical migration. Therefore once the tooth is extracted, interdental papillae are rarely at the desired height and are most often apically depressed. Soft tissue manipulation to restore their proper contour

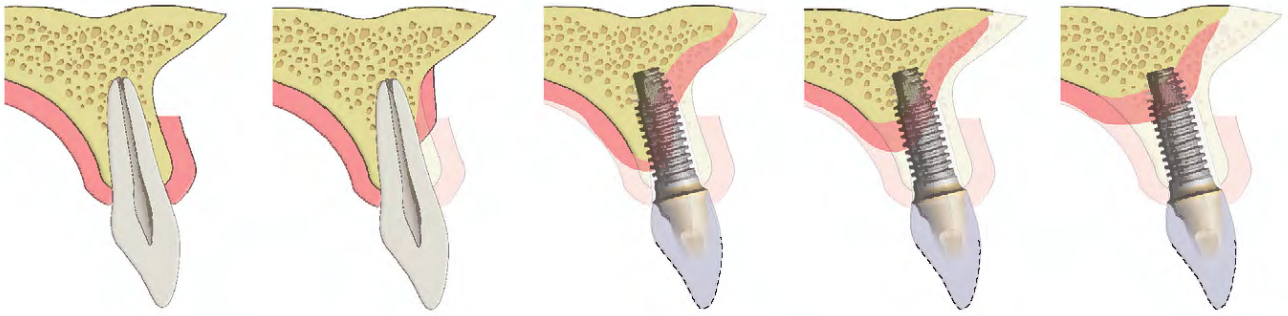

Figure 16-32 The initial bone loss on an anterior tooth before failure frequently occurs on the facial bone. Once the tooth is extracted, the bone volume is decreased in width and then height (division A, B, C–w, C–h).

is often required in conjunction with implant therapy. Several authors have proposed additional parameters for predictable papillae that may guide the practitioner in the choice of the most appropriate modality.[108-111]

Transitional Prosthesis

The transitional restoration for a three-unit bridge is an acrylic fixed prosthesis that is fabricated the day the procedure is started. The transitional restoration for a single-tooth implant is often a removable prosthesis, which lacks stability and retention (hence the name *flipper*). Instead, it is strongly suggested that a resin-bonded fixed restoration be fabricated to provide improved function, especially when crestal bone regeneration is performed. The soft tissue–borne transitional restoration enhances crestal bone loss during the graft healing, may cause bone loss around the implant during Stage I healing (or even implant failure from the early loading), and may depress the interdental papillae of the adjacent teeth (Figure 16-34). As a result, a resin-bonded fixed prosthesis is fabricated for the extended healing, and a removable devise may be used short term for cosmetic emergencies should the device become debonded. When a resin-bonded restoration is used, the adjacent teeth are not prepared and the device is bonded to the tooth regions below the centric occlusal contacts of the teeth.

The transitional restoration for the single-tooth implant has the benefits of being off the soft tissue drape, the developing bone augmented site, and the healing implant-bone interface. Several options to the resin-bonded device permit these goals. An Essix appliance is an acrylic shell, similar to a bleaching tray, that has a denture tooth attached to replace the missing tooth.[112] This device is the easiest for tooth replacement postsurgical procedures. When an adjacent tooth requires a crown in the overall treatment plan, the adjacent tooth may be prepared and a cantilevered transitional FPD with a pontic over the surgical site may be used. When the patient requires orthodontics, a denture tooth and an attached bracket may be added to the orthodontic wire. A cast-clasp RPD with indirect rest seats to prevent rotation movements on the surgical site is also an excellent option.

SPECIFIC SINGLE-TOOTH IMPLANT INDICATIONS

Anodontia

The most common maxillary anterior tooth replaced by an implant is a central incisor lost from trauma (e.g., endodontic failure, fracture, root resorption) and/or a lateral incisor lost as a result of agenesis.[113-116] The absence of one or more teeth is known as *anodontia* and may be complete (very rare) or partial (also called *hypodontia*). It is many times more common than supernumerary teeth.[117] The primary cause of partial anodontia is familial heredity, and incidence ranges from 1.5% to as high as 10% in the U.S. population.[113] In addition, a number of syndromes exist in the literature that include multiple missing teeth, of which ectodermal dysplasia is the most common.

A high correlation is found between primary tooth absence and a permanent missing tooth; however, a missing tooth occurs more frequently in the permanent dentition. Caprioglio et al.[116] evaluated the records of almost 10,000 patients between the ages of 5 to 15 years of age. Of all the missing single teeth, the mandibular second premolar was most often missing (38.6%), followed by the maxillary lateral incisor (29.3%), the maxillary second premolar (16.5%), and the mandibular central incisor (4.0%). The remaining teeth were absent at a rate of only 0.5% to 1.8%, with the maxillary first molar being the least affected. The missing mandibular second premolar primarily occurred in male patients, whereas the maxillary lateral incisor primarily occurred in female patients (Figure 16-35). The most common multiple teeth lost (other than third molars) are the

WWW.HIGHDENT.IR

Figure 16-35 **A,** A periapical radiograph of a deciduous second molar and no permanent second premolar in a male patient. **B,** A periapical radiograph of a missing lateral incisor in a female patient.

maxillary lateral incisors, followed by the mandibular second premolars and maxillary second premolars. Congenitally missing teeth are therefore a common scenario in a general practice. Fortunately less than1% of those missing teeth are missing more than two teeth, and less than 0.5% of this group are missing more than five permanent teeth.

An emotional aspect exists to the replacement of a congenitally missing tooth. Because the cause is genetic, the parent with the genetic defect often feels a psychological healing when the implant returns their son or daughter to normal. An implant appears to be less traumatic, because the adjacent healthy teeth do not require preparation. These conditions make the parent eager for an implant, regardless of the time or cost of the procedure. However, if the bone graft, implant, or both should fail, then emotional consequences result. It is especially dangerous to put an adjacent tooth at risk under these conditions. If the young patient loses an adjacent tooth because of improper implant insertion or a consequence of a bone graft, then the patient-doctor relationship is stretched to the limit. As such, the clinician should use highly predictable augmentation procedures with care, ensuring that adequate space and bone are present before implant placement.

When acceptable conditions can be created, an anterior single-tooth implant is the treatment of choice for a congenitally missing anterior tooth (Figure 16-36). This condition is especially of benefit for a lateral incisor, because the ideal cervical region of the tooth is similar to the implant diameter. However, the roots of the adjacent natural teeth often impinge on the edentulous bone, or the mesiodistal length is insufficient. As a consequence, orthodontic therapy before implant placement should often be considered.[80,118] An additional advantage of orthodontics before or in conjunction with implant treatment for the congenital missing tooth is that the missing lateral incisor may be restored provisionally by a denture tooth attached to the orthodontic wire, to provide an esthetic replacement without trauma to the augmented ridge or implant during healing.

The missing maxillary lateral incisor is the tooth most often replaced with a dental implant, because the other orthodontic or prosthetic options are usually poor alternatives. The dentist should first determine whether space-opening (maintenance) procedures or space closure (orthodontics) is the treatment of choice for the missing tooth. The treatment options are usually different for a mandibular second premolar compared with a maxillary lateral incisor.

A congenital missing mandibular second premolar most often has a deciduous second molar. When the patient is 5 to 6 years old, the deciduous molar may be extracted. The permanent first molar may then erupt in a more mesial position. When the first deciduous molar is lost naturally (around the age of 9 to 11 years) the first permanent premolar and first molar may be orthodontically positioned adjacent to each other. This approach eliminates the need for a second premolar replacement. Because the second premolar space is eliminated with orthodontics, no bone graft, implant surgery, or crown (or combination of these treatments) is required to replace the tooth. Very few disadvantages exist to the use of orthodontics to eliminate this posterior missing tooth space.

When the deciduous second molar is maintained, it often becomes ankylotic. As a result, the opposing maxillary second premolar extrudes. Because the deciduous molar is 1.9 mm larger than a premolar, the mesiodistal space is larger than the usual premolar space after the deciduous molar is lost at a later date in the adult patient's life. The deciduous tooth does not

These radiographs demonstrate no crestal bone loss on the BioHorizons implants after 1 year.

have a buccolingual width of bone that is adequate for a larger-diameter implant. The crown for this larger tooth dimension is supported by a regular-size implant, which increases forces on the abutment screw and increases the risk of screw-loosening complications.

When the patient is missing a maxillary lateral incisor, space closure is less often indicated. When a maxillary canine is orthodontically moved to a lateral position, several compromises occur. The midline between the central incisors is often shifted to the missing tooth side. The canine eminence over the canine root is positioned under the nose, rather than in the usual position. This results in a depression, lateral to the naris, and a less full maxillary lip on one side of the midline. These differences are more evident as the patient ages. The maxillary canine is larger faciopalatally than mesiodistally. As a result, the cervical emergence is different from the contralateral incisor, even when restored with a laminate facing. The height of gingival contour is also higher than the lateral incisor on the other side of the arch. As a consequence of these limitations, a space-opening and maintenance procedure followed by an implant and single-crown restoration is usually the treatment of choice for a missing maxillary lateral incisor.

Graber[117] noted a strong correlation between a missing single tooth and altered tooth size, shape, or both. A common condition is a missing lateral incisor, where the contralateral lateral incisor is smaller than usual or a peg lateral. As such, the mesiodistal space is often limited to less than 6.5 mm. In these instances a nonfunctional, small-diameter implant of 2.5 to 3.0 mm may be considered. When the intratooth space is smaller than 5 mm, a cantilevered FPD from the canine abutment is considered.

Orthodontic Implant Site Development

In specific situations, the management of the patient in the early treatment phase may require orthodontics before the implant insertion to replace the missing tooth. Situations exist in which orthodontic site development is advantageous. If the patient has a missing tooth because of the loss of the permanent teeth, then it is likely that some soft and hard tissue reconstruction will be necessary to restore the proper context for the missing tooth. If bone height is insufficient and bone loss is also present on the adjacent teeth, then orthodontic extrusion of the adjacent teeth, followed by individual crowns, may be considered to improve the overall situation before bone grafting the edentulous site.

WWW.HIGHDENT.IR

Figure 16-37 Internal resorption may be stopped using endodontic therapy. This periapical radiograph indicates that structural failure of the tooth is eminent. Extraction of the canine is indicated.

In some cases, specifically congenitally missing teeth, the preparation of the implant site with orthodontic treatment can favorably influence the treatment outcome (presented in the next section). In other instances, when the patient has a failing tooth, a strategy may be developed to preserve as many features of the hard and soft tissue architecture with orthodontic extraction of the tooth instead of trying to recreate the tissues after tooth loss. The following are specific situations that illustrate the importance of early planning, not only for replacement of a tooth but also for the integration of hard and soft tissue management to restore the area.

For situations in which the doctor detects a missing lateral incisor in a child before the eruption of the permanent canine, Kokich[119] and Kokich et al.[120] proposed the following treatment modality:

1. The maxillary deciduous lateral incisor is prematurely extracted.
2. The permanent canine is encouraged to erupt in the missing lateral incisor position. In this way the bone around the canine (which is larger than usual in the site and may be greater than 7 mm in diameter) forms in the lateral incisor position.
3. The deciduous canine is extracted after the eruption of the permanent canine in the lateral position.
4. The canine is orthodontically retracted into the ideal canine position.
5. The remaining lateral incisor bone volume is abundant and ideal for an endosteal single-tooth implant.
6. After growth and development of the child has occurred, an implant may be inserted. In this manner, a bone graft will not be required before implant insertion, even when the implant procedure is delayed several years.

Box 16-16 Orthodontic Extraction

Advantages

- Improved bone volume
- Lower cost
- Less time
- Improved tissue drape
- Allows immediate extraction implant

Disadvantages

- Poor esthetics during treatment
- Higher patient cooperation
- Ankylosed teeth
- More difficult if porcelain-fused-to-metal crown on tooth

Root Resorption

Root resorption may cause the loss of a single anterior tooth. Two major categories of root resorption exist: (1) external and (2) internal. Each entity is related to trauma and consists of several different categories beyond the scope of this chapter. However, when structural failure is evident and the extraction of the tooth is eminent, two different treatment options related to the type of resorption exist.

Endodontic therapy is often warranted for internal root resorption and may stop the process. However, when structural failure has occurred or is likely, the treatment of choice is often orthodontic extraction[121] (Figure 16-37). The periodontal ligament space is still evident with internal root resorption. Orthodontic extrusion may be used to slowly extract the tooth with minimum risk of root fracture, which might result in labial plate bone loss and the need for more extensive augmentation. As the tooth migrates coronally during orthodontic extrusion, bone fills in the previous apical region. Because the tooth root is tapered, a 3-month extraction process produces sufficient movement so that the remaining root diameter in the bone is smaller than the implant diameter. As a consequence, after 3 months of orthodontic extrusion, no void exists around the implant at the time of extraction and implant insertion. An immediate implant insertion after extraction may be selected that fills the extraction site, yet is 1.5 to 2 mm away from each of the adjacent teeth.[121,122] In addition, the soft tissue drape often follows the coronal migration of the tooth and provides an improved condition for interdental papilla and soft tissue cervical profile for the implant reconstruction (Figure 16-38).

The time required for orthodontic extraction is often less than that required for bone regeneration after extraction and socket grafting (Box 16-16). The cost of treatment is usually less with orthodontic extraction

WWW.HIGHDENT.IR

than with hard and soft tissue grafting. The orthodontic extraction method is often the treatment of choice when a tooth requires extraction before implant insertion and when clinical conditions permit.

When external root resorption is the cause of structural failure of the tooth root, resorption may be taking place in conjunction with bone replacing the root defect. No evidence of a periodontal ligament space around the defect is seen, and orthodontic extrusion is not possible under these conditions. Instead the root is usually ankylosed, at least in the region of the lesion. Although some atraumatic techniques of extraction have been proposed for ankylosed teeth that core out the tooth from incorporated bone without encroaching on the lateral bone surfaces, they are not always applicable. The extraction of an ankylosed tooth often is accomplished at the cost of extensive labial bone loss and resultant bony wall defects. The bone graft needed to restore the defect is more of a clinical challenge than grafting a socket with intact bony walls. The soft tissue management of

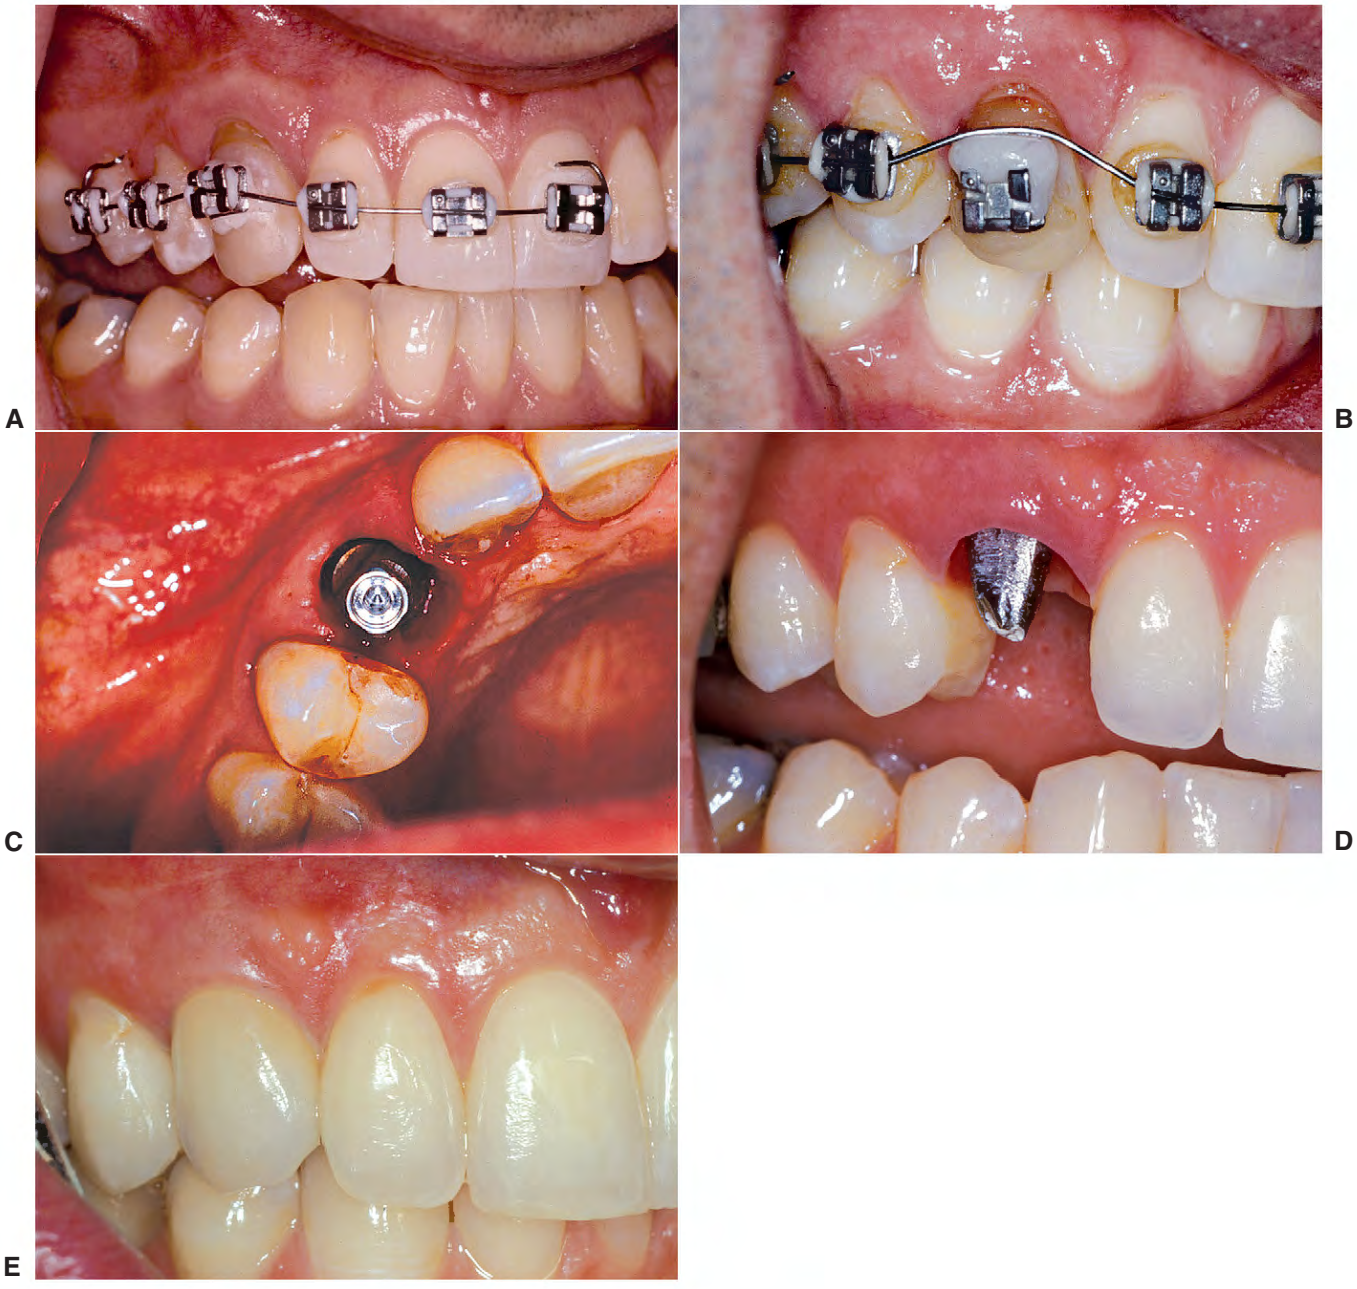

Figure 16-38 **A,** Orthodontic extrusion before extraction allows growth of the surrounding bone, a decrease in size of the root defect, and positioning of the soft tissue drape more incisal to compensate for shrinkage after extraction. **B,** The tooth is usually ready for extraction after 3 months. The canine orthodontic bracket is now near the incisal position of the tooth. **C,** The canine is extracted. If the bony walls are intact, then the implant may be inserted. Because the tooth root is tapered and has been extruded, the surrounding walls of bone are in direct contact with the implant. **D,** The implant and soft tissue drape after initial healing of 5 months. **E,** The implant crown in position replacing the maxillary right canine after orthodontic extraction.

WWW.HIGHDENT.IR

the area is an even greater task, because this situation often leads to the loss of interseptal bone height and loss of papilla height.

Because the replacement resorption is replacing the tooth with bone, consideration is given to delaying the extraction as long as possible. Once the structural failure is eminent , the remaining root segments may be cored out during the implant osteotomy procedure. As a result, the remaining tooth structures may be removed at the same time as the implant insertion. If the surgical defect is too large for immediate implant insertion, then the osteotomy is grafted and the implant procedure is delayed.

Remaining Maxillary Anterior Teeth

The anterior implant is successful only if the final restoration it supports is fully integrated within the adjacent dentition. The exponential growth of the field of implant dentistry has been paralleled by an exciting growth of esthetic dentistry and plastic regenerative surgery. This has brought the profession to realize that the restoration of the peri-implant soft and hard tissue to an optimal architecture is the key to a successful implant restoration. It is no longer sufficient to only achieve osteointegration with an implant. The implant restoration complex in the esthetic zone should be achieved in a context that respects all biological tissues.

When the goal of the restoring dentist for maxillary incisor single-tooth replacement is to obtain an ideal result, the practitioner should first evaluate not only the edentulous site but also the remaining anterior teeth. Because only one tooth is missing, the adjacent teeth most often dictate its length, contour, shape, and position. If not satisfactory, then a potential modification may need to be integrated into the overall treatment plan.

Figure 16-39 The patient's left maxillary central incisor was replaced with an implant and crown. The tooth is wider than the right central incisor. Orthodontics could have reduced the horizontal overjet of the lateral and central incisors and resulted in more symmetrical teeth. A second option is a veneer on the right central incisor to correct the rotation and make the natural tooth more symmetrical to the implant crown.

Parameters for a healthy esthetic anterior restoration have been established. The following guidelines have been proposed by esthetic and cosmetic dentistry colleagues. All these parameters play a determinant role in the final result and should not be overlooked. The patient must be educated about their present status before the onset of treatment, and the starting point should be documented. The patient, once fully informed of the existing discrepancies and their potential negative effect on the envisioned result, may decide to address and correct the existing problems of the adjacent teeth or simply elect to accept the compromise. Correction may be as simple as bleaching the remaining teeth or as complex as full esthetic rehabilitation with crown lengthening, soft tissue plastic surgery, veneers or crowns, and orthodontic therapy (or a combination of these procedures).

Tooth Size

The two maxillary central incisors should appear symmetrical and of similar size. This is most important to evaluate when the missing tooth is one central incisor (Figure 16-39). Outline asymmetry is visually acceptable the more distal from the midline that the eye travels. When one maxillary tooth is missing, the remaining space may be compromised from drifting of the adjacent teeth. Orthodontic correction is strongly encouraged when the missing tooth is a central incisor with a mesiodistal space less or more than the size of the corresponding central incisor.[123,124] The other option is to modify the existing central incisor with a veneer to make it similar in size and shape to the missing tooth restoration. This has the advantage of lowering the mesial interproximal contact and making the two centrals more square shaped, which decreases the height requirement of the papilla. The shades of the two centrals are also easier to match when made at the same time in the laboratory.

The average clinical crown length of the maxillary central incisor is 10.2 mm for a male patient and 9.4 mm for a female patient.[125] Surgical crown lengthening and longer anterior teeth may be indicated to reduce gingival exposure during a high-smile lip position. Because the clinical crown height of an implant-supported central incisor is often longer than the adjacent tooth, an esthetic crown lengthening on the natural tooth may be used to align the gingival margins. When an implant crown is longer than the corresponding natural tooth, a crown-lengthening procedure may be more predictable on the natural tooth than attempting to cover the implant crown with soft tissue. However, the clinical crowns of natural teeth are rarely more than 12 mm high.

The width of the average maxillary central is 8.6 mm for a male patient and 8.1 mm for a female patient.

WWW.HIGHDENT.IR

Figure 16-40 A triangular tooth shape has the steepest gingival scallop, and the interproximal bone is farthest from the tip of the papilla. After an extraction, shrinkage of the tissue makes the soft tissue drape in this tooth shape the most difficult to restore.

Although the male teeth are slightly longer and wider, the length-to-width ratio is similar to female teeth, (0.85 for male patients and 0.86 for female patients). A ratio range of 0.70 to 0.86 has been reported to be acceptable for the central incisors when they are similar. When the anterior teeth are made longer and both centrals have the same width, an acceptable result may be obtained.

The average clinical crown length of the maxillary lateral incisor is 8.7 mm for a male patient and 7.8 mm for a female patient. Therefore the average lateral incisor is almost 1.5 mm shorter than the central (at both the gingival region and the incisal edge). Gingival margins of the maxillary lateral incisors may be similar to centrals and canines, but should not be higher than the neighboring teeth. Therefore an implant crown on the lateral incisor should not be longer than the central or canine.

The average width of a lateral incisor is 6.6 mm for a male patient and 6.1 mm for a female patient, but this is more variable than for any other anterior tooth. The length-to-width ratio is slightly greater for a female patient (0.79, compared with the male patient ratio of 0.76). A lateral incisor space may be slightly narrower than the other natural tooth; however, when replacing the lateral incisor, it may be preferable to perform a slight mesial stripping of the adjacent canine to even out the size of the lateral incisors.

The average male canine clinical crown length is 10.1 mm and width is 7.6 mm, with a ratio of 0.77. The canine is essentially the same height as the central but 1 mm narrower—yet 1 mm wider than the lateral incisor. The female canine height averages 8.9 mm (0.5 mm shorter than the central) and 7.2 mm in width (1 mm narrower), with a ratio of 0.81. As a general rule, regardless of sex, the central incisor is 2 mm wider than the lateral incisor and 1 mm wider than the canine. However, on the horizontal plane, the canine is 1 to 2 mm shorter than the central incisor and corresponds to the curvature of the lower lip during smiling.

Tooth Shape

Three basic shapes of maxillary anterior teeth exist: (1) square, (2) ovoid, and (3) triangular. The tooth shape will influence the interproximal contact and the gingival embrasure. The square tooth shape is the most favorable to obtain an ideal soft tissue drape and papillae around the crown, because the interproximal contact is more apical and more tooth structure fills the interproximal region. In contrast, a triangular tooth shape has a more incisal interproximal contact, a steeper gingival scallop, and is farther from the interproximal bone (Figure 16-40). As a result, a space often exists between the interproximal contact and the interdental papilla of the remaining teeth. This is especially noteworthy to observe at the initial examination. When the soft tissue fills the interproximal space of the remaining anterior teeth that have a triangular shape, the tissues may be very liable and easily vanish during the healing phases after implant surgery. Care should be taken if the adjacent soft tissue requires reflection for a bone graft before the implant insertion. The ideal restoration of the soft tissue with a triangular-shaped tooth is less predictable.

The cervical embrasure of the adjacent teeth to the edentulous site should be particularly evaluated. A triangular tooth is narrow at the cervical, and the base of the interproximal tissue is wide. In addition, the adjacent tooth contact is often higher off the tissue, with an increased risk of a black triangular space. When such a condition is present on the adjacent teeth of the missing tooth, it is likely that the interdental papillae region will also be compromised on the implant crown.

The tooth shape also affects the topography of the underlying hard tissues. The roots of triangular tooth shapes are positioned farther apart and therefore have thicker facial and interproximal bone. This may decrease the amount of crestal bone loss after an extraction. In addition, the prognosis for an immediate implant insertion is more favorable, because the bone defect is smaller in diameter and the interproximal bone more likely to provide the recommended 1.5 mm or more of interproximal bone from the adjacent tooth. The square-shaped tooth is more likely to have less interproximal bone between the roots. Therefore it presents a greater risk of crestal or interproximal bone loss with an immediate implant insertion, making it less favorable for immediate implant insertion after extraction.

Soft Tissue Drape

The height of the maxillary lip when smiling (high lip line) is one of the most important criterion to evaluate when observing the cervical region of the maxillary anterior teeth. Its position is usually related to age, with older men showing the least amount of teeth and soft

WWW.HIGHDENT.IR

tissue and younger female patients displaying the most. Some patients (15% of male patients and 6% of female patients) show only the incisal half of the anterior teeth when they smile.[126] Those patients should be identified and told an ideal soft tissue result in the gingival region is not mandatory. Clinical results in emergence contours, interdental papilla presence, and even shade and contour of the crown are much less demanding. Therefore the extra surgeries and cost may not be necessary when these patients are willing to accept a slight compromise in ideal esthetics (Figure 16-41).

Ideally the height of the maxillary lip should rest at the junction of the free gingival margin on the facial aspect of the maxillary centrals and canine teeth.[126-128] Thus the interdental papillae are visible, but little gingival display is seen over the clinical crowns. Almost 70% of patients have this ideal smile position. A "gummy" smile displays more than 2 mm of soft tissue above the clinical maxillary crowns and is more acceptable in the female patient. It may occur in more than 14% of the female population and 7% of the male population. The higher the high lip line is, the more ideal the esthetic requirements are for the remaining teeth and for the single-tooth replacement. Therefore the existing maxillary anterior teeth condition is closely scrutinized when a high lip line exists and ideal results are desired.

The soft tissue drape of the remaining teeth should also be evaluated, especially if exposed during the high lip position of smiling. Under ideal conditions, soft tissue completely fills the interproximal space, with no dark triangles from the absence of light within the oral cavity. The interproximal contact between the maxillary central incisors should begin in the incisal third of the teeth and continue to the height of the central interdental papilla. In a healthy patient, very little to no space is seen between the papillae and interproximal contact. According to Kois,[129] the distance from the facial free gingival margin to the height of the central midinterproximal papilla is usually 4 to 5 mm; therefore the interdental papilla height is approximately 40% to 50% of the exposed tooth length.[129] Interproximal contacts at the incisal position start progressively more gingivally from central to canine. The greatest papilla height is often between the centrals, slightly lower between the centrals and laterals, and even lower between laterals and canines (Figure 16-42). However, the papilla height is often similar between the centrals and from the centrals to the laterals.

Under ideal conditions the osseous scallop of bone in the maxillary anterior region begins 2 mm below the CEJ midfacial to a point 3 mm more incisal in the interproximal region. The soft tissue follows this osseous scallop. A soft tissue biological dimension of approximately 3 mm in height above the bone is present at the midfacial position (1 mm above the CEJ) and 3 to 5 mm above the interproximal bone. Therefore if the interproximal contact is within 3 to 5 mm of the interproximal bone, then the interdental papilla will most often completely fill the space.

Figure 16-41 **A,** The maxillary left central incisor was restored with an implant restoration. The patient desired a soft tissue graft to cover the implant crest module. **B,** The high lip position during smiling did not display the cervical region of the patient's central incisors. Although this is not an ideal result, additional surgeries would not improve the crown's appearance within the esthetic zone, and the soft tissue pocket created may increase the risk of peri-implantitis.

Tarnow et al.[130] and Norland and Tarnow[131] measured the distance from the bottom of the interproximal contact to the vertical height of interproximal bone on natural teeth and observed how frequently the interproximal space would be completely filled by soft tissue. The distances ranged from 3 to 10 mm, with 88% of the contacts to the bone at 5, 6, or 7 mm; the most common measurement was 6 mm (40%), followed by 5 mm (25%) and 7 mm (22%) (Figure 16-43).

When the contact point to bone was 3 to 5 mm, the papilla almost always filled the space. When the contact was 6 mm, an absence of papilla was noted almost 45% of the time; at a 7-mm distance the papilla did not fill the space 75% of the time (Figure 16-44). In other words, a difference of 1 to 2 mm from the interproximal contact to the interseptal bone is very significant in relation to the interproximal soft tissue. Therefore it is critical to evaluate this dimension before implant surgery. If the height of the interproximal bone is lost or the interproximal contact is more incisal, then the soft tissue will less likely fill the interproximal space. In addition, contact distances to bone of 7 mm sometimes present a papilla initially, but after surgical reflection the

WWW.HIGHDENT.IR

Figure 16-42 The interdental papillae are often highest between the central incisor, with progressively less height as they proceed distal. The high lip line during smiling shows the interdistal papillae in more than 85% of the patients. (NOTE: The maxillary right lateral incisor is an implant restoration.)

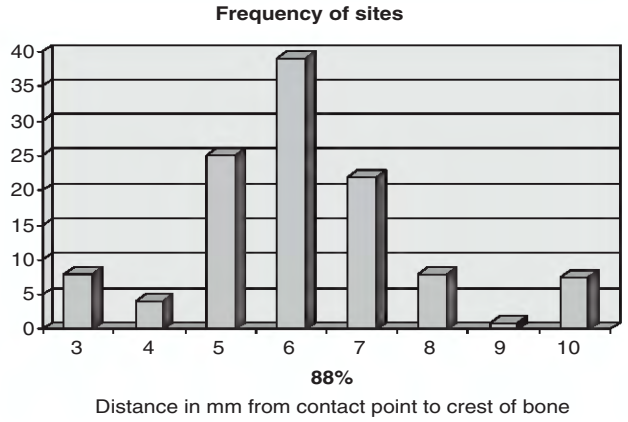

Figure 16-43 The distance from the interproximal contact to the crest of bone with natural teeth most often measures 5, 6, or 7 mm.[58] *(Data from Tarnow DP, Magner AW, Fletcher P: The effect of the distance from the contact point to crest of bone on the presence or absence of the interproximal papilla,* J Periodontol *63:995-996, 1992.)*

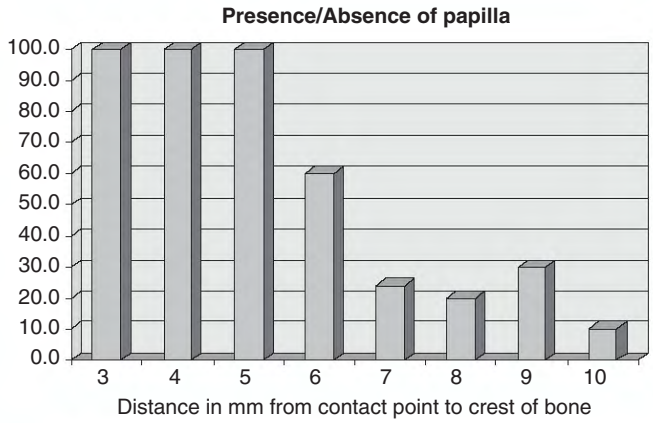

Figure 16-44 When the interproximal contact-to-bone distance is 5 mm or less, the interdental papilla completely fills the space between the teeth. When the contact-bone distance is 6 mm (the most common measurement), almost 40% of the time a black triangular space occurs between the teeth from the absence of papilla filling the space. A 7-mm or greater contact-bone distance nearly always has an incomplete fill of the interproximal space with the soft tissue.

chance this papilla will return to the original position may be less than 25%.

The higher the gingival scallop, or difference between the height of the papilla and the free gingival margin, the higher the risk for gingival loss after extraction. Likewise, once the tooth is extracted and an edentulous site is healed, the less likely the surgical and restorative procedures will be able to restore an ideal soft tissue contour. In contrast, a flatter gingival scallop and an interproximal tissue close to the osseous crest are conducive to minimal tissue shrinkage and a more ideal outcome.

The height of the facial gingival contour is in the middle of the tooth for the maxillary lateral incisors and the four mandibular anterior teeth. However, it is slightly to the distal on the central incisors and canines. The height of the free gingival margins of the two centrals are similar to both canines. The cervical height of the lateral incisors may be level or below the centrals and canines but symmetrical to each other. It may be easier to lengthen the cervical contour of the contralateral incisor when replacing a missing lateral incisor with an implant, rather than attempting to lower the gingival contour on the implant crown when gingiva and bone shrinkage has occurred. The least desirable gingival contour is seen when one anterior tooth is higher than the rest. Unfortunately this is a common occurrence with an implant crown when the bone and/or soft tissue is not augmented in conjunction with implant insertion or uncovery.

The color and texture of the tissue is also evaluated in the edentulous tooth site. The attached keratinized gingival tone and coral-pink color should be similar around the implant abutment compared with the healthy adjacent teeth. The biotype of the gingiva is usually called *thick* or *thin*. Thicker tissue is more resistant to the shrinkage or recession and more often leads to the formation of a periodontal pocket after bone loss. Thin gingival tissues around the teeth are more prone to shrinkage after tooth extraction and are more difficult to elevate or augment after tooth loss. Gingival recession is the most common esthetic complication of thin biotypes after anterior single-tooth extraction and is also a concern after implant surgery, uncovery, or both.

According to Kois,[108] predictability of the maxillary anterior single-tooth implant is ultimately determined by the patient's own presenting anatomy.[108] Favorable conditions include the following: (1) when the tooth position is more coronal relative to the full gingival margin, (2) square tooth shapes, (3) flat scallop periodontium forms, (4) thick periodontium biotypes, and (5) high (<3 mm) facial osseous crest positions of the teeth and midcrestal. Unfavorable patient anatomy

WWW.HIGHDENT.IR

includes the following: (1) aligned or apical preexisting tooth (relative to the free gingival margin), (2) triangular tooth shapes, (3) high scallop periodontium form, (4) thin periodontium types, and (5) low (>4 mm) facial osseous crest positions in relation to adjacent teeth and midcrestal.

IMPLANT CREST MODULE DESIGN

The two most common complications of anterior single-tooth implant replacement are abutment screw loosening and crestal bone loss. The crestal bone loss causes an increased risk of peri-implantitis or shrinkage of the tissue and poor cosmetic results. Both of these conditions are in part related to the implant crest module design. An implant body with an antirotational feature should be used for the single-tooth implant. The greater the dimension of the external or internal hex (or antirotational feature), the greater the resistance to shear forces once the abutment is inserted, which corresponds to a decrease in abutment screw loosening.

The crest module of an implant body should also be designed to transmit some compression and tensile forces to the crestal bone. Smooth metal on the crest module increases the crestal bone loss of the biological width (once the implant is uncovered) and transmits shear forces to the bone. Both these conditions increase the risk of crestal bone loss around the implant. The crestal bone loss may cause a shrinkage of the soft tissue drape and compromise esthetics (see Figure 16-41, *A*). Therefore smooth metal collars on the implant crest module should be limited to approximately 0.5 mm.

Implant Size

The first factor that influences the size of an implant is the mesiodistal dimension of the missing tooth. The average mesiodistal dimension of a central incisor is 8.6 mm for a male patient and 8.1 mm for a female patient. For a lateral incisor it is 6.6 mm for a male patient and 6.1 mm for a female patient, and for a canine it is 7.6 mm for a male patient and 7.2 mm for a female patient. However, the implant body should obviously not be as wide as the natural tooth or clinical crown. Otherwise, the emergence contour and interdental papillae region cannot be properly established.

The teeth become narrower as they proceed toward the bone. The mesiodistal dimensions of the maxillary central incisor at the cervix (ideally 1 mm below the free gingival margin) averages 6.4 mm; the lateral incisor dimension is 4.7 mm, and canine natural teeth at the cervix are 5.6 mm[99,100] (see Table 16-4). However, these dimensions are also too large for an implant.

The bone level on natural teeth is 2 mm below the CEJ, and the natural tooth dimensions at this bone level are reduced to 5.5 mm for central incisors, 4.3 mm for lateral incisors, and 4.6 mm for canines[132] (Figure 16-45). Therefore the latter dimensions most closely resemble an ideal implant diameter to mimic the emergence profile of a natural tooth. However, this ideal dimension is usually too large to adequately restore the soft tissue drape of the missing anterior tooth.

The second factor that determines the mesiodistal ideal implant diameter is the necessary distance from an adjacent tooth root.[102] Initial vertical bone loss around an implant during the first year of loading is variable and ranges from 0.5 to more than 3 mm. The horizontal dimension of a wedge-shaped bone defect around an implant from the biological width, implant design, or occlusal overload at the crest of the ridge is approximately 1.4 mm. When the implant is closer than 1.5 mm to an adjacent root, the wedge-shaped vertical defect may become a horizontal defect, causing bone loss on the adjacent tooth root (Figures 16-46 and 16-47).

The height of the interseptal (interimplant) bone in part determines the incidence of presence or absence of the interdental papillae between the teeth.[130] When the distance from the interseptal bone to interproximal contact is 5 mm or less, the papilla fills the space. When the distance is 6 mm, a partial absence of papilla exists 45% of the time; at 7 mm the risk of a compromise in the interproximal space is 75%. Therefore the intraseptal bone height is relative to the maintenance of the interdental papilla and should be preserved. As a consequence, the implant should be at least 1.5 mm from the adjacent teeth whenever possible, and the interseptal bone on the adjacent teeth should be within 5 mm of the eventual interproximal crown contact position.

In summary, two mesiodistal parameters determine the ideal implant size. The ideal width of the single-tooth implant should ideally correspond to the width of the

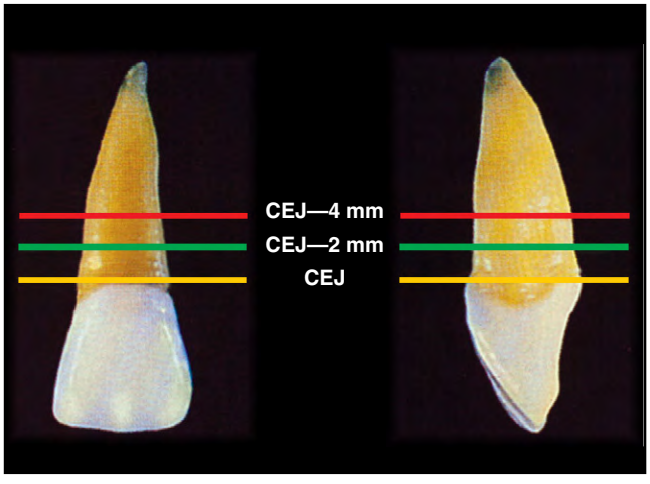

Figure 16-45 The ideal facial bone level on a natural tooth is 1 to 2 mm below the cement-enamel junction (CEJ) to accommodate for the connective tissue attachment zone The ideal implant size should relate to the root dimension at this level, with at least 1.5 mm of distance from the natural tooth on each side of the implant.

WWW.HIGHDENT.IR

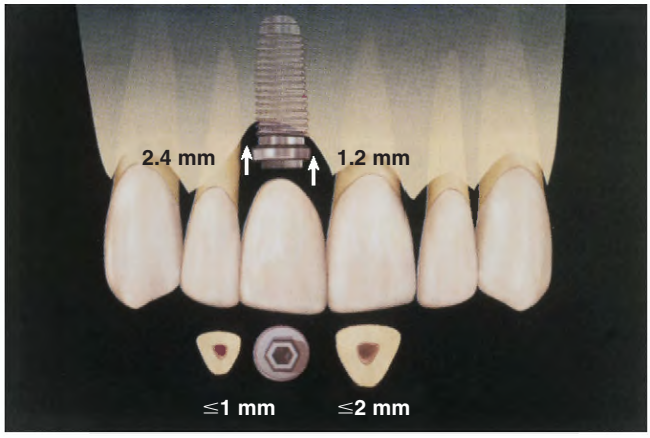

Figure 16-46 When the implant is placed closer than 1.5 mm next to the adjacent tooth, crestal bone loss on the implant (or tooth) results in a horizontal defect between both entities. Therefore 2-mm vertical bone loss on the implant can result in 2-mm bone loss on the tooth and an increase in the interproximal contact-bone distance. When the implant is more than 1.5 mm from the adjacent tooth, bone loss on the implant (or tooth) results in a vertical defect, and the interproximal contact-bone dimension remains the same.

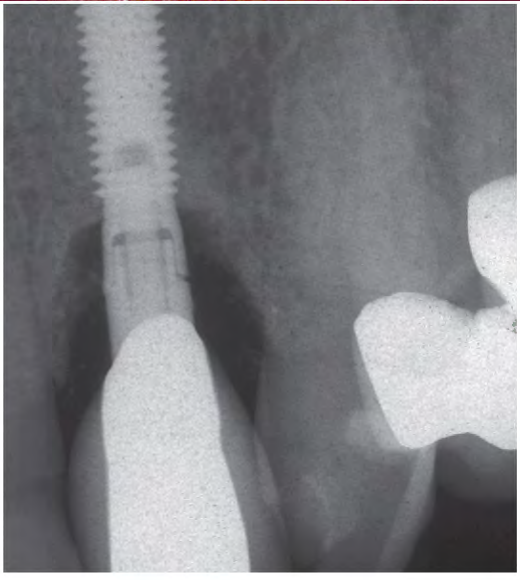
missing natural tooth, 2 mm below the CEJ. However, the distance between the roots of the adjacent teeth should also be measured. The implant diameter plus 3 mm (1.5 mm on each side) should be equal to or less than the distance between the adjacent roots at the crest of the ridge (which is 2 mm below the interproximal CEJ).

The next dimension that determines the width of an anterior implant is the faciopalatal dimension of bone. The ideal width of bone would allow at least 1.5 mm on the facial aspect of the implant so that if a vertical defect forms around the crest module, that defect would not become horizontal and change the cervical contour of the facial gingiva (Figure 16-48). In a report by Spray et al.,[59] facial crestal bone loss incidence was greatest when the facial bone was less than 1.4 mm thick on the facial implant. However, the faciopalatal width dimension is not as critical on the palatal aspect of the implant. The reasons for this include the following: (1) the palatal bone is dense cortical bone and more resistant to bone loss, and (2) the palatal area is not within the esthetic zone, and a change in bone and soft tissue dimension is not an esthetic consequence. Therefore the faciopalatal width of bone at the crest for an anterior implant should have at least 1.5 mm on the facial, plus the dimension of the implant at the crest module, plus 1 mm on the palatal. Facial bone grafting at the time of implant insertion is frequently needed because the bone volume in width is often compromised.

The dimensions of the implant reflect the size of the crest module, not the implant body dimension. For example, a 4.1-mm crest module (on a 3.75-mm implant body) needs 7.1 mm of mesiodistal bone, a 3.5-mm crest module (on a 3.25-mm implant body) should have 6.5 mm of bone, and a 5.2-mm crest module requires 8.2 mm of bone.

A



B

Figure 16-47 A clinical view **(A)** and radiographic image **(B)** of the consequence of an implant placed too close to the lateral incisor and crestal bone loss. The horizontal defect on the implant crown causes a black triangular space and bone loss on the implant and natural tooth. The gingival shrinkage resulting from the bone loss also increases the clinical crown dimension of the natural incisor and implant crown. The contact-bone distance has been maintained on one side, because the natural tooth interproximal bone is unaffected by the implant bone loss when the implant is greater than 1.5 mm from the tooth.

The ideal width of the implant should not only mimic the emergence of a natural tooth but also help preserve the bone and health of the adjacent teeth. The natural intraroot distance of the two central incisors distance is approximately 2 mm. However, the natural roots of the central to lateral and lateral to canine are often less than 1.5 mm apart, and often only 0.5 mm separates them. As a consequence, the ideal size of the single-tooth implant is usually *smaller* in diameter than the natural tooth root. Often the implant ideal diameters used to replace the average-size tooth result in a 4.2-mm to 5.2-mm implant for a central incisor, a 3.0- to 3.5-mm implant for a lateral incisor, and a 3.7- to 4.2-mm implant for a canine.

The difference in the emergence profile of a 4-mm-diameter implant and a 5-mm-diameter implant is

WWW.HIGHDENT.IR

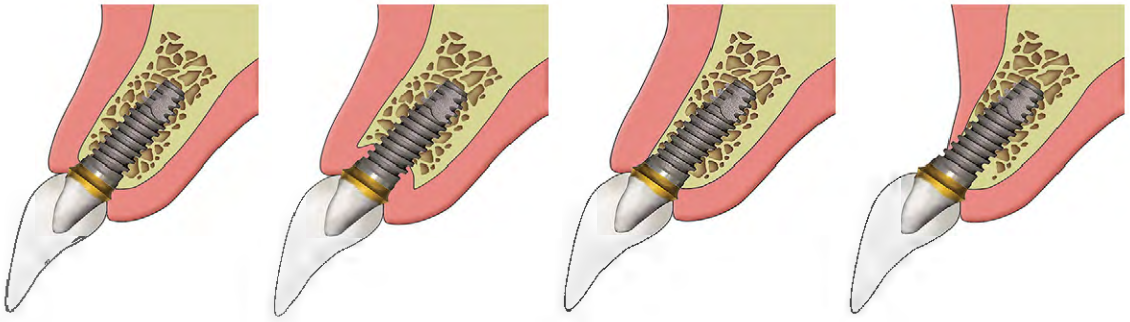


Figure 16-48 **A,** When the faciopalatal width of bone allows 1.5 mm or more of bone on the facial of the implant, crestal bone loss will not cause gingival shrinkage and maintain proper crown contour emergence **(B). C,** When the facial palatal bone is less than 1.5 mm thick, bone loss will be accompanied by soft tissue shrinkage and poor esthetics **(D).**

negligible and often not clinically relevant for an anterior tooth, because a 0.5-mm difference occurs on each side of the implant (Figure 16-49). Therefore when in doubt, the clinician should use an implant with a smaller diameter. As such, a 4-mm-diameter implant may often be used in the central implant position for a single-tooth replacement. Likewise, a 3.0- to 3.5-mm implant is often used for a lateral incisor single-tooth restoration. The exceptions to this rule may be their use in patients with moderate to severe bruxing or when placing an implant in the posterior regions of the mouth (where bite forces are higher). The larger-diameter implant will decrease abutment screw loosening, crestal bone loss, and risk of long-term implant body failure.

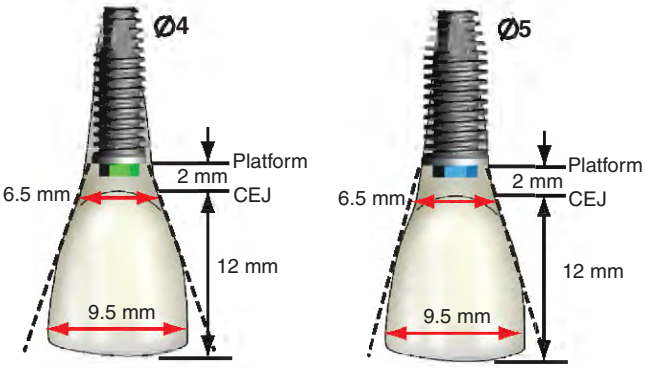

Figure 16-49 The emergence profiles of a 4-mm **(A)** and 5-mm **(B)** diameter implant are similar as the tooth emerges from the soft tissue drape. Placement of an implant slightly narrower than the natural tooth root often is indicated to decrease the risk of lateral perforation of the bone, intrusion on the incisive canal (for central incisors), or position next to the adjacent tooth root.

SUMMARY

A missing single tooth is a common scenario in restorative dentistry. The options for single-tooth replacement usually are an FPD or a single-tooth implant. Rarely are FPDs the primary treatment option in the posterior regions of the mouth. Abutment teeth caries and endodontic procedures place these teeth at increased risk of loss. On occasion, the posterior tooth may not be replaced (e.g., a mandibular second molar or a small space in which the surrounding teeth are interdigitated to prevent extrusion or tipping). The primary method of placement should be a single-tooth implant of adequate size, design, and material.

An anterior missing tooth more often may require the use of a traditional three-unit FPD or cantilever (to restore a lateral incisor). However, these indications are unusual and include adjacent tooth mobility and inadequate mesiodistal dimensions. When the intratooth is adequate and bone is present or can be created, the implant restoration is the treatment of choice.

It should be noted that use of an anterior single-implant crown to replace a central incisor is one of the more difficult procedures in dentistry. Several soft tissue, hard tissue, and implant surgical procedures may be necessary for an ideal result. Despite this, the single-tooth implant in the posterior and anterior regions of the mouth is the treatment of choice in the majority of patients.

Chapter 17

Maxillary Arch Implant Considerations: Fixed and Overdenture Prostheses

Carl E. Misch

More than 18 million people, or 10.5% of the adult population of the United States, are completely edentulous. Maxillary dentures usually are tolerated better by patients than their mandibular counterparts. As such, many treatment plans initially concentrate on the problems associated with the mandibular denture (Figure 17-1). However, once the patient enjoys a stable, retentive, and perhaps fixed mandibular prosthesis, often the patient's attention is brought to the inadequacies of the maxillary prosthesis. In addition to this segment of the population without any teeth, 7% of the adult population wears a maxillary denture opposing some remaining mandibular teeth. This means that 17% of the U.S. population (30 million adults) have no natural maxillary teeth.

The first chapter of this book addressed the esthetic and psychological consequences of the loss of maxillary teeth. Once patients become aware of the anatomical and esthetic consequences of missing teeth, the desire for implant restorations increases. As a result of patient and doctor education related to the loss of teeth, implant restoration of the edentulous maxilla will become more prevalent.

EDENTULOUS ANTERIOR MAXILLA

In a 20-year review of the literature compiled by Goodacre et al., restorations associated with the edentulous maxilla have the highest early implant failure rate compared with any other situation. In this review, overdentures in the maxillary arch averaged 19% implant failure. Fixed prostheses in the edentulous maxilla had an early implant failure of 10%. In comparison, mandibular overdentures or fixed restorations demonstrated a 3% implant failure rate.[1]

Several factors affect the condition of the edentulous maxilla and may result in a decrease in implant survival or an increase in prosthetic complications. The facial cortical plate of the premaxilla is thin over the roots of the teeth and may be resorbed from periodontal disease or is often fractured during the extraction of these teeth. In addition, the facial cortical plate rapidly resorbs during initial bone remodeling, and the anterior ridge loses 25% of its width within the first year after tooth loss and 40% to 50% over 1 year, mostly at the expense of the labial plate. As a result, the residual available bone migrates to a more palatal position.[2-7]

The patient is more likely to wear and functionally accommodate a maxillary complete denture compared with its mandibular counterpart. The greater retention, support, and stability compared with the lower restoration are well documented. As such, the patient often is able to wear the maxillary removable prosthesis for longer periods before complications arise. From a patient's perspective, the need to replace the denture is more related to a desire for a fixed restoration as the motivating factor. By the time the patient notices problems of stability and retention caused by resorption of the premaxilla, the maxillary bone often has advanced atrophy and may be Division C–h or D in volume. Therefore the completely edentulous, anterior bony

Figure 17-1 Implant treatment plans for the completely edentulous patient often address the mandible, as it is the least stable unit. The maxilla is often restored with a traditional denture.

WWW.HIGHDENT.IR

ridge is often inadequate for ideal endosteal implant insertion.

As the bone resorbs from Division B to C–w in the anterior edentulous mandible, the cross section of the residual ridge is triangular (with a wide base). As a consequence, an osteoplasty removes the narrower crestal bone and the residual ridge becomes wider, often converted to a Division A bone volume. In the maxilla, however, the Division B to C–w crest often remains narrow almost to the floor of the nose. An osteoplasty to gain bone width results in a Division C–h to D ridge. Therefore bone augmentation is more often required in the anterior maxilla compared with the anterior mandible.

It is the doctor's responsibility to inform the patient about the continued bone loss in the maxilla before complications arise. Bone grafting is much more predictable for width gains rather than increases in height. Division B bone grafting may use a synthetic bone component for the graft; Division C–w often requires autologous bone from the mandible as a donor. However, when an edentulous maxilla requires height augmentation (C–h or D), the dentist often must resort to the iliac crest or other extraoral donor sites for large volumes of bone. As such, the maxillary completely edentulous patient should understand that the surgical rehabilitation is much more complex and extensive as the volume of bone needed to reconstruct the atrophic maxilla increases. Therefore notifying patients of their continued maxillary bone loss is even more important than in the anterior mandible, rather than waiting until problems with their removable restoration develop.

In most patients with available bone, the bone is less dense in the anterior maxilla than in the anterior mandible, where a dense cortical layer surrounds coarse trabeculae of adequate bone strength to provide implant support. In contrast, the maxilla presents thin porous bone on the labial aspect, very thin porous cortical bone on the floor of the nasal and sinus region, and a more dense cortical bone on the palatal aspect.[8,9] The trabecular bone is usually fine and is less dense than the anterior region of the mandible. The trabecular bone of D3, often found in the maxilla, is 45% to 65% weaker than the trabecular bone of D2, usually found in the anterior mandible.

To achieve predictable esthetics for a maxillary full-arch fixed prosthesis, the hard and soft tissue, volume, and character should be adequate in most aspects. Available bone should be evaluated closely for implant insertion in esthetic regions because of its influence on the soft tissue drape, implant size, implant insertion (angulation and depth), and the final prosthetic result. Bone loss after maxillary anterior tooth loss is rapid and has considerable consequences. Therefore most maxillary anterior edentulous sites require at least some bone and soft tissue augmentation before or during implant insertion and at implant uncovery.

Box 17-1 Premaxilla Compromised Anatomical Conditions

- Narrow ridge
- Esthetics required—facial cantilevers
- Oblique centric contacts
- Increased moment loads with lateral forces during mandibular excursions
- Reduced trabecular bone density
- Absence of thick cortical plate
- Accelerated bone loss in incisor region
- Crown height space often greater than ideal

The farther forward the maxillary anterior teeth are positioned from the implants, the greater the moment force leverage on the bone-implant interface, abutment screws, and implants. Yet many dentists attempt to do plastic surgery with plastic, hoping to eliminate vertical lines in the lip by bulking out the labial flange and teeth of an overdenture and positioning the teeth farther forward than the natural tooth position. Patients desiring to eliminate wrinkles in the lips from bone loss should have plastic surgery and bone augmentation, not plastic added to a maxillary prosthesis. This is even more important when the patient desires a fixed prosthesis. Bone and soft tissue augmentation is usually required to restore the natural appearance of the face without the help of a labial denture flange when a fixed restoration is planned. The facial position of the lip relative to esthetics is an important criterion to evaluate at the onset of treatment, before the placement of the implants. This criterion alone may indicate an overdenture rather than a fixed prosthesis.

From a biomechanical perspective, the implant-restored anterior maxilla is often the weakest section compared with other regions of the mouth. Compromised anatomical conditions and their consequences include the following (Box 17-1):

1. Narrow ridges form soon after tooth extractions. Bone augmentation is often necessary and may mandate the need for smaller-diameter implants. Their use results in increased stress concentrations in the implant and contiguous interfacial tissues, particularly at the crestal region.
2. In the premaxilla, esthetics and phonetics dictate that the replacement teeth be placed at or near their original position, often cantilevered from the implants and the residual ridge, which usually is resorbed palatally and superiorly. The use of facial cantilevers results in increased moment loads at the implant crest and often leads to localized crestal remodeling bone loss and soft tissue recession.
3. The arc of closure of the mandible is anterior to the maxillary residual ridge; as a consequence, the moment force is great against the maxillary anterior

WWW.HIGHDENT.IR

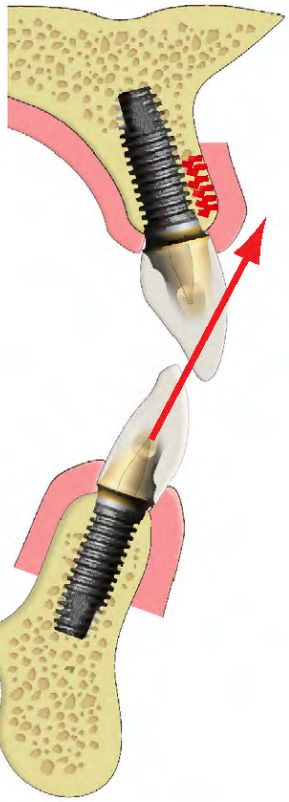

Figure 17-2 The arc of closure is anterior to the maxillary ridge and, as a result, increased forces are applied to the thinner facial cortical plate.

Figure 17-3 Mandibular excursions place lateral forces on maxillary anterior implants, which increase the resultant stresses.

crowns supported by implants. The force is also directed against the thinner facial bone (Figure 17-2). Oblique centric contacts result in potentially harmful, off-axis load components.

4. All mandibular excursions place lateral forces on the maxillary anterior teeth, with resulting increased stress on the crestal bone of the supporting implants, especially on the labial aspect. These lateral loads in excursion further increases the moment loads applied to the implant (Figure 17-3).
5. A mandibular arch receives a load from the outside of the arch toward the center (on the top left). An arch is constructed for this force direction. A maxillary arch receives a force from within the arch to the outside of the structure (on the right). An arch is not as effective to resist this type of force (Figure 17-4).

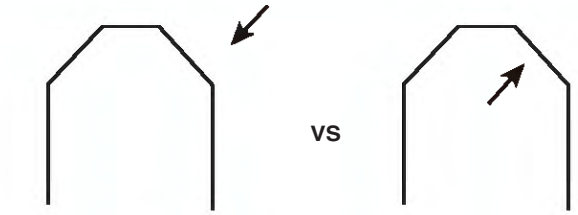

Figure 17-4 During function, the forces are directed against the mandibular arch form, which is designed to reduce stresses *(left)*. In the maxilla, forces are directed outside the arch form *(right)*. An arch is much less effective against outward forces than inward forces.

6. Reduced trabecular bone density of the maxilla results in compromised bone strength and a weaker implant-bone interface.
7. Absence of thick cortical plate at the crest of the premaxilla results in loss of high-strength implant support and less resistance to angled loads.
8. The accelerated bone volume loss in the incisor region often results in the inability to place central and lateral incisor implants without substantial augmentation procedures.
9. Crown height space (CHS) is often greater than ideal and is a force magnifier to any angled or cantilevered force.

TREATMENT OPTIONS

The treatment options for the restoration of a complete or partially edentulous patient with all six maxillary anterior teeth missing include a removable partial or complete denture, an implant-supported overdenture, or an implant-supported fixed prosthesis.

An independent, fixed implant-supported restoration has become the treatment of choice for most patients with complete or partial edentulism. A fixed prosthesis presents several advantages over an overdenture for a maxillary edentulous patient. Because many traditional maxillary dentures have adequate retention and stability, function and sore spots are rarely a problem. Therefore little benefit is perceived with an implant overdenture (IOD). The major disadvantage of the maxillary denture is most often the psychological aspect of removable teeth. In contrast, a fixed prosthesis presents significant benefits for the maxillary denture patient. In fact, after 3 years of function, most patients feel the maxillary fixed prosthesis is as good as or better than their natural teeth. On the other hand, an IOD is always considered by the patient as a removable prosthesis. Contraindications to a fixed partial denture include long edentulous spans, poor abutment support, and inadequate edentulous bone for proper prosthetic contour.

WWW.HIGHDENT.IR

The primary reason for a conventional maxillary removable denture is economic reasons or because a patient is unwilling to undergo implant surgery. However, the easiest interim treatment prosthesis for the replacement of several anterior teeth during implant submerged healing is a removable restoration. If bone augmentation is necessary, this prosthesis may need to be used for longer than 1 year before delivery of the final implant restoration.

Sequence of Treatment

Maxillary Labial Lip Position

Whether a denture, an overdenture, or a fixed prosthesis is being fabricated, a full-arch maxillary reconstruction begins with the determination of the facial position of the maxillary incisal edge. Its modification at a later step may alter all other measurements. A baseplate and wax rim may determine the labial contour of the maxillary lip. Most often the facial surfaces of the central incisors are 12.5 mm from the most posterior aspect of the incisive papilla.[10,11] The wax rim is initially positioned with this in mind. The farther forward the labial flange and teeth position, the higher the resting position of the lip and the greater the incisal edge exposure. The philtrum of the lip should have a visible depression in the midline under the nose. If the philtrum is too flat, the lip is extended too far, and wax should be removed from the labial aspect of the wax rim.

The position of the maxillary lip also may be determined by the position of the lower lip and chin. A horizontal line, represented by the Frankfort plane, may be drawn from the highest point of the auditory meatus (top of the tragus) to the lowest point on the margin of the orbit, with the patient's head in a vertical position. Ideally, a vertical line drawn from the Frankfort plane to the lower lip should have the maxillary lip anterior to this landmark 1 to 2 mm and the chin 2 mm posterior to this line.

The labial position of the lip in relationship to the premaxilla is the primary criterion to determine whether a fixed restoration, a bone graft and fixed restoration, or a maxillary overdenture is indicated. When the labial position of the wax rim is forward of the residual ridge more than 5 mm, a bone graft prior to implants is required for a fixed restoration, or a maxillary overdenture is considered (Figure 17-5). The maxillary anterior region with multiple teeth missing often is restored with an overdenture or FP-3 prosthesis.

Key Implant Positions

Once the prosthesis type and tooth position are determined, the patient force factors and bone density in the implant sites are evaluated. The key implant positions are then determined for the maxillary restoration.[12-14] An important parameter in treatment planning is to provide adequate biomechanical position and surface area of support for the load transmitted to the prosthesis. Four guidelines were presented in Chapter 8 for key implant positions in an implant prosthesis include:

1. No cantilever.
2. No three adjacent pontics.
3. The canines and first molar implant sites.
4. An arch is a five-sided open pentagon and should have at least one implant in each section of missing teeth.

Of these guidelines, number 3 and number 4 are often violated in the treatment plan of an edentulous maxilla, and therefore deserve further discussion.

Guideline 3: The Canine and First Molar Site

A fixed prosthesis replacing a canine tooth is at greater risk than most any other tooth in the mouth. The maxillary lateral incisor is the weakest anterior tooth, and the first premolar is often the weakest posterior tooth. A traditional prosthodontic axiom indicates a fixed prosthesis is contraindicated when a canine and two or more adjacent teeth are missing.[15] Therefore if a patient desires a fixed restoration, implants are required whenever the following adjacent teeth are missing: (1) the first premolar, canine, and lateral incisor (Figure 17-6); (2) the canine, lateral incisor, and central incisor (Figure 17-7, *A*); and (3) the canine, first premolar, and second premolar (Figure 17-7, *B*).

When any of these three missing teeth combinations are present, a fixed restoration is contraindicated because of the length of the span (three pontics), the amount of force (forces greater in the canine region compared with the anterior), and the direction of the force (angled forces to the canine region).

A tooth-supported prosthesis is less at risk than an implant-supported restoration when the canine and

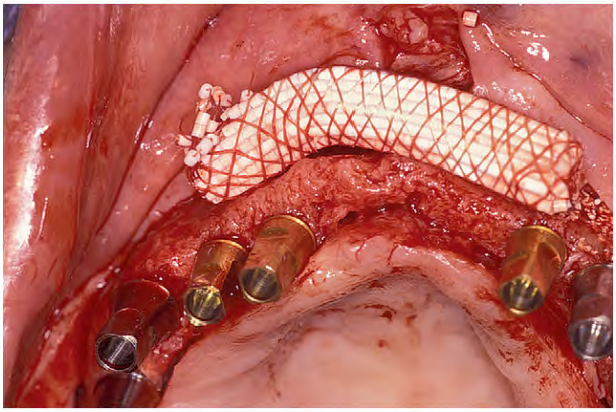

Figure 17-5 When the labial position of the teeth needed to support the upper lip is more than 5 mm anterior to the residual ridge, a bone graft or hydroxyapatite graft is required for a fixed prosthesis. Another method to support the maxillary lip is an implant overdenture with a labial flange.

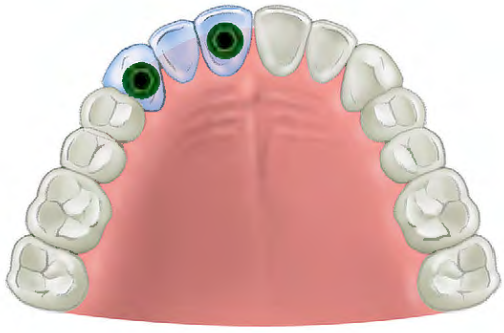
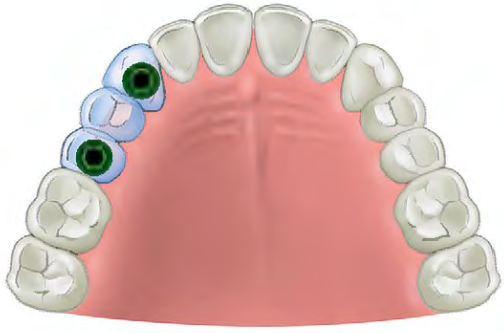
Figure 17-6 When the patient is missing a first premolar, canine, and lateral incisor, two to three implants are indicated.



A

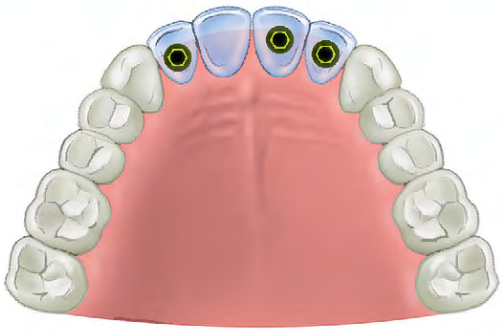


B

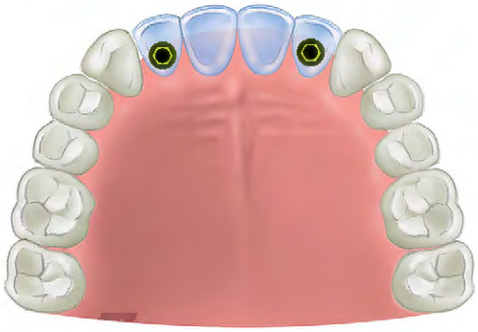
Figure 17-7 **A,** A patient missing a canine, lateral, and central incisor requires at least two implants to restore these teeth. **B,** A patient missing a second premolar, first premolar, and canine requires at least two implants to restore these three missing teeth.

two adjacent teeth are missing. Because teeth are more mobile than implants, a stress relief mechanism reduces the flexure, force, and effect of an angled force. Despite this, it is contraindicated to design three pontics in a fixed prosthesis whenever the natural canine and two adjacent teeth are missing. Therefore, under these conditions with implant treatment plans, at least two implants are indicated to support an independent fixed restoration (usually in the terminal positions of the span to eliminate cantilever forces) (Figure 17-8).

Using the missing canine and two adjacent natural teeth guideline, a fixed prosthesis is also contraindicated when missing a right canine, right lateral incisor, right central incisor, left central incisor, left lateral incisor,



A



B

Figure 17-8 **A,** When all four incisors are missing and the dental arch form is ovoid, three implants are indicated to support the prosthesis. To ensure adequate implant spacing, narrow-diameter implants may be placed in the central and adjacent lateral position. **B,** When all four incisors are missing and the dental arch is square, two implants in the lateral position may be sufficient to support a final prosthesis. In such cases, the implant diameter should be a standard dimension.

Figure 17-9 It is contraindicated to replace three adjacent teeth, which include a canine. This implant prosthesis has at least five pontics that include a canine.

and left canine without considerable anterior implant support (Figure 17-9). Yet in some improper treatment plans, implants are placed in each posterior maxillary quadrant and a fixed restoration with six pontics is fabricated to replace the anterior teeth (Figure 17-10).

WWW.HIGHDENT.IR

Figure 17-10 A panoramic radiograph of a fixed prosthesis with five adjacent pontics, including a canine. This prosthesis is undersupported, especially as it opposes natural dentition in a younger patient.

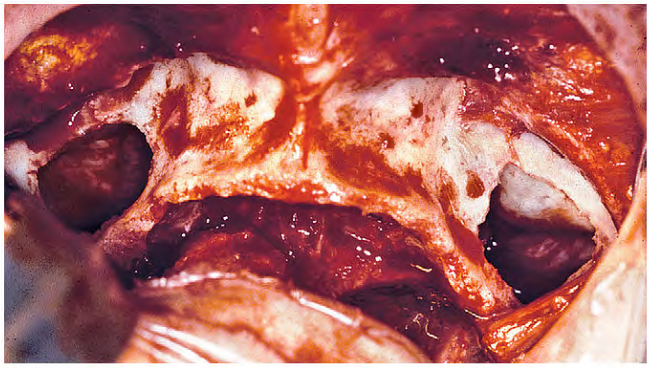


Figure 17-11 In the posterior maxillary, a Tatum lateral wall approach is used to graft the floor of the maxillary sinus with synthetic bone materials. For predictable results, the premaxilla and premolar regions most often require autologous bone. When six to eight sites need augmentation, an extraoral bone graft may be indicated.

Apparently the rationales for violating the prosthetic guidelines established in the literature for teeth are the following:

1. To augment a premaxilla, autologous bone grafts are usually necessary, whereas synthetic materials can be used to predictably graft in the posterior maxilla. The large volumes of bone required for the premaxilla often requires an iliac crest graft (which patients do not want, and for which few doctors are properly trained) (Figure 17-11).
2. The impression is that implants are more rigid and therefore stronger than natural roots. However, this is false security. The fact that implants are more rigid than teeth makes the three adjacent pontics and canine position guidelines more important to follow when the adjacent abutments are implants. The rigid abutments magnify the problem of flexibility of the metal and the direction of force applied to the prosthesis. Therefore, the canine is an especially important implant site when the anterior six teeth are missing. When available bone is not present, an autologous graft in the canine position is indicated before implant insertion, or an implant in both the lateral and first premolar site to compensate for the missing canine may be considered.

The first molar is an important abutment position in an edentulous maxilla. The first molar natural tooth surface area is two times greater than the premolars. The bite force in this region increases to 200 lb, compared with half this amount in the premolar sites. In addition, the bone density in the molar region is often poorer than the premolar regions of the jaws. As a result, larger-diameter implants are also suggested.

The anatomical problem for implant treatment in the posterior maxilla is the rapid expansion of the maxillary sinus after tooth loss. As a result, the edentulous posterior maxilla rarely has enough bone height without sinus grafting. A trend to cantilever the posterior missing teeth from anterior implants has developed. Posterior cantilevers from anterior maxillary implants are less predictable than cantilevers from anterior mandibular implants for all the reasons addressed in the beginning of this chapter. Instead, sinus grafting and larger-diameter implants (or two implants instead of one) are indicated in the first molar region.

Posterior implants (premolar and molar) without implant support in the premaxilla are sometimes connected with a full-arch bar for a maxillary overdenture. When a bar extends from molar to molar around an arch, the overdenture prosthesis is completely implant supported (RP-4), because it does not move during function or parafunction. As such, the overdenture acts as a fixed restoration (Figure 17-12). The removable implant prosthesis under these conditions should have the same implant support as a complete arch fixed restoration (not less).

Guideline 4: Five-Sided Arch

The maxillary arch may be divided into five segments, similar to an open pentagon (Figure 17-13). The central

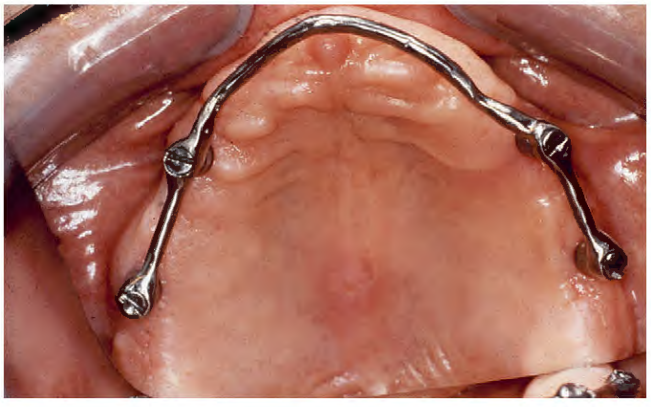

Figure 17-12 This overdenture bar extends from second premolar to second premolar. The anterior bar represents a span of eight pontics and is too long for proper prosthetic support. The overdenture, when in place, is rigid over this bar design, and as such, requires as much support as a fixed prosthesis.

WWW.HIGHDENT.IR

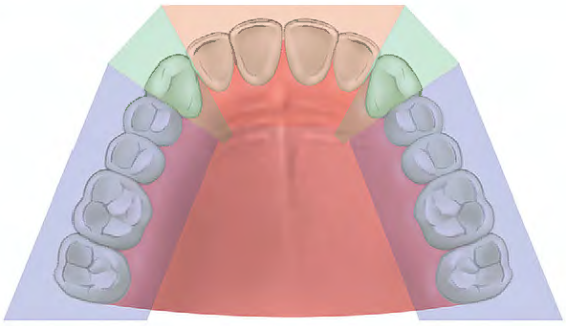

Figure 17-13 The maxillary arch may be treated as an open pentagon, with five straight-line segments. When teeth are missing in multiple segments, at least one implant is required in each section.

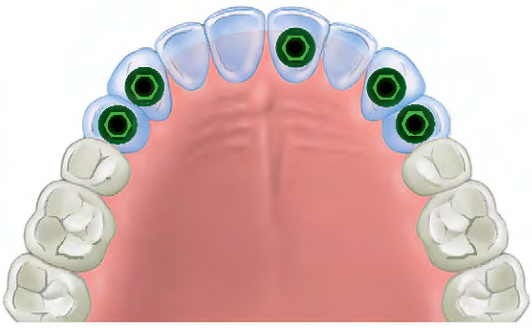

Figure 17-14 When eight anterior teeth (first premolar to first premolar) are missing, implants should be placed in each segment to provide adequate support.

and lateral incisors represent one segment, each canine a separate segment, and the posterior premolars and molars individual segments. In other words, each segment is essentially a straight line, with little resistance to lateral forces. However, when splinted together, an arch form dynamic becomes evident.

At least one implant should be placed in each of the five sections missing teeth and then splinted together when replacing multiple adjacent teeth missing in the maxilla. At least three implants usually are required to replace the anterior six teeth in the premaxilla: one in each canine position and one in any of the four incisor positions.[12-16] When posterior teeth are also missing, additional posterior implants are required (Figures 17-14 and 17-15).

Previous studies by Bidez and Misch have shown that the force distributed over three abutments results in less localized stress to the crestal bone than two abutments.[17] Because these three elements are aligned along an arch, connecting at least three segments creates a tripod effect and provides an anteroposterior distance (A-P spread) with mechanical properties superior to a straight line and with greater resistance to lateral forces. The A-P distance for the anterior cantilevers in the premaxilla restoration corresponds to the distance between the center of the most distal implants on each side (in the splint) and the anterior aspect of the most anterior implant.

A poor treatment option for fully edentulous maxillae is the placement of implants in each posterior quadrant

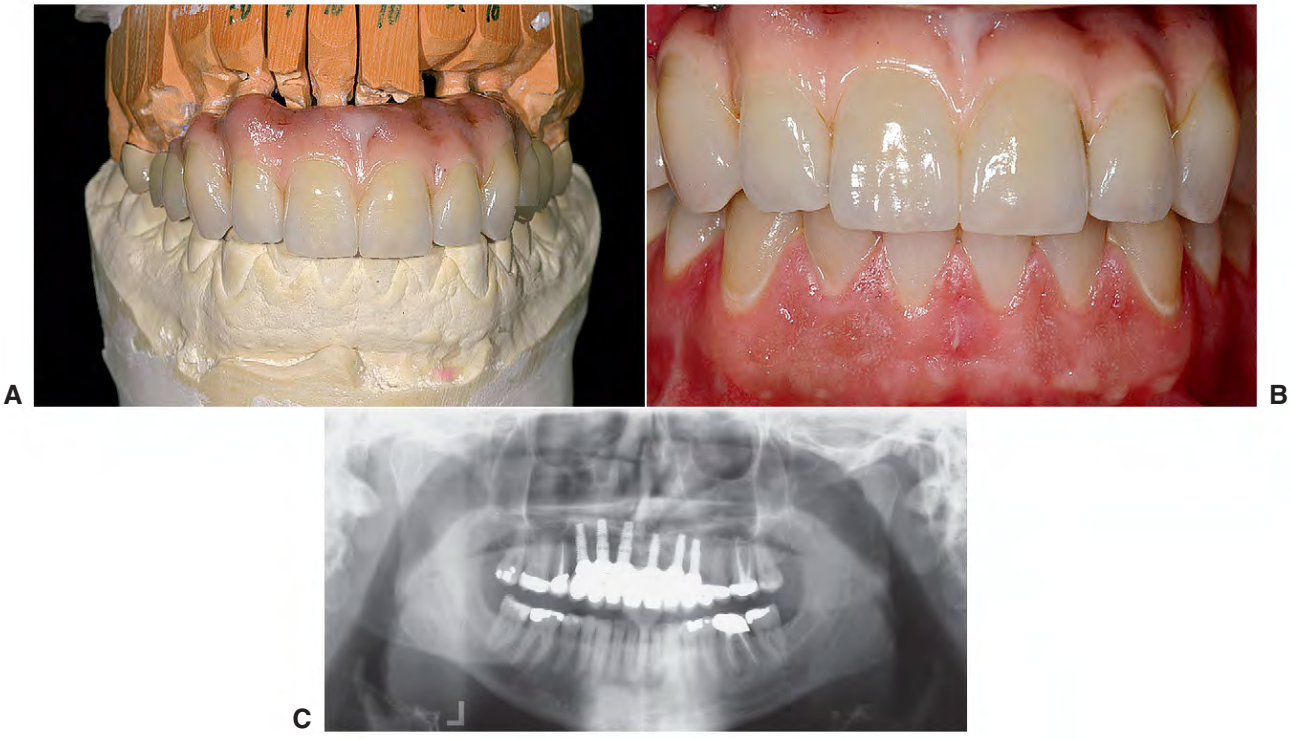

Figure 17-15 **A,** The dentate arch form may be different than the residual bone form, as the ridge resorbs apically and away from the original tooth position. In such cases, the prosthesis is designed to restore the proper tooth contour and lip support. **B,** The fixed FP-3 prosthesis replaces eight adjacent anterior teeth and is supported by six implants. **C,** Panoramic radiograph of the same patient.

Ovoid	8-12	3	Two canines and one incisor
Tapering	> 12	4	Two canines and two incisors

with independent bar segments and an overdenture. This treatment option is prone to failure. The maxillary overdenture rocks back and forth during excursions (if not, the overdenture is really a fixed restoration). The posterior implants are in a straight line and cannot resist the lateral forces. Eventually, almost all the implants on one side are lost. Maxillary complete prostheses and overdentures have a greater incidence of implant failure and complications than mandibular counterparts.[1,18,19] These observations further emphasize the need for more implants and fewer pontics in the restoration of a maxilla compared with the mandible.

Premaxilla Arch Form

The arch form of the maxilla influences the fixed prosthesis treatment plan of the edentulous premaxilla. Three typical dental arch forms for the maxilla are square, ovoid, and tapering. As a consequence of bone resorption, the edentulous ridge arch form may be different from the dentate arch form. The dental arch form of the patient is determined by the final teeth position in the premaxilla and not the arch shape of the residual ridge. A residual ridge may appear square because of resorption or trauma. However, the final teeth position may need to be cantilevered facially with the final prosthesis. In other words, a dental ovoid arch form may be needed to restore a residual edentulous square arch form. The number and position of implants are related to the arch form of the final dentition (restoration), not the existing edentulous arch form (Table 17-1).

The dental arch form in the anterior maxilla is determined by the distance from two horizontal lines. The first line is drawn from one canine incisal edge tip to the other. This line most often bisects the incisive papilla. The second line is drawn parallel to the first line, along the facial position of the anterior teeth (Figure 17-16). When the distance between these two lines is less than 8 mm, a square dental arch form is present. When the distance between these two lines is 8 to 12 mm, an ovoid dentate arch form is present—the most commonly observed. When the distance between the two lines is greater than 12 mm, the dentate arch form is tapering.

In a dental square arch form, lateral and central incisors are not cantilevered very much facially from the canine position. Therefore mandibular excursions and occlusal forces exert less stress on the canine

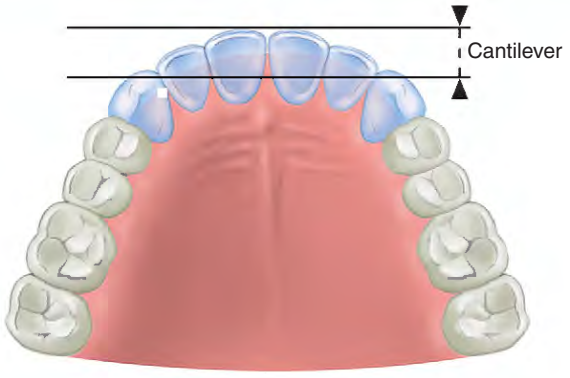

Figure 17-16 Two horizontal lines are drawn. The first line bisects the incisal papilla and connects the tips of the canines. The second line is parallel and along the facial position of the central incisor. The distance between these lines determines whether the dentate arch form is square, ovoid, or tapering.

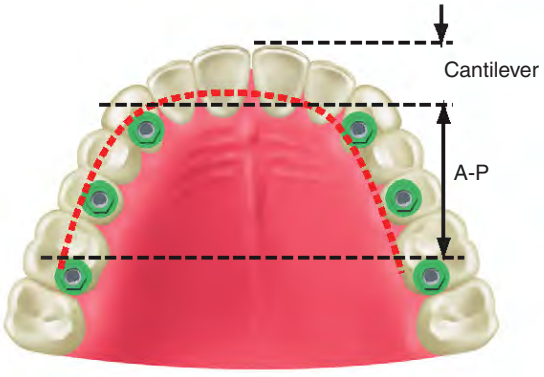

Figure 17-17 When force factors are low, a square dentate arch form may use six implants for a fixed or RP-4 prosthesis. *A-P,* Anteroposterior distance.

implants. As a result, implants in the canine position to replace the six anterior teeth may suffice when the force factors are low and if they are splinted to additional posterior implants (Figure 17-17). The four pontics between the canines counters Rule 2 of key implant positions (no three adjacent pontics) because (1) the forces are lowest in the incisor region and (2) in a square arch form in the maxilla, minimal cantilevers are placed on the canines (Figures 17-18 to 17-20).

If the final teeth position is an ovoid arch form, at least three implants should be inserted into the premaxilla: one in each canine and preferably one in a central incisor position (Figure 17-21). The central

Figure 17-20 A panoramic radiograph of the patient from Figures 17-18 and 17-19 with a square arch form. Additional implants were indicated, as the patient is a male and the opposing fixed prosthesis is implant supported.

incisor position increases the anterior posterior distance from the canine to central and provides improved biomechanical support to the prosthesis. In long-term edentulous maxillae, this most likely will require bone augmentation before implant insertion. When patient force factors are low to moderate, the anterior implant may be positioned in a lateral incisor site. These three implant positions resist the additional forces created in this arch form, enhance prosthesis retention, and reduce the risk of abutment screw loosening (Figures 17-22 to 17-25).

The restoration of a tapered dental arch form places the greatest forces on anterior implants, especially during mandibular excursions when the residual bone is an ovoid or square ridge form. The anterior teeth create a significant facial cantilever from the canine position. As such, four implants should be considered to replace the six anterior teeth (Figure 17-26).

The bilateral canine and central incisor positions represent the best option. These positions are preferred when other force factors are greater, such as crown height, parafunction, and masticatory muscular dynamics. When more than six anterior teeth are missing, additional posterior implants also should be splinted to the anterior segment (Rule 4). The worst-case scenario is a patient requiring restoration of a dental tapered arch form with a square residual ridge form. Not only are four implants then ideally required to compensate for the cantilevered tooth position, but these implants should be connected to additional posterior implants,

preferably to include implants as far distal as the second molar sites (Figure 17-27 to 17-30).

When one canine region cannot be used to place an implant in the edentulous premaxilla, at least one implant on each side of the missing canine is required to compensate for this vital position (a first premolar and lateral incisor implant). A central incisor implant and canine position in the contralateral section can be splinted to these other two implants to act as abutments for the fixed or overdenture restoration.

When force factors are greater than usual, four implants in the premaxilla are suggested. The four implants in

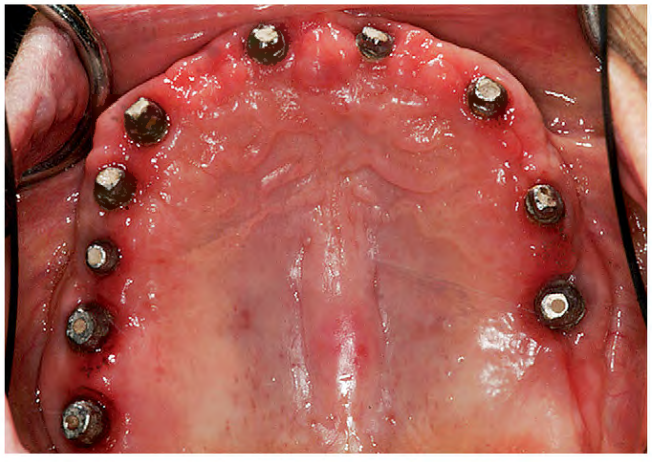

Figure 17-31 Moderate force factors usually require four implants in the premaxilla, splinted to additional posterior implants.

the premaxilla should be splinted together and share any lateral forces during excursions. This means a minimum of four implants are needed to replace the anterior six teeth with high force factors. In the presence of these forces (e.g., moderate to severe bruxism), larger-diameter implants also should be used, especially in the canine positions (which have increased load angulation

Figure 17-32 A fixed FP-3 porcelain-fused-to-metal restoration supported by 10 implants on a patient with moderate force factors and softer bone type.

Figure 17-33 Panoramic radiograph of the patient in Figures 17-31 and 17-32, illustrating the 10 maxillary implants opposing an implant prosthesis in the mandible.

in excursions and higher bite forces). In other words, in most instances the completely edentulous anterior maxilla is restored with three or four implants splinted together to replace the anterior six teeth.

Posterior cantilevers should not be placed on maxillary anterior implants. (Rule 2 in key implant positions). If posterior teeth also are being replaced in the prosthesis, additional implants are required. Seven to 10 implants often are inserted to restore a completely edentulous maxilla with a fixed prosthesis, especially when opposing natural dentition or a fixed restoration (Figures 17-31 to 17-34).

It should be noted that most full-arch maxillary prostheses are FP-3 fixed restorations or RP-4 overdentures. In either scenario a mesiodistal implant position does not have to strictly correlate with tooth position. In other words, the faciopalatal position is often more important than the mesiodistal tooth site, as the gingival aspect of the restoration separates the clinical crown from the implant site. As such, the implant site is determined more for biomechanics, interimplant spacing, or available bone, rather than a strict tooth site position (as in an FP-1 prosthesis).

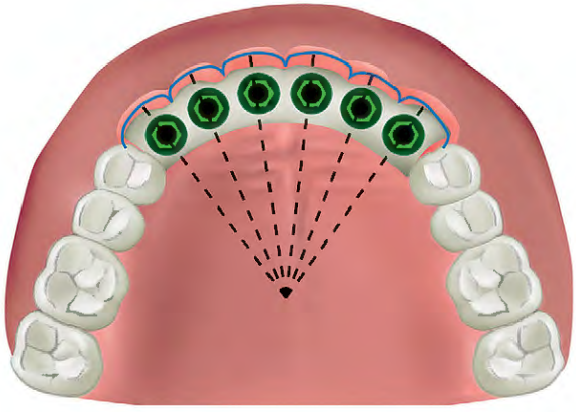

Figure 17-35 When implants are placed in a premaxilla with abundant bone, the arch dimension allows implant placement in the original teeth location.

PREMAXILLA PARTIALLY EDENTULOUS TREATMENT PLANS

Several factors affect the strategic selection of implant size and position to restore a completely edentulous maxillary arch. In general, two implant bodies should be more than 3 mm apart. Tarnow et al.[20] have observed that the horizontal dimension of a crestal defect next to an implant measures almost 1.5 mm. As such, if two implants are closer than 3.0 mm, a vertical angular defect on each implant may result in horizontal bone loss between the two implants. This bone loss in turn may favor the proliferation of anaerobic bacteria in the sulcular environment, or the tissues may shrink and compromise the interdental/implant soft tissue contours in a highly esthetic area. Degidi and Misch have found the vertical defect width may be 0.5 mm rather than 1.3 mm, dependent upon implant design.[21] However, the 3-mm guideline is an ideal safety factor for an implant distance.

The edentulous square-to-ovoid arch form dimension often does not accommodate interimplant spacing for more than four anterior implants. The largest interimplant distance is typically found in a tapered arch form. As the radius of the circle becomes smaller (from labial resorption or patient size), the premaxilla interimplant distance is reduced (Figures 17-35 and 17-36). As a result, usually no more than four implants are used to replace the anterior six teeth, even when bone grafting restores a more compatible residual ridge form.

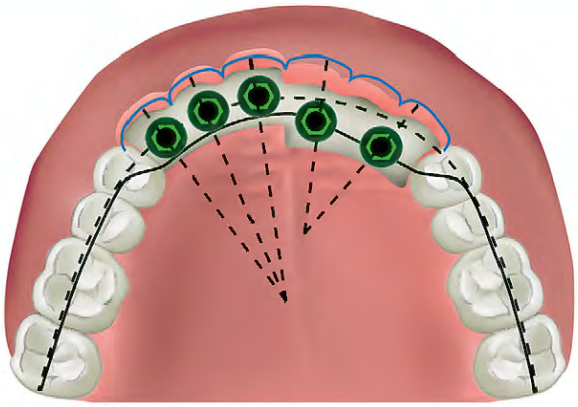

Figure 17-36 When the arch form is reduced, most often only two implants can be positioned to replace the three teeth *(on the right)*.

When the natural canines are present and the missing teeth are the four maxillary incisors, the implant number is not as dependent upon the dental arch form. As a general rule, the remaining arc of bone is smaller than the dentate arch. As a result, one implant per tooth results in the implants being too close to each other (less than 3 mm). Therefore the most common scenario is to place three Division B root forms (3.5 mm wide) in the lateral incisors and one central incisor region.

When four anterior teeth are missing in an FP-1 prosthesis with a high smile lip position, the interdental papilla and cervical emergence of a pontic may be more esthetic than the soft tissue drape between two implants in the central incisor regions. Therefore the treatment plan may include only two implants in the lateral incisor sites to replace the four anterior teeth. However, if the patient has a tapered arch form or parafunction, this treatment plan is insufficient. The risk of screw loosening, crestal bone loss and resultant soft tissue changes is greater and rarely warrants the risk of reducing the implant number. The two-implant treatment option is often designed for a square dental arch form, in an older female, with little to no parafunction to fabricate an FP-1 prosthesis and a high lip line when the natural canines are present.

When the patient is missing a lateral and both central incisors, the three missing teeth may be safely restored with two implants. One implant (Division B) is positioned in the lateral incisor region, and the other implant (Division A) is placed in the opposite central incisor area (Figure 17-37, *A*). This eliminates a cantilever and decreases the risk of screw loosening. The

WWW.HIGHDENT.IR

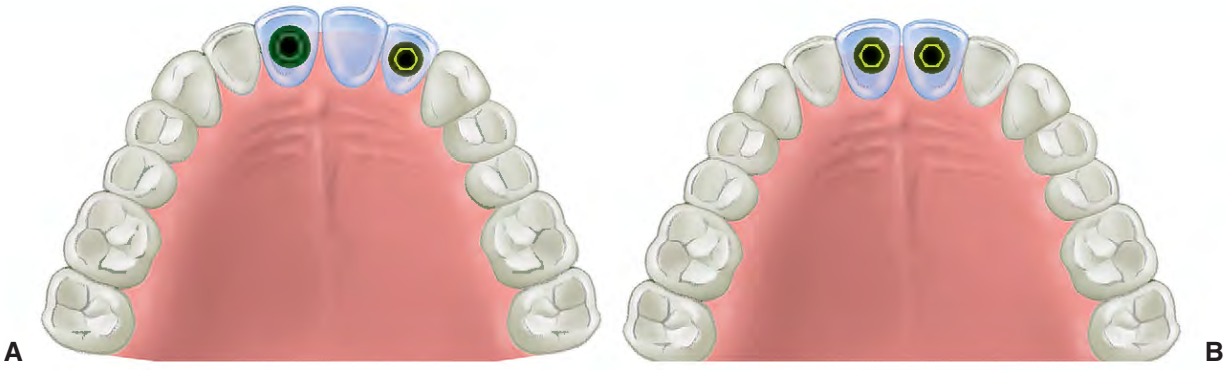

Figure 17-37 **A,** When two central and a lateral incisors are missing, two implants are indicated to restore the missing span. A smaller-diameter implant may be used in the lateral incisor position. **B,** Missing central incisors should be restored with two implants. Most often, narrow-diameter implants are indicated.

interdental papilla of the adjacent natural canine and lateral incisor determine the papilla height next to the adjacent implant crowns.

In the presence of horizontal marginal bone loss on the anterior teeth adjacent to an implant site, orthodontic extrusion may be indicated to correct the interproximal bone level. When this option is used, a veneer is usually required to restore the adjacent tooth after orthodontic extrusion. The restoring dentist may place a veneer and lower the adjacent contact and modify the crown shapes on the implant and natural teeth to a more square form, which decreases the height requirements of the papilla and eliminates the absence of tissue in the interproximal area found in the original condition. These treatment plan decisions should be made before implant insertion.

When the patient is missing the two central incisors, there should be two implants to restore the site. One implant with a cantilevered pontic increases the risk of screw loosening, crestal bone loss, and component fracture. Whenever two implants are used to replace two adjacent central incisors, the implant diameter should most often be Division B (3.5 mm) (Figure 17-37, *B*). This provides greater soft tissue volume between the implants, allows the surgeon to place the implant more distal to avoid the incisive foramen, and leaves a thicker facial cortical plate.

When the patient is missing a lateral and central incisor, two Division B implants may also be used to restore this condition, rather than using a Division A implant in the central incisor position. The additional interproximal space permits an improved soft tissue drape condition.

In general, the premaxilla requires the most varied surgical approaches to improve success and is the most critical region for esthetics and phonetics. Options for Division B and C–w bone more often require augmentation rather than osteoplasty, as advocated in other intraoral regions. The opposing landmark is the floor of the nose, and this structure may be modified slightly by nasal elevation of 1 to 2 mm to improve implant support in C–h ridges for FP-3 or RP-4 prostheses.

COMPLETELY EDENTULOUS MAXILLAE TREATMENT PLANS

A review of the literature indicates that full maxillary fixed implant–supported prostheses are fabricated on an average of six standard-diameter implants with posterior molar cantilevers. An average of four to six implants also are used to support bar overdentures. Yet the edentulous maxilla has the lowest implant survival for either fixed or removable implant restorations, compared with mandibular prostheses.[22-27] All reports concur with the finding that maxillary bone tends to be of poorer quality and volume and presents several biomechanical disadvantages. The author suggests that to compensate for the poor local conditions, a greater number of implants should be planned, along with a greater A-P distance. Therefore there is usually a need for sinus grafts and premaxilla reconstruction to restore the edentulous maxillary arch.

With these concerns in mind, the minimum implant number for a completely edentulous maxillary fixed or RP-4 prosthesis is usually seven in the ovoid arch form. The suggested locations for this arch are: at least one central (or lateral) incisor position, bilateral canine positions, bilateral second premolar sites, and bilateral distal half of the maxillary first molar sites. These are the same positions as for a fixed restoration (see Figure 17-21). These seven implants should be splinted together to function as an arch. These implant positions create sufficient space between each implant to allow for greater implant diameters (when required for force or bone density factors), without concern for the adjacent site. A square dental arch form may use a minimum of six implants: bilateral canines, bilateral second premolars and bilateral first molar sites. The first molar implant sites in a completely edentulous maxilla

WWW.HIGHDENT.IR

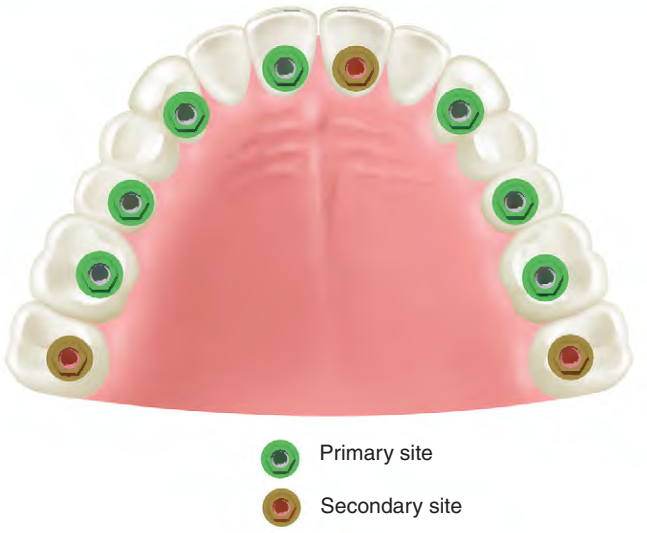

Figure 17-38 The ideal seven-implant positioning for a maxillary edentulous arch includes at least one central incisor position, bilateral canine positions, bilateral second premolar sites, and bilateral sites in the distal half of the first molars. In case of heavy stress factors, an additional anterior implant and bilateral second molar positions (to increase the anteroposterior distance) may be of benefit.

almost always require sinus grafting, because most edentulous maxillary posterior regions are inadequate in height.

When force factors are moderate or the dental arch form is tapered, the minimum implant number should increase to eight implants. When eight implants are selected, the additional implant is usually placed in the premaxilla, in the contralateral central (or lateral) incisor position. When force factors are greater than usual or bone density is poorer, additional implants should be used in any of the arch forms. In the square and ovoid arch form, at least one additional implant is positioned in the premaxilla. In addition, for patients with higher force factors or poor bone density, two additional implants are planned in the distal half of the second molar position to improve the arch form, increase the A-P distance compared with the first molar site, and add an additional implant where the bone density is poor and force factors are increased (Figure 17-38). This also is an excellent biomechanical design to minimize stress when a dentate tapered arch form is restored in an ovoid or square residual ridge form. These implant number and position guidelines also may counter the effect of an incisal cantilever off the residual anterior bone for an esthetic tooth position and is indicated for patients with chronic parafunction (such as bruxism).

The disadvantage of second molar implants for an ideal treatment plan is the additional cost of the second molar implant and restorations. Many patients do not display the second molar and do not require this tooth for function. As such, to decrease the cost, the restoring dentist may use a coping splinted to the arch, rather than a porcelain-fused-to-metal crown. The reason for this implant position is for force transfer, not necessarily esthetics or function.

Box 17-2 Multiple Implant Size Selection Criteria for FP-1 Prostheses in the Maxilla

- Natural tooth 2 mm below cement-enamel junction
- 1.5 mm from adjacent tooth
- 1.5-mm facial bone
- 3 mm from adjacent implant
- 3- to 4-mm-diameter for anterior maxilla
- 4-mm-diameter minimum for posterior maxilla

In conclusion, the number of implants used in an edentulous maxilla may range from 6 to 10. The number of implants needed in an edentulous premaxilla is related to arch shape. When force factors are moderate to severe or bone density is poor, more implants should be inserted and in greater diameter to enhance the surface area. In addition, the A-P distance should be increased.

Multiple Anterior Implant Sizes: Anterior Tooth Replacement

Several conditions should be considered for the proper implant diameter, including tooth size, distance from an adjacent tooth, interimplant distance, facial bone dimension, and loading forces.

A primary factor for implant size is the necessary distance from an adjacent tooth root or implant. The horizontal dimension of a wedge-shaped bone defect around an implant at the crest of the ridge from the biological width, implant design, or occlusal overload ranges from 0.5 to 1.4 mm.[20,21] Initial vertical bone loss around an implant during the first year of loading varies and ranges from 0.5 to more than 3 mm. When the implant is closer than 1.5 mm to an adjacent natural root, the wedge-shaped vertical defect may evolve into a horizontal defect, creating bone loss on the adjacent tooth root. This is of utmost importance because the interseptal bone height in part determines the incidence of presence or absence of the interdental papillae between the teeth or implants, as well as the incidence of probing depth greater than 5 mm.[28] As a consequence, whenever possible, an implant should be at least 1.5 mm from the adjacent teeth (Box 17-2).

When implants are placed adjacent to each other, a minimum distance of 3 mm is suggested to accommodate eventual crestal bone loss and maintain interseptal bone levels.[20] When placing two adjacent implants, their diameter should often be reduced, compared with the ideal dimensions of a single-tooth implant. The ideal diameter of an implant for an FP-1 prosthesis also should consider the faciopalatal dimension of bone.

Table 17-2 Maxillary Teeth Dimensions (Average)

TYPE OF TEETH	CERVICO-INCISAL HEIGHT (mm)	MESIODISTAL CROWN (mm)	MESIODISTAL CERVIX (mm)	MESIODISTAL CEJ (–2 mm)	FACIOLINGUAL CROWN (mm)	FACIOLINGUAL CERVIX (mm)
Central incisor	10	8.6	6.4	5.5	7.1	6.4
Lateral incisor	9	6.6	4.7	4.3	6.2	5.8
Canine	10	7.6	5.6	4.6	8.1	7.6
First premolar	8	7.1	4.8	4.2	9.2	8.2
Second premolar	8	6.6	4.7	4.1	9.0	8.1
First molar	8	10.4	7.9	7.0	11.5	10.7
Second molar	7	9.8	7.6	7.0	11.4	10.7

CEJ, Cement-enamel junction.

The 1.4-mm-wide defect, which may form next to the implant after loading, forms 360 degrees around the implant crest module. As such, if less than 1.5 mm of bone is present on the facial aspect of an implant, the vertical defect becomes a horizontal defect and the tissue recedes when it is thin or forms a soft tissue pocket when it is thick. The first condition decreases esthetics, as the implant crest module may even become visible, whereas the second condition increases the risk of peri-implantitis and further bone loss. Therefore the ideal implant position and implant diameter should have 1.5 mm or more of bone on the facial of the implant.

The mean papilla height between two adjacent teeth is 3.4 mm, ranging from 1 to 7 mm, and the usual range of interimplant papillary height is 2 to 4 mm. Therefore, when an FP-1 restoration is desired, the prosthesis design (square tooth forms) and implant positions may need to be altered accordingly to optimize an esthetic result.[28]

The amount of force transmitted to the implant body and abutment screw is also a consideration for implant diameter. The larger the diameter, the less stress to the crestal bone and components. Therefore, in a patient with moderate to severe bruxism, a larger-diameter implant should be used, especially in the canine position, to assist in posterior disclusion of the teeth and canine guidance.

The implant dimension in question is the size of the crest module, not the implant body dimension. For example, a 4.1-mm crest module (on a 3.75-mm implant body) needs 7.1 mm of mesiodistal crestal bone, a 3.5-mm crest module (on a 3.25-mm implant body) is indicated for 6.5 mm of bone, and a 5.2-mm crest module requires 8.2 mm of bone.

The difference in the emergence profile between a 4-mm-diameter implant and a 5-mm-diameter implant is negligible and often not clinically relevant. However, the larger implant diameter has less surrounding soft tissue and is more difficult to control the creation of a papilla. Therefore, when in doubt, a smaller-diameter implant should be selected in the esthetic zone. Thus a 3.5- to 4-mm-diameter implant often is used in the central implant position for an FP-1 prosthesis. Likewise, a 3-mm-diameter implant often is used for a lateral incisor FP-1 restoration. The exceptions to this rule may be in a bruxing patient when the benefits of a larger-diameter implant with decreased occurrence of abutment screw loosening, crestal bone loss, and long-term body failure are more desirable. However, splinting multiple implants is more effective than implant diameter to decrease stress complications.

When the implants are out of the esthetic zone (FP-2, FP-3, RP-4, RP-5 prostheses), the diameter of the implant is more related to the amount of force applied to the implant-bone-prosthetic system. Facial bone dimensions and interimplant spacing may be less important. The posterior regions should most often use 3.7- to 4.2-mm-diameter implants in premolars and 5-mm diameter implants in molars, because the force factors are greater and the bone density is poorer. The natural maxillary molars have the greatest diameter and largest surface area of any teeth. The maxillary molars have a 200% increase in surface area compared with the premolar teeth. The first molar is 10.4 mm in mesiodistal dimension, and the second molar is 9.8 mm. The cement-enamel junction (CEJ) dimensions of these teeth are 7.9 mm and 7.6 mm, respectively, and 2 mm below the CEJ, these teeth are both 7 mm in size (Table 17-2). However, the ideal implant diameter is 5 mm to 6 mm for the maxillary molars. Because titanium is 5 to 10 times more rigid than natural teeth, the modulus of elasticity for an implant of sizes greater than 6 mm

Figure 17-39 A large crown height space may be restored with a hybrid prosthesis of a metal framework, porcelain denture teeth, and acrylic.

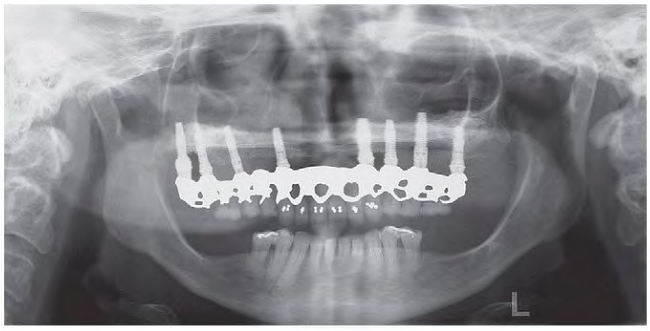

Figure 17-40 Panoramic radiograph of an FP-3 hybrid maxillary prosthesis, with a metal framework, porcelain denture teeth, and acrylic.

may be too great and may cause stress shielding and bone loss. The 6-mm diameter should not be used in the anterior regions, because the magnitude of the force is not large enough to strain the bone within the ideal physiologic window next to such a large implant. As a consequence, more crestal bone loss is often observed.

When the diameter or designs of molar implants do not provide sufficient surface area, the number of implants should be increased. Rather than one implant replacing a molar, two implants of 4 mm in diameter should be considered to compensate for very soft bone types or unfavorable force factors (e.g., parafunction).

The number of implants in the patient with multiple missing posterior teeth is often increased, especially when force factors are high, bone density is poor, and larger implant diameters are not used. When multiple adjacent posterior teeth are missing, the number of implants is more important than the implant size. When adjacent molars are missing, three regular-size implants are often considered when implant diameter cannot be increased to 5 or 6 mm.

The dentist may use the following guidelines for implant locations in a completely edentulous maxilla:

1. The bilateral midcanine position is a key implant position and is planned for 4-mm-diameter implants (Guideline 3).
2. The center of the first premolar is planned 7 mm distal from the center of the canine implant (for a 4.1-mm-diameter implant). This is an optional implant site when parafunction is moderate to severe.
3. The center of the second premolar is 7 mm distal from the first premolar site (14 mm from the midcanine position) for a 4.1-mm-diameter implant on each side. This is a key implant position (Guideline 2).
4. The center of the first molar is 8 to 10 mm distal from the mid second premolar implant (this places the implant in the distal of the first molar and increases the A-P distance. Ideally, the implant should be 5 to 6 mm in diameter. This is a key implant position (Guideline 3).
5. The center of the second molar is 8 to 10 mm distal from the center of the first molar. This position is most important for the edentulous arch with a tapered dentate arch form, D4 bone types, or severe force factors.

Figure 17-41 The hybrid fixed maxillary prosthesis in Figure 17-40 may be made esthetic, has reduced laboratory costs, is lightweight, and may be repaired more easily.

Fixed Prosthesis Design

The amount of CHS in an edentulous region greatly varies. The larger crown height space may facilitate the fabrication process of removable prostheses through easier denture tooth setup and greater bulk of acrylic to strengthen the prosthesis. However, the same space may be of concern for porcelain-metal fixed restorations. The replacement teeth appear elongated and often need the addition of gingival tone materials to replace the soft tissue in the esthetic regions. The greater impact force on implants compared with teeth, coupled with an increased crown height, results in increased moment forces on implants and increased risk of component and material fracture. These problems are noted especially with less favorable biomechanics on cantilevered sections of fixed restorations. An excessive crown height may cause greater prosthesis failure through mechanical increase in force (vertical cantilever) and fabrication complications (metal and porcelain shrinkage after casting or baking). In addition, the increased crown height dramatically increases the weight and the cost of the prosthesis.

An alternative method to fabricate fixed prostheses for a CHS of 15 mm or more is the fixed complete denture hybrid prosthesis, with a smaller metal framework, denture teeth, and acrylic resin (Figures 17-39 to 17-41). This restoration design was made popular by Zarb et al.[29] and has been used on osteointegrated implants for more than two decades. This design is less expensive to fabricate, is highly esthetic (premade denture teeth), easily replaces teeth and soft tissue in appearance (pink acrylic) (FP-3), is lightweight, and is easier to repair. The denture teeth in these prostheses should not be acrylic or composite, owing to a high fracture rate. Instead, porcelain denture teeth are suggested. Because acrylic resin acts as an intermediary between the porcelain denture teeth and metal substructure, the impact force during dynamic occlusal loading may be reduced compared with a porcelain-metal restoration. As a general rule, fixed hybrid prostheses (FP-3) are used for situations with CHSs of 15 mm or greater. However, when the CHS is less than 15 mm, the decrease in bulk of acrylic increases the risk of fracture and complications. Therefore a porcelain-metal restoration is suggested.

Maxillary Overdenture Options

The primary advantage of a maxillary IOD compared with a fixed prosthesis is the ability to provide a flange for maxillary lip support and the reduced fee compared with a fixed restoration. As a consequence, before the selection of a specific prosthesis type and to facilitate the diagnosis, the labial flange above the maxillary teeth of the existing denture (or wax try-in of a new prosthesis) may be removed and the facial appearance of the maxillary lip without labial support assessed. If the maxillary lip requires additional support, two options are available:

1. A bone graft to the premaxilla is performed before or in conjunction with implant insertion or at uncovery for a fixed implant prosthesis.
2. A maxillary IOD is fabricated with a labial flange on the prosthesis.

Maxillary IOD complications, such as attachment wear and prosthesis or component fracture, are more frequent than with a fixed restoration and primarily occur as a result of inadequate bulk of acrylic and minimal strength of the small framework, compared with a fixed restoration (Table 17-3).

Fewer reports have been published for maxillary IOD compared with the mandible. Most of these reports discuss RP-5 restorations with posterior soft tissue support and anterior implant retention. According to Goodacre, the restoration with the highest implant failure rate is a maxillary overdenture (19% failure rate).[1]

In 1994, Palmqvist et al.[30] reported similar poor results in a 5-year prospective, multicenter study on 30 maxillae and 103 mandibles. Jemt and Lekholm[31] reported that the survival rate of mandibular implants was 94.5% versus 100% for mandibular prostheses. In the maxillae the implant survival was 72.4% and the prosthesis survival was 77.9%. The authors suggested that the treatment outcome may be predicted by bone volume and quantity. A prospective study by Johns et al. reported on maxillary IODs at 1 year, 3 years, and 5 years.[32-34] Sixteen patients were followed throughout the whole study with a cumulative success rate of 78% for prostheses and 72% for implants. A pooled implant survival of maxillary removable designs was reported at 76.6% at 5 years.[22-27,29-35]

Alternatively, Misch followed 75 maxillary IODs (RP-4) and 615 implants for 10 years with 97% implant survival and 100% prosthesis survival. The primary differences in these treatment modalities have been a completely implant-supported, retained, and stabilized maxillary IOD (RP-4); a greater implant number; and key implant positions following the guidelines of treatment planning based upon basic biomechanical concepts to reduce failure and decrease risks.

Maxillary Implant Overdenture Treatment Options

Only two treatment options are available for maxillary IODs, whereas five treatment options are available for the mandibular IOD. The difference is due primarily to biomechanical disadvantages of the maxilla compared with the mandible. Independent implants are not an option because bone quality and force direction are severely compromised. Cantilever bars usually are not recommended for the same reasons.[36,37] As such, the two treatment options are limited to an RP-5 restoration

WWW.HIGHDENT.IR

with four to six implants with some posterior soft tissue support, or an RP-4 restoration with 7 to 10 implants (which is completely supported, retained, and stabilized by implants). The CHS is critical for maxillary overdentures, and more often a lack of space may compromise tooth position compared with the mandibular situation (Figure 17-42). The maxillary anterior CHS requirement is greater than the posterior dimension. A minimum of 15 mm of anterior CHS and 12 mm of posterior space is required for IOD because of the greater anterior teeth coronal dimensions and specific locations.

Option 1: Maxillary RP-5 Implant Overdenture

The first treatment option is an RP-5 prosthesis. This option is not as beneficial to the patient, compared with mandibular RP-5 restorations. A maxillary denture often has good retention, support, and stability. An RP-5 maxillary IOD may rock and have more movement than a denture, as the anterior implants act as a fulcrum under the prosthesis. The major advantages of an RP-5 maxillary IOD is the maintenance of the anterior bone and a less-expensive treatment option than an RP-4 or fixed prosthesis. The treatment is less expensive because bilateral sinus grafts are not required and molar implants are not required. Therefore this treatment plan is often used as a transition to an RP-4 prosthesis when financial considerations of the patient require a staged treatment over several years.

The first treatment option for a completely edentulous maxilla uses four to six implants supporting an RP-5 prosthesis, of which at least three are positioned in the premaxilla (Figure 17-43). Based on the poor success rates reported in the literature, specific biomechanical requirements, and poor bone quality, the fewest number of implants for an RP-5 maxillary overdenture should be four, with a wide A-P spread. Implant number and location are more important than implant size, but the implants should be at least 9 mm in length and 3.5 mm in body diameter. The key implants are positioned in the bilateral canine regions (Guideline 3 of treatment planning) and at least one central incisor position (Guideline 2 of treatment planning). Other secondary implants may be placed in the first or second premolar region (Guideline 4 of treatment planning). When an implant cannot be placed in at least one central incisal position, the incisive foramen may be considered for implant insertion. Another alternative is the use of a lateral incisor implant. In such cases, owing to the reduced A-P spread and the lateral incisor in the anterior-most implant site, the second premolar position also should be used on the contralateral side (along with

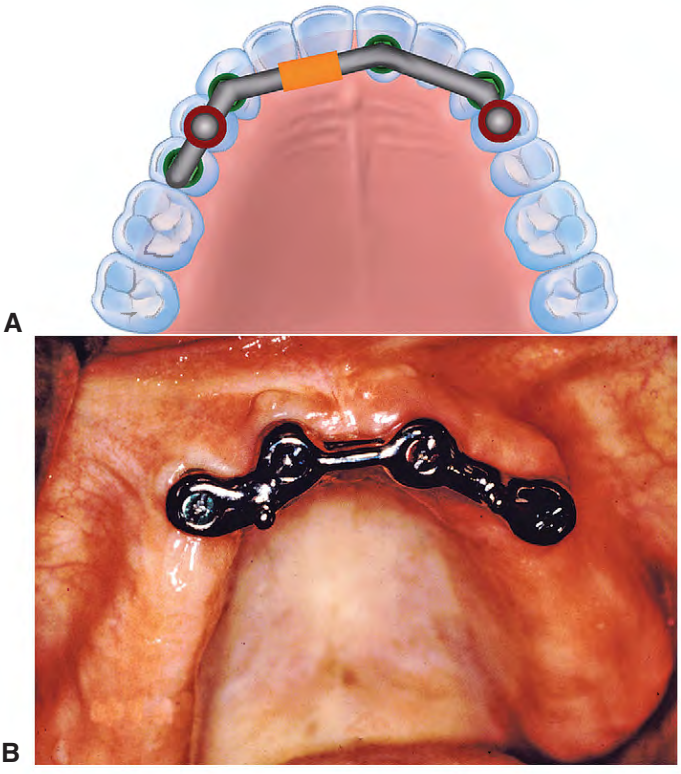

Figure 17-43 **A,** At least four implants, splinted together, are indicated for a maxillary IOD, at least three of which are placed in the premaxilla **(B)**.

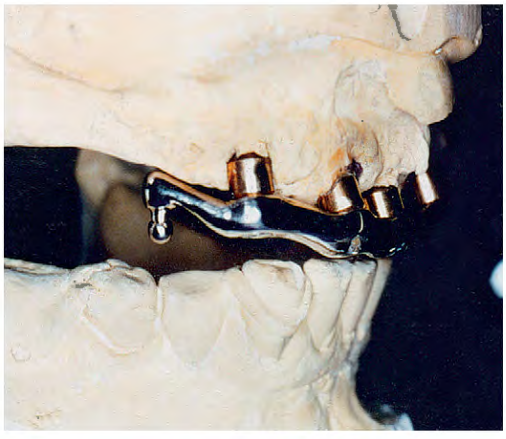

Figure 17-42 An insufficient crown height space is a major problem for the fabrication of a maxillary overdenture.

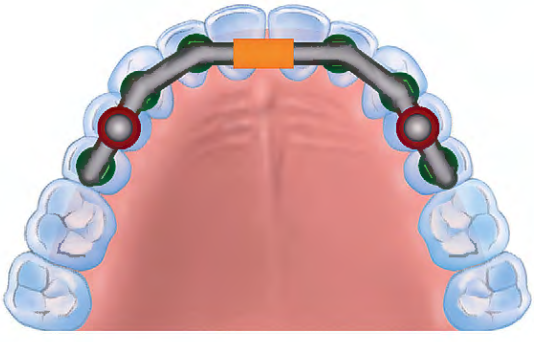

Figure 17-44 An alternate design with six implants includes key implants in the canine regions, implants in the lateral incisor regions, and secondary implants in the second premolar regions to improve the anteroposterior (A-P) spread. Dolder clips or O-rings can be used in such a way as to allow two directions of prosthesis movement.

WWW.HIGHDENT.IR

the canine) to improve the A-P spread. Six implants are often indicated for an RP-5 prosthesis when force factors are greater (Figure 17-44).

The implants are always splinted together with a rigid bar. There is no distal cantilever, and the bar design should follow the dental arch form but slightly lingual to the maxillary anterior teeth. The prosthesis should have at least two directions of movement; however, three or more are preferred. Therefore a Dolder clip or O-ring may be used if it is placed in the center of the arch and perpendicular to the midline. A Dolder clip has a spacer over the clip to allow some vertical movement before rotation. O-rings may be used just distal to the last abutment on each side or between the implants. When intermediate O-rings are used, relief is provided over the top of the implants distal to the bar to allow prosthesis movement toward the tissue under posterior occlusal forces.

The maxillary RP-5 IOD is designed exactly as a complete denture with fully extended palate and flanges. When O-rings are used to retain the restoration, they may be positioned more distal than a Hader clip, often immediately distal to the canine position. The restoration should be allowed to move slightly in the incisal region during function so that the restoration may rotate toward the posterior soft tissue around a fulcrum located in the canine or premolar position. The benefits of an RP-5 maxillary overdenture are retention and stability from the implants. Posterior support is obtained from the soft tissue. Of course, the other primary benefit is the maintenance of the premaxilla bone, because of the implant stimulation. There is also a reduced fee compared with an RP-4 prosthesis, as bilateral sinus grafts are not required for molar implants and the number of implants may be as few as four.

Option 2: Maxillary RP-4 Implant Overdenture

The second option for a maxillary IOD is an RP-4 prosthesis with 7 to 10 implants, which is rigid during function (Figure 17-45). This option is the preferred IOD design because it maintains greater bone volume and provides improved security and confidence to the patient compared with a denture or RP-5 restoration. However, the cost of treatment is similar to a fixed prosthesis. The loss of bone in the premaxilla requires a bone graft or hydroxyapatite graft for lip support for a fixed prosthesis or a labial flange for lip support for a maxillary IOD.

Unfortunately, many practitioners believe that the RP-4 overdenture requires fewer implants and less attention to the biomechanics of occlusal load, just because the restoration is removable. In the author's opinion, this is a primary cause of implant failure in maxillary IODs.

Combined factors such as reduced cost, patient fear of bone grafting, and lack of advanced training of the doctor are often the determining factors motivating the choice for a maxillary IOD. Bone grafts for the entire premaxilla for a fixed prosthesis may require the iliac crest as a donor site because larger volumes of bone are required.

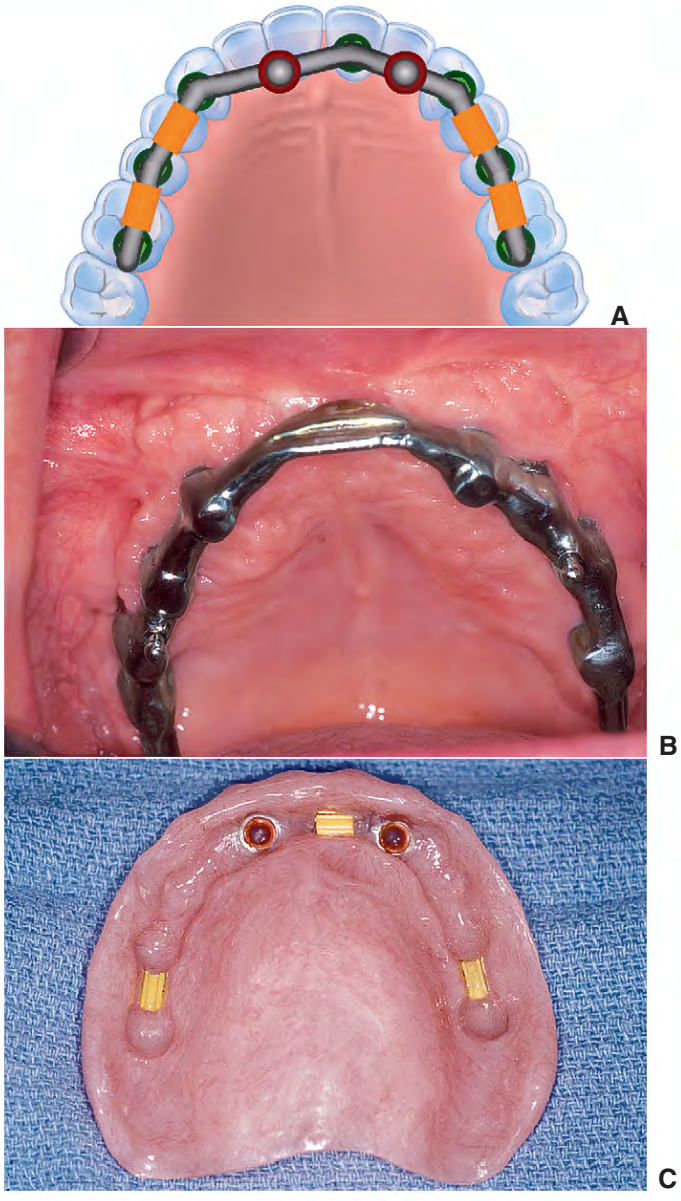

Figure 17-45 **A** and **B,** A maxillary overdenture bar RP-4 prosthesis is supported by 7 to 10 implants and is rigid during function. **C,** A maxillary IOD should have a palatal coverage to decrease fracture, food impaction, and speech problems.

Treatment planning for RP-4 maxillary overdentures is very similar to fixed prosthesis, because the IOD is fixed during function. Two of the key implant positions for the RP-4 maxillary IOD are in the bilateral canines and distal half of the first molar positions (Guideline 3 in treatment planning). These positions usually require sinus grafts in the molar position. Additional posterior implants are located bilaterally in the premolar position (Guideline 2 in treatment planning), preferably the second premolar site. In addition, at least one anterior implant between the canines often is required (Guideline 2 in treatment planning). The anterior implant often

WWW.HIGHDENT.IR

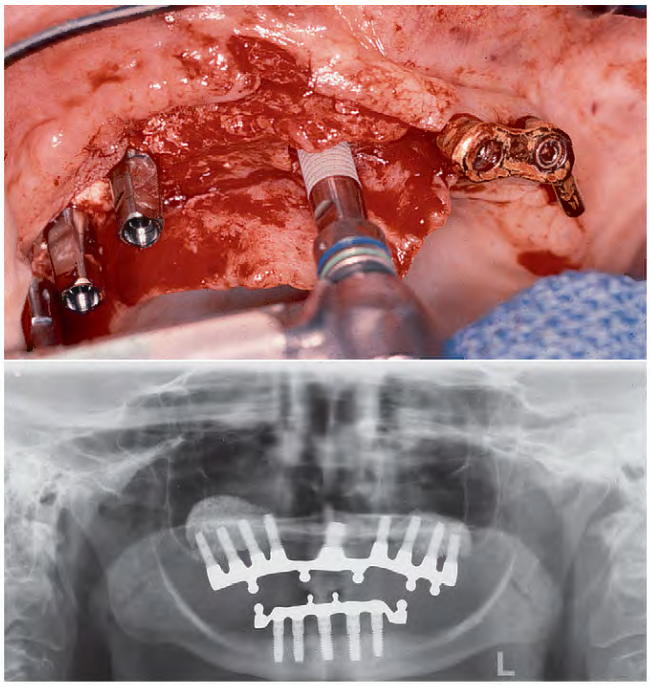

Figure 17-46 **A,** An anterior implant may be positioned in the incisive canal when the residual ridge is insufficient for an implant in the central incisor position. **B,** A panoramic radiograph of maxillary and mandibular implants supporting RP-4 prostheses. The central incisive implant allows the use of three implants in the premaxilla, splinted to posterior implants.

may be placed in the incisive canal, when inadequate bone width is present (Figure 17-46). Therefore, seven implants is the minimum number for an RP-4 treatment option. When force factors are greater, the next most important sites are the second molar positions (bilaterally) to increase the A-P spread and improve the biomechanics of the system. A tenth implant may be placed in the premaxilla for a tapered arch form.

The 7 to 10 implants are splinted together around the arch with a rigid bar (Guideline 5 in treatment planning). Four or more attachments are usually positioned around the arch. This provides a retentive, stable overdenture prosthesis. Usually palatal coverage is maintained. This helps prevent speech problems and food impaction.

The occlusal scheme for this RP-4 restoration is similar to a fixed prosthesis: centric occlusion around the arch and only anterior contact during mandibular excursions (unless opposing a mandibular complete denture). The maxillary overdenture should be removed during sleep to prevent nocturnal parafunction. If the patient wears maxillary and mandibular overdentures, only the mandibular restoration needs to be removed.

Fixed Prosthesis versus Overdenture Complications

The palatal coverage of most maxillary IODs should be similar to a complete denture. The extent of range from full to horseshoe palate designs has been reported in the literature with varied degrees of success.[26,27,36] Many maxillary denture wearers accommodate easily to the acrylic resin palate. Yet many restoring dentists routinely eliminate the palate on maxillary implant, overdentures with consequences such as food entrapment (because the tongue often crushes food against the palate and pushes the food debris under the restoration) and impaired speech (because air is forced under the palatal flange and over the labial flange of the denture). The patient rarely complains of these two problems with a denture and, as a result, is unhappy with the final implant restoration. In addition, the risk of prosthesis fracture is increased when the palate is removed because the bulk of acrylic is reduced. Therefore, the palate of the prosthesis usually should be maintained with the IOD.

Some patients express a primary desire to eliminate the palate of the maxillary complete denture. These patients include gaggers and patients uncomfortable with anything approaching the soft palate, patients with tori or exostoses, singers and actors because of a perceived change of voice caused by the change in volume from the prosthesis, food and wine consumers who use their palate to taste subtle differences in preparations, and a new denture wearer unfamiliar with the palatal aspect of a maxillary denture. As a result, patient needs and desires may require the natural palate of the patient to be left uncovered when wearing a maxillary overdenture.[38,39]

To reduce the complications of speech or food impaction, the following technique has been used with some success. The palate of the preexisting prosthesis is coated with a pressure-indicating paste or spray. The patient is asked to pronounce the linguoalveolar consonants *T* and *D*. In dentate patients, when these sounds are produced, the tip of the tongue contacts the anterior alveolar ridge and the sides of the tongue are in tight contact with the maxillary teeth and palatal gingiva. The maxillary overdenture palate is not eliminated any farther than 5 mm posterior to the tongue contact area. This ensures that the tongue will still contact the acrylic resin on the palate and will prevent food and air from being forced under the denture. The processing model for the prosthesis then is scored 1 mm wide and 1 mm deep with a round bur corresponding to this position. The score line proceeds from the hamular notch in the posterior, along the hard palate 5 mm medial to the alveolar ridge–palatal line angle (position of the greater palatine artery), to the anterior aspect 5 mm distal to the tongue position noted previously. The cast is not scored over the midpalatal suture because this soft tissue is very thin and cannot be depressed readily. When the denture is processed, a small lip of acrylic resin fills this score line, and when the overdenture is inserted, it will depress the tissue along this region gently and ensure intimate tissue contact. This further

WWW.HIGHDENT.IR

prevents food and air from being pushed under the overdenture. Because the "D" and "T" position of the tongue is several millimeters posterior to the position of the maxillary teeth, several millimeters of acrylic resin remain on the premaxilla. This reduces the risk of fracture of the maxillary overdenture.

The anterior implants, connection bar, and attachments should be lingual to the position of the anterior teeth so as not to interfere with proper denture tooth position. However, this position may increase the height of the palatal slope in the region of the premaxilla compared with the original denture. To reduce this occurrence, a low-profile bar and attachment is often the design of choice to minimize the prosthesis bulk. Before designing the connecting bar and attachment design, a vacuum or press form is made of the contour of the preexisting denture and overdenture try-in prosthesis (similar to the method used for the surgical template), and the template helps design the bar-attachment system within the confines of the final prosthesis.

SUMMARY

Maxillary IODs may be as predictable as mandibular overdentures when biomechanical considerations specific to the maxilla are incorporated in the treatment plan. In general, this requires implants in greater numbers and a greater awareness of prosthetic principles.

Only two maxillary IOD treatment options are available. The fewest number of implants for this restoration is four to six implants to support an RP-5 prosthesis. A rigid IOD (RP-4) most often requires the placement of seven or more implants. In other words, maxillary IODs are completely different than their mandibular counterpart. In the completely edentulous maxilla, an IOD is often the treatment of choice. Unlike in the mandible, the maxillary lip often requires additional support as a consequence of bone loss. An ideal high lip line exposes the interdental papillae between the anterior teeth. Using overdentures to replace the hard and soft tissue is easier than attempting to do this with bone and soft tissue or porcelain-to-metal restorations.

A completely implant-supported overdenture requires the same number and position of implants as a fixed restoration. Thus sinus grafts and anterior implants usually are indicated, whether the restoration is fixed or removable.

Chapter 18

Treatment Planning for the Edentulous Posterior Maxilla

Carl E. Misch

Maxillary posterior partial or complete edentulism is one of the most common occurrences in dentistry. Seven percent of the adult population in the United States (12 million people) are missing all of their maxillary teeth and have at least some mandibular dentition—a condition that occurs 35 times more frequently than complete mandibular edentulism opposing maxillary teeth.[1,2] In addition, 10.5% of the adult population has no teeth. Therefore 30 million people in the United States or 17.5% of the adult population are missing all of their maxillary teeth. In addition, 20% to 30% of the adult partially edentulous population older than 45 years of age is missing maxillary posterior teeth in one quadrant, and 15% of this age group is missing maxillary dentition in both posterior regions.[2] In other words, approximately 40% of adult patients are missing at least some maxillary posterior teeth. Therefore the maxillary posterior region is one of the most common areas to be involved in an implant treatment plan to support a fixed or removable prosthesis.

The maxillary posterior edentulous region presents many unique and challenging conditions in implant dentistry. However, existing proven treatment modalities make procedures in this region as predictable as in any other intraoral region. Most noteworthy surgical methods include sinus grafts to increase available bone height, onlay grafting to increase bone width, and modified surgical approaches to insert implants in poorer bone density.[3] Grafting of the maxillary sinus to overcome the problem of reduced vertical available bone has become a very popular and predictable procedure over the last decades. After the initial introduction by Tatum in the mid-1970s and the initial publication of Boyne and James in 1980, many studies have been published about sinus grafting with results higher than 90%.[4-30]

This chapter addresses the treatment planning concepts specific to the maxillary posterior partial or complete edentulous regions.

ANATOMICAL CONSIDERATIONS FOR THE POSTERIOR MAXILLA

Local anatomical conditions of the edentulous alveolar ridges in the posterior maxilla may be unfavorable for implant placement. The available alveolar bone height is lost in the posterior maxilla as a result of periodontal disease before tooth loss. The maxillary molar regions have distal furcation involvement frequently, because the furca is directly under the distal contact and has no facial or palatal access for hygiene. The furca is also narrower than many dental curettes, and it is difficult to eliminate calculus after it has formed. As a result, periodontal disease is common and is associated with loss of bone height before tooth loss.

The dentate maxilla has a thinner cortical plate on the facial compared with the mandible. In addition, the trabecular bone of the posterior maxilla is finer than other dentate regions. The loss of maxillary posterior teeth results in an initial decrease in bone width at the expense of the labial bony plate. The width of the posterior maxilla decreases at a more rapid rate than in any other region of the jaws.[27] The resorption phenomenon is accelerated by the loss of vascularization of the alveolar bone and the existing fine trabecular bone type. However, because the initial residual ridge is so wide in the posterior maxilla, even with a 60% decrease in the width of the ridge, adequate-diameter root form implants usually can be placed. Moreover, the ridge progressively shifts toward the palate until the ridge is resorbed into a medially positioned narrower bone volume.[31] The posterior maxilla continues to progressively remodel toward the midline as the bone resorption process continues. This will result in the buccal cusp of the final restoration often being cantilevered facially to satisfy esthetic requirements at the expense of biomechanics in the moderate to severe atrophic ridges (Figure 18-1).

WWW.HIGHDENT.IR

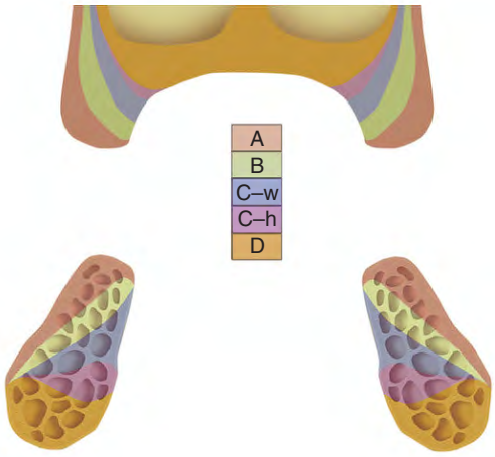

Figure 18-1 The loss of posterior teeth causes resorption of the posterior maxilla. As the edentulous ridge resorbs from Division A to Division D, the crest of the ridge shifts toward the palate. As a consequence, without facial augmentation, the endosteal implant may be placed under the lingual cusp of the original natural tooth position.

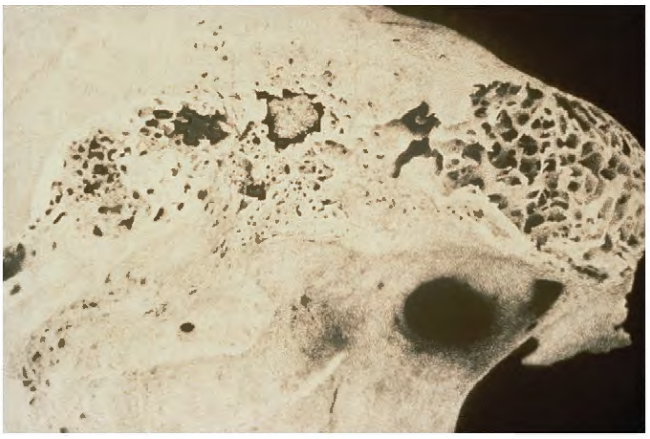

Figure 18-2 The density of the bone in the edentulous posterior maxilla is poorer than in any other region. Because of the lack of cortical bone on the crest, the thin trabecular bone is less strong and has a lower modulus of elasticity.

Special Considerations for the Posterior Maxilla

The crown height space should be evaluated before implant placement. After the occlusal plane is properly restored or modified, the crown height space ideally should be greater than 8 mm. When less clinical space is available for prosthodontic reconstruction, a gingivectomy is first considered, because it is not uncommon for excess tissue thickness to be present in this region. However, if tissue reduction cannot correct the clinical crown height problem, osteoplasty, or vertical osteotomy of the maxillary posterior alveolar process are indicated to restore the correct ridge orientation before surgery.

Poor Bone Density

In general, the bone quality is poorest in the edentulous posterior maxilla compared with any other intraoral region.[32] A literature review of clinical studies from 1981 to 2001 reveals the poorest bone density may decrease implant loading survival by an average of 16% and has been reported as low as 40%.[33] The cause of these failures is related to several factors. Bone strength is directly related to its density, and the poor density bone of this region is often 5 to 10 times weaker in comparison to bone found in the anterior mandible.[34] Bone densities directly influence the percent of implant-bone surface contact, which accounts for the force transmission to the bone. The bone-implant contact is least in D4 bone compared with other bone densities. The stress patterns developed in poor bone density migrate farther toward the apex of the implant. As a result, bone loss is more pronounced and occurs also along the implant body, rather than only crestally as in other denser bone conditions. Type IV (D4) bone also exhibits the greatest biomechanical elastic modulus difference when compared with titanium under load.[34] This biomechanical mismatch develops a higher strain condition to the bone, which may be in the pathologic overload range. As such, strategic choices to increase bone-implant contact are suggested.

In the posterior maxilla, the deficient osseous structures and an absence of cortical plate on the crest of the ridge further compromise the initial implant stability at the time of insertion (Figure 18-2). The labial cortical plate is thin and the ridge is often wide. As a result, the lateral cortical bone-implant contact to stabilize the implant is often insignificant. Therefore initial healing of an implant in Type IV bone is often compromised, and clinical reports indicate a higher initial healing success than with D2 or D3 bone.

ANATOMY

The maxillary sinuses were first illustrated and described by Leonardo Da Vinci in 1489 and later documented by the English anatomist Nathaniel Highmore in 1651.[35] The maxillary sinus—or antrum of Highmore—lies within the body of the maxillary bone and is the largest and first to develop of the paranasal sinuses (Figure 18-3). Adult maxillary sinuses are pyramid-shaped, air-filled cavities that are bordered by the nasal cavity. There is much debate about the actual function of the maxillary sinus. Possible theorized roles of the sinus include weight reduction of the skull, phonetic resonance, participation of warming and humidification of inspired air, and olfaction. A biomechanical adaptation of the maxillary sinus directs forces away from the orbit and cranial cavity when a blow is delivered to the midface.

Expansion of the Maxillary Sinus

A primary pneumatization occurs at about 3 months of fetal development by an outpouching of the nasal

WWW.HIGHDENT.IR

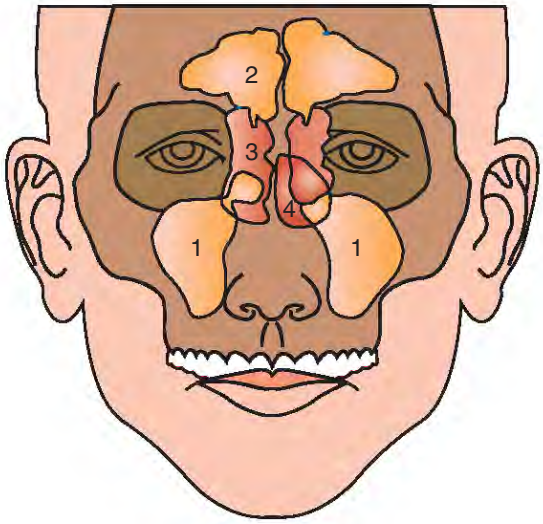

Figure 18-3 The maxillary sinus *(1)* is the largest of the four paranasal sinuses. The initial maxillary sinus formation is completed at age 16 to 18 years. *2,* Frontal sinus; *3,* ethmoid sinus; *4,* sphenoid sinus.

mucosa within the ethmoid infundibulum. At that time, the maxillary sinus is a bud situated at the infralateral surface of the ethmoid infundibulum between the upper and middle meatus.[36] Prenatally, a secondary pneumatization occurs. At birth, the sinus is still an oblong groove on the mesial side of the maxilla just above the germ of the first deciduous molar.[36]

At birth, the sinus cavities are filled with fluid. Postnatally and until the child is 3 months old, the growth of the maxillary sinus is closely related to the pressure exerted by the eye on the orbit floor, the tension of the superficial musculature on the maxilla, and the forming dentition. As the skull matures, these three elements influence its three-dimensional development. At 5 months, the sinus appears as a triangular area medial to the infraorbital foramen.[37,38]

During the child's first year, the maxillary sinus expands laterally underneath the infraorbital canal, which is protected by a thin bony ridge. The antrum grows apically and progressively replaces the space formerly occupied by the developing dentition. The growth in height is best reflected by the relative position of the sinus floor. At 12 years of age, pneumatization extends to the plane of the lateral orbital wall, and the sinus floor is level with the floor of the nose. During later years, pneumatization spreads inferiorly as the permanent teeth erupt. The adult sinus has a volume of approximately 15 mL ($34 \times 33 \times 23$ mm). The main development of the antrum occurs as the permanent dentition erupts and pneumatization extends throughout the body of the maxilla and the maxillary process of the zygomatic bone. Extension into the alveolar process lowers the floor of the sinus about 5 mm. Anteroposteriorly, the sinus expansion corresponds to the growth of the midface and is completed only with the eruption of the third permanent molars when the young person is about 16 to 18 years of age.[35-39]

In the adult, the sinus appears as a pyramid of four bony walls, the base of which faces the lateral nasal wall and the apex of which extends toward the zygomatic bone (Figure 18-4). The floor of the maxillary sinus cavity is reinforced by bony or membranous septa joining the medial or lateral walls with oblique or transverse buttresslike webs. They develop as a result of genetics and stress transfer within the bone over the roots of teeth. These have the appearance of reinforcement webs in a wooden boat and rarely divide the antrum into separate compartments. These elements are present from the canine to the molar region and tend to disappear in the maxilla of the long-term edentulous patient when stresses to the bone are reduced. Karmody found that the most common oblique septum is located in the superior anterior corner of the sinus or infraorbital recess (which may expand anteriorly to the nasolacrimal duct).[40] The medial wall is juxtaposed with the middle and inferior meatus.

Although the maxillary sinus maintains its overall size while the teeth are present, an expansion phenomenon of the maxillary sinus occurs with the loss of posterior teeth.[37] The antrum expands in both inferior and lateral dimensions. This expansion may even invade the canine eminence region and proceed to the lateral piriform rim of the nose. The dimension of available bone height of the posterior maxilla is greatly reduced as a result of dual resorption from the crest of the ridge and pneumatization of the sinus after the loss of teeth. The sinus expansion is more rapid than the crestal bone height changes. As a result of the inferior sinus expansion, the amount of available bone in the posterior maxilla greatly decreases in height (Figure 18-5).

After periodontal disease, tooth loss, and sinus expansion, frequently less than 10 mm remain between the alveolar ridge crest and the floor of the maxillary sinus, resulting in inadequate bone quantity for implant placement. A limited review of the literature reveals implants that were 9 mm or less in height may have a 16% lower survival rate compared with those implants longer than 10 mm.[33] Therefore the height of bone is of primary importance for predictable implant support. This limited dimension is compounded by the decrease in bone density and the problem of the resultant medial posterior position of the ridge after resorption of bone width. As a result, failure and complications in the long term of many endosteal implant systems are reported.

Implant Treatment Plans for the Posterior Maxilla

High Occlusal Forces

The occlusal forces in the posterior region are greater than in the anterior regions of the mouth. Studies have shown that the maximum bite force in the anterior

WWW.HIGHDENT.IR

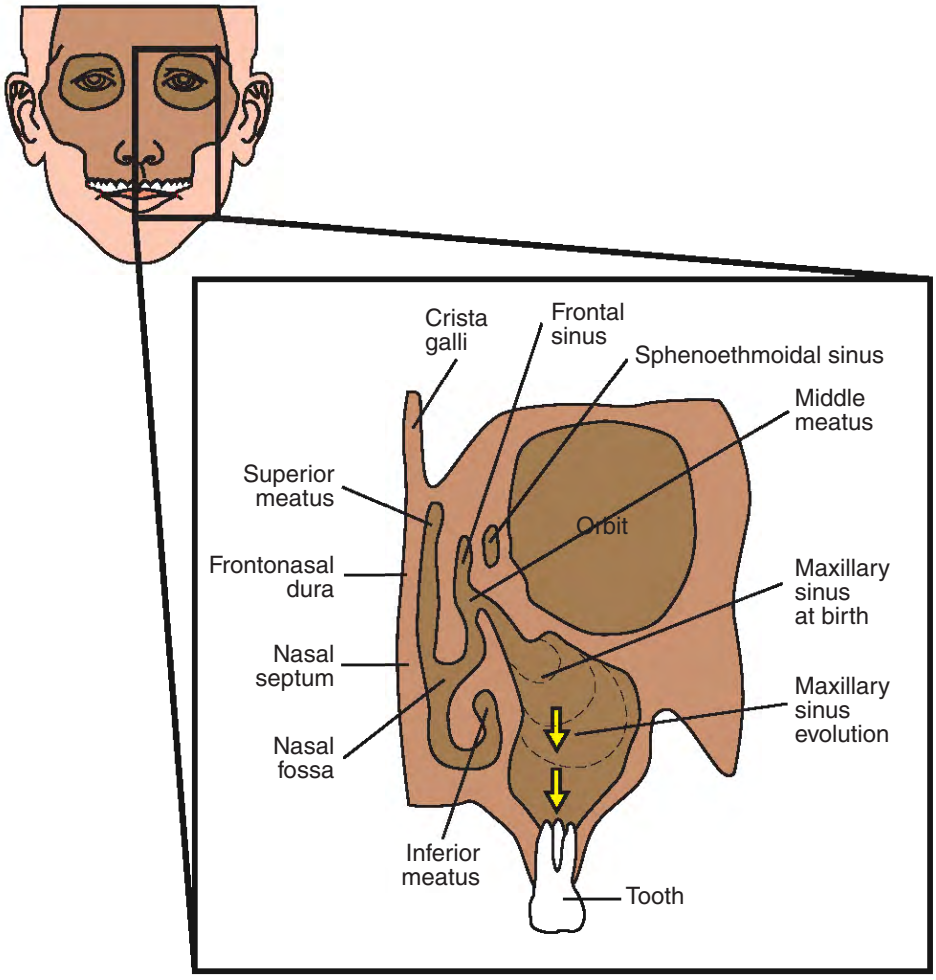

Figure 18-4 The maxillary sinus begins to form in the fetus and by 5 months is the size of a pea, under the eye, and close to the ostium for drainage. By 16 years of age, the maxillary sinus has four thin, bony walls around it. The superior wall separates it from the floor of the orbit. The medial wall contains the ostium to drain the sinus and separates it from the nasal fossa. The lateral wall forms the maxillary bone below the zygomatic arch. The floor of the antrum rests above the roots of the teeth.

region ranges from 35 to 50 lb/in^2. The bite force in the molar region of a dentate person ranges from 200 to 250 lb/in^2. As a consequence, the maxillary molars of the natural teeth have 200% more surface area than even the premolars and are significantly wider in diameter (Figure 18-6).[3] Both these features reduce the stress to bone, which also reduces the strain of the bone. Following this natural selection, implant support should be greater in the posterior molar region than any other area of the mouth.[3] Therefore the decrease in bone quantity and quality and increased forces should be considered in the treatment plan of this region of the mouth.[41]

Implant Size

Implant treatment plans should attempt to simulate the conditions found with natural teeth in the posterior maxilla. Because stresses occur primarily at the crestal region, biomechanical designs of implants to minimize their noxious effects should be implemented.[41] Implant diameter is an effective method to increase surface area at the crestal region.[41,42] Ideally, Division B implants are not used in the posterior maxilla. A 12-year retrospective study from 1982 to 1994 of 653 sinus grafts performed by the author revealed 14 implant failures. Eight implant failures were caused by implant fracture at the neck of smaller-diameter implants. Therefore implants of at least 4 mm in diameter are suggested, and 5-mm implants are encouraged in the molar region.

The length of the implant is directly related to the implant width, design, amount of the forces, and bone density. Because implant success after loading is reduced in implants 10 mm and shorter, it is logical to plan for longer implants in the region. In general, 4-mm threaded root form implants should be at least 12 mm in length when the bone density is poor (D3). This usually provides adequate bone-implant contact to dissipate the loads applied to the prosthesis. When the bone density is very poor (D4), 5-mm implants are suggested, also at least 12 mm in length.

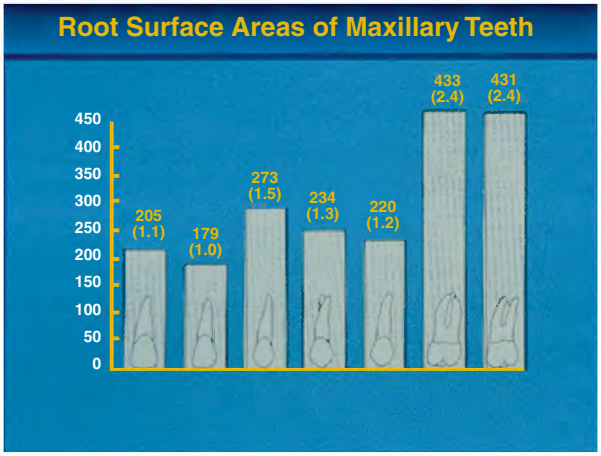

Figure 18-6 The posterior molars have the largest diameter and most surface area of root support compared with any other teeth in the mouth. An implant treatment plan should duplicate this support.

Figure 18-7 The bone-implant contact percentage is lowest in the less dense bone of the posterior maxilla. Therefore implant treatment plans should use a larger and a greater number of implants to compensate for the higher stress conditions.

Implant Number

Implant number is an excellent method to decrease crestal stresses. As a general rule in this area, one implant for each missing tooth is indicated (Figure 18-7). Implants should always be splinted together to reduce stresses to the bone. If stress factors are magnified, two implants for each missing molar are suggested.

Implant Design

Implant design can increase surface area of support. A threaded design implant has 30% to 200% greater surface area compared with a cylinder implant of the same size. Although more difficult to place, the threaded implant in poorer density bone is strongly encouraged. Biomechanical aspects of thread designs affect the total increase in the surface area (i.e., thread pitch, shape, and depth).[41]

Roughened surface conditions or hydroxyapatite coating on the implant have been shown to increase the rate of osseous adaptation to implants, provide greater initial rigid fixation, increase the surface of bone contact

WWW.HIGHDENT.IR

and amount of lamellar bone, and give relative greater strength of the coronal bone around the roughened surface implants when compared with machined or smooth titanium implants.[43-45] Therefore coatings or roughened surfaces are suggested in the compromised D3/D4 bone density.

Dental Contraindications for Implant Treatment of the Posterior Maxilla

A key to long-term success of posterior maxillary implants is the presence of adequate anterior teeth or implants. Therefore the treatment plan should provide for the maintenance or restoration of healthy anterior teeth or Division A bone in the premaxilla for implant placement. A minimum of a healthy natural canine tooth or implant abutments in the canine region for each posterior quadrant are required before posterior implants are considered.

A rule in traditional prosthetics is that a fixed prosthesis is contraindicated when the canine and two adjacent teeth are missing. Therefore when the canine and both premolars are missing, a fixed restoration is contraindicated. A removable prosthesis that has no movement under function is considered a fixed prosthesis and therefore should follow the rules of treatment planning for a fixed prosthesis in relation to implant number and position. The treatment plan of a posterior maxilla should provide for the maintenance or restoration of healthy anterior teeth or adequate bone in the premaxilla for root form implant placement. A minimum of a healthy natural canine tooth or an implant abutment in the canine region is required before posterior implants are considered in the quadrant.

Abnormal intraoral conditions may also compromise the final outcome of sinus grafting procedures or the survival rates of dental implants placed in the grafted sinuses. Therefore relative dental contraindications are similar to those reported in cases of standard implant treatment of edentulous patients.

TREATMENT HISTORY

Treatment of the Posterior Maxilla—Literature Review

Over the years, several strategies have been advocated to restore the posterior maxilla and address the deficiency of bone volume and poor bone quality. The various approaches can be categorized as follows:

- Avoid the sinus and place implants anteriorly, posteriorly, or medially[46-48]
- Place implants and perforate the sinus floor[49,50]
- Use subperiosteal implants[51,52]
- Perform horizontal osteotomy, interpositional bone grafting, and endosteal implants[53,54]
- Elevate sinus floor during implant placement[4,5,7,55-60]
- Perform lateral wall approach sinus graft and simultaneous or delayed implant placement[4-8,15,55,56,61-64]

In the past, implants were inserted in the posterior maxilla without modifying the maxillary sinus topography. Small implants were often placed below the antrum. The decreased surface area compounded by poor bone quality resulted in poor implant stability. Attempts to place larger endosteal implants posterior to the antrum and into the tuberosity and pterygoid plates also resulted in compromised situations. In addition, although feasible from a surgical standpoint, rarely are third- or fourth-molar abutments indicated for proper prosthodontic support. This approach often requires three or more pontics between the anterior and posterior implants. The typical span results with excessive flexibility of the prosthesis, unretained restorations, excess stresses, and implant failure. The thin, porous compact bone often present on the crest of the ridge and on the lateral aspect of the maxilla serves as a poor foundation for subperiosteal implants. Lack of adequate bone height often results in the subperiosteal implant being displaced laterally, off the bony ridge, from occlusal and parafunctional forces.

In the late 1960s, Linkow reported that the blade-vent implant could be blunted and the maxillary sinus membrane slightly elevated to allow implant placement "into" the sinus in the posterior maxilla.[55] This technique required the presence of at least 7 mm of vertical bone height below the antrum. For long-term predictable results, vertical bone height of at least 10 mm for D3 bone in the posterior maxilla has been clinically determined to be necessary when the diameter is 4 mm or more. Because the posterior maxilla often has D3 or D4 bone, implants of traditional design should have even greater height requirements.

Geiger reported that ceramic implants placed through the maxillary sinus floor could heal and stabilize without complication.[49] Brånemark et al. have shown that implants may be placed into the maxillary sinus without consequence if integration occurs between the implants and the bone below the sinus. Yet they also report a higher failure rate (70% success for 5 to 10 years) for this technique.[50] Ashkinazy[48] and others have reported on using tomographic radiographs to determine whether adequate bone exists on the palatal aspect of the maxillary sinus for blade implants. However, Stoler[65] stated that after 25 consecutive computed tomographic scans of maxillae, adequate bone for implant support was not found on the medial aspect of the sinus. Thus it seems that if sufficient bone is present medial to the sinus, it is the rare exception.

In the early 1970s, Tatum[4,5,56,57] began to augment the posterior maxilla with onlay autogenous rib bone to produce adequate vertical bone for implant support. He found that onlay grafts below the existing alveolar

WWW.HIGHDENT.IR

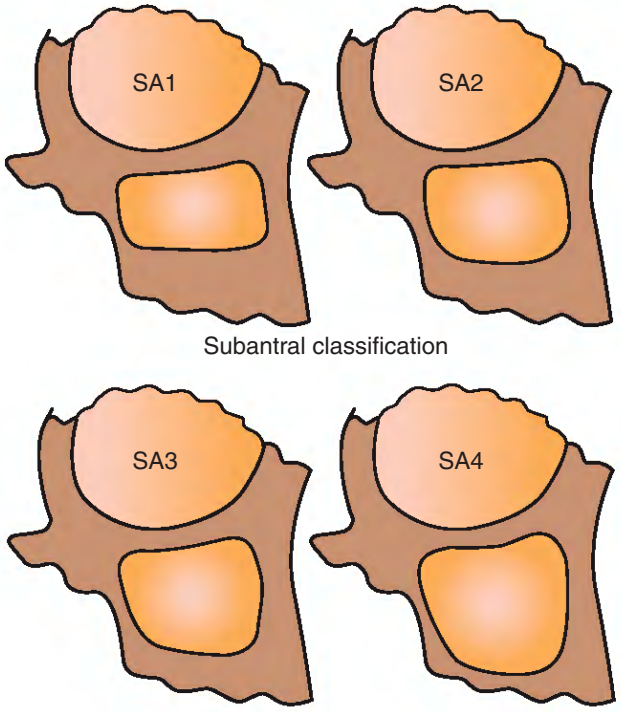

Figure 18-8 In 1987, Misch presented four subantral treatment options based on the amount of bone below the maxillary sinus. Subantral augmentation category 1 (SA1) sinus used traditional implant approaches. Category SA2 used a sinus lift procedure within the osteotomy. For SA3 and SA4 categories, a Tatum sinus graft procedure is performed before implant insertion.

crest would decrease the posterior intradental height significantly, yet very little bone for endosteal implants would be gained. Therefore in 1974 Tatum developed a modified Caldwell-Luc procedure for elevation of the sinus membrane and subantral (SA) augmentation.[4,5] The crestal ridge of the maxilla was infractured and used to elevate the maxillary sinus membrane. Autogenous bone was then added in the area previously occupied by the inferior third of the sinus. Endosteal implants were inserted in this grafted bone after approximately 6 months. Implants were then loaded with final prostheses after an additional 6 months.[4,5]

In 1975, Tatum developed a lateral approach surgical technique that allowed the elevation of the sinus membrane and implant placement in the same surgical appointment. The implant system used was a one-piece ceramic implant, and a permucosal post was required during the healing period. Early ceramic implants were not designed adequately for this procedure and results with the technique were unpredictable. In 1981, Tatum developed a submerged titanium implant for use in the posterior maxilla.[5,56] The advantages of submerged healing, the use of titanium instead of aluminum oxide as a biomaterial, improved biomechanics, and improved surgical technique made this implant modality more predictable.

From 1974 to 1979, the primary graft material for the sinus graft procedure was autologous bone. In 1980 the application of the SA augmentation technique with a lateral maxillary approach was further expanded by Tatum with the use of synthetic bone. The same year, Boyne and James reported on the use of autogenous bone for subantral grafts.[6] Most of the data published in the 1980s were anecdotal or based on very small sample sizes. In 1987, Misch organized a treatment approach to the posterior maxilla based on the amount of bone below the antrum, and in 1989 he expanded the treatment approach to include the available bone width related to surgical approach and implant design (Figure 18-8).[7,63,64] Since then, minor modifications regarding the graft materials or surgical approach have also been proposed.

In the 1990s, the profession developed a much greater interest in the sinus graft technique.[15] Several reports have flourished in the literature, reporting on minor changes in the technique, different materials used in the graft, different origins for the autogenous portion of the graft, histomorphometric data relative to the graft healing, and other retrospective studies relative to the survival rates of implants placed in grafted sinuses with a simultaneous or delayed approach.[62-79]

Long-term results have been reported by Tatum[62] to be above 95%, more than 1500 subantral augmentations performed. The sinus graft procedure has been the most predictable method to grow bone height from 5 to 20 mm compared with any other intraoral bone grafting technique, with a graft success rate and an implant survival rate greater than 95%.

Sinus Graft Options for the Posterior Maxilla

A bone volume classification was published by Misch and Judy in 1987, which followed the bone resorption pattern of edentulous ridges in the maxilla and mandible.[80] The abundant-width ridge for available bone was classified as a Division A ridge. The dimensions of this ridge were described as >5 mm in width, >7 mm in length, >12 mm in height, and an angulation <30 degrees to occlusal load. A residual width of 5 mm was selected for this bone volume because this dimension may adequately support at least a 4-mm-diameter implant, which is the most frequent diameter used as an implant abutment. A Division B edentulous ridge was described as 2.5 to 5 mm in width, 7 mm in mesiodistal length, >12 mm in height, and an angulation to occlusal load of <20 degrees. The decreased width of the bone in all jaw locations primarily occurs from the facial toward the medial aspects of the remaining available bone. Division C–w ridges consisted of 1 to 2.5 mm in width and >12 mm in height. A C–h ridge was inadequate in height (<12 mm) and a crown height space to bone ratio exists greater than 1. A Misch/Judy Division D severely atrophic ridge had significant height resorption and the remaining bone had a crown height to remaining bone ratio >5:1.

WWW.HIGHDENT.IR

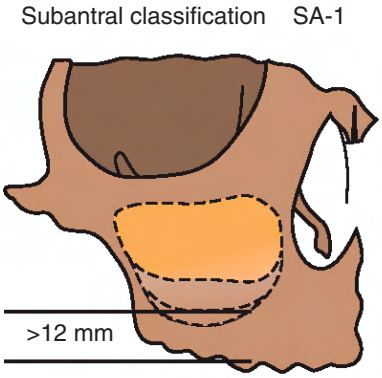

Figure 18-9 Posterior maxilla, with greater than 12-mm height of bone is placed in subantral augmentation option 1. When more than 5-mm width is present, the ridge is Division A; when 2.5 to 5 mm is present, the ridge is Division B and should be augmented in width.

A classification based on a treatment option approach to providing additional prosthodontic abutments in the maxillary posterior edentulous region was presented by Misch in 1987,[7] dependent on the available bone height between the floor of the antrum and the crest of the residual ridge in the region of the ideal implant locations (Table 18-1). This protocol also suggested a surgical approach, bone graft material, and time table for healing before prosthetic reconstruction. In 1988, Cawood and Howell also classified the edentulous posterior maxilla, which included the loss of bone and pneumatization of the maxillary sinus.[79]

In 1995, Misch modified his 1987 classification to include the lateral dimension of the sinus cavity and this dimension was used to modify the healing period protocol, because smaller-width sinuses (0 to 10 mm) form bone faster than larger-width (>15 mm) sinuses. Other classifications of the sinus graft procedure have been proposed by Jensen in 1991[82] and Chiapasco in 2003.[72,83]

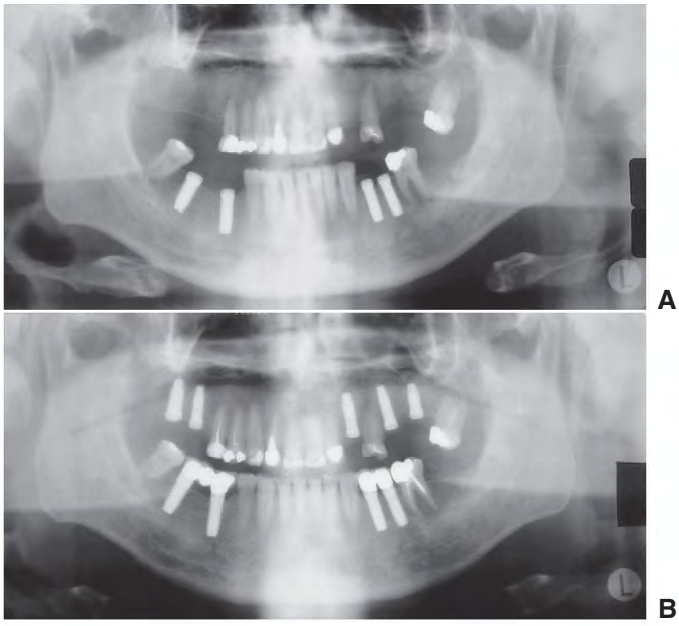

Figure 18-10 **A,** A panoramic radiograph of posterior maxillae with a subantral option 1 condition. **B,** Root form implants, one for each tooth, are the treatment of choice for subantral option 1 conditons.

Misch Maxillary Posterior Classification

Subantral Option 1: Conventional Implant Placement

The first SA treatment option, SA-1, occurs when there is sufficient available bone height to permit the placement of endosteal implants after a usual surgical protocol. In the abundant bone volume (Division A), root form implants are used for prosthetic support. The minimum "ideal" bone height is related to implant design and bone density; however, at least a 12-mm implant in height is suggested for a 4-mm-diameter threaded implant (Figures 18-9 and 18-10).

Patients with narrower bone volume (Division B) may be treated with osteoplasty or augmentation to increase

Table 18-1 Healing Times for Treatment Categories

TIME TREATMENT	HEIGHT (mm)	PROCEDURE	HEALING TIME (MONTHS): GRAFT	HEALING TIME (MONTHS): IMPLANT
SA-1*	>12	Division A root form placement	—	4-6
SA-2	10-12	Sinus lift; simultaneous Division A root form placement	—	6-8
SA-3	5-10	Lateral wall approach sinus graft; delayed Division A root form placement	2-4	4-8†
SA-4	<5	Lateral wall approach sinus graft; delayed Division A root form placement	6-10	4-10†

* Subantral augmentation option.
† Evaluate at implant insertion.

WWW.HIGHDENT.IR

the width of bone. The insertion of smaller surface area implants is not suggested because the forces are greater in the posterior regions of the mouth and the bone density is less than in most regions. In addition, the narrow ridge is often more medial than the central fossa of the mandibular teeth and will result in an offset load on the restoration, which will increase the strain to the bone.

Osteoplasty in the SA-1 posterior maxilla may change the SA category if the height of the remaining bone is less than 12 mm after the bone modification is completed. Augmentation for width may be accomplished with bone spreading, autogenous onlay or appositional grafts. Larger-diameter implants are often required in the molar region, and bone spreading to place wider implants is the most common approach when the bone density is poor. If less than 2.5 mm of width is available in the posterior edentulous region (Division C–w), the most predictable treatment option is to increase width with onlay autogenous bone grafts.[84] After graft maturation, the area is then reevaluated to determine the proper treatment plan classification.

Although a common axiom in implant dentistry is to remain 2 mm or more from an opposing landmark, this is not indicated in the subantral region. As long as the antrum is healthy and instruments do not perforate the thin sinus muscosa lining the sinus floor, no contraindications exist to the preparation or placement of implants at the level of or even through the cortical plate of the sinus floor.

Endosteal implants in the SA-1 category are left to heal in a nonfunctional environment for approximately 4 to 8 months (depending on bone density) before the abutment posts are added for prosthodontic reconstruction. Care is taken to ensure that the implants are not traumatized in any way during the initial healing period. Progressive loading during the prosthetic phases of the treatment are suggested in D3 or D4 bone.

Subantral Option 2: Sinus Lift and Simultaneous Implant Placement

The second subantral option, SA-2, is selected when 10 to 12 mm of vertical bone is present (0 to 2 mm less than the minimum height in SA-1) (Figure 18-11). To obtain the 12 or more millimeters of vertical bone necessary for improved implant survival in ridges of adequate width (Division A), the antral floor is elevated through the implant osteotomy (Figures 18-12 and 18-13). This technique was originally developed by Tatum in 1970 and published by Misch in 1987[7] and many years later by Summers.[4,5,85]

The endosteal implant osteotomy is prepared as determined by the density of bone protocol. The depth of the osteotomy is approximately 1 to 2 mm short of the floor of the antrum. A cupped-shape osteotome of the same diameter as the final osteotomy is selected.[86] It is of a different end shape than osteotomes used for bone spreading.[85] The osteotome is inserted and tapped firmly

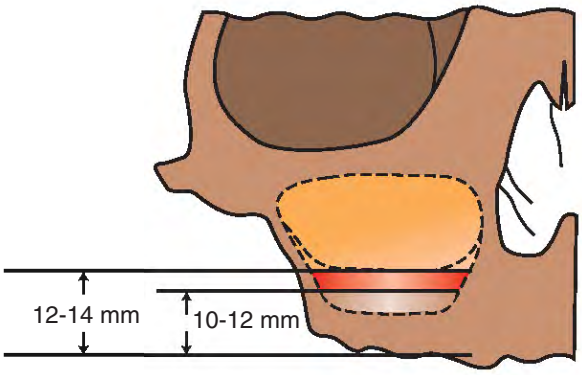

Figure 18-11 A posterior maxilla with 10 to 12 mm of vertical height is treated with a subantral option 2. The sinus floor is raised with the implant osteotomy (sinus lift). When the width of bone is greater than 5 mm, treatment follows Division A with a sinus lift. A width of 2.5 to 5 mm is Division B and should be augmented in width.

in 0.5- to 1-mm increments beyond the osteotomy until its final position up to 2 mm beyond the prepared implant osteotomy. This surgical approach causes a greenstick-type fracture in the antral floor and slowly elevates the unprepared bone and sinus membrane over the broad-based osteotome.

The implant may be inserted into the osteotomy after the sinus lift and extend up to 2 mm above the floor of the sinus. The implant is slowly threaded into position so that the membrane is less likely to tear as it is elevated. The apical portion of the implant engages the more dense bone on the cortical floor, with bone over the apex, and an intact sinus membrane. The implant may extend up to 2 mm beyond the sinus floor and the 1- to 2-mm bony covering over the apex results in as much as a 4-mm elevation of the sinus mucosa (Figure 18-14). Because of the autologous bone present above the apical portion of the implant, new bone formation is accelerated.

The success of the intact sinus membrane lift cannot be confirmed before or at the time of implant placement. Attempts to feel the elevation of the membrane from within an 8-mm-deep implant osteotomy that is approximately 3 mm in diameter may easily cause tearing of the sinus lining. Four to six months after the surgical procedure, a radiograph may be used to indicate the success of the 0- to 2-mm increased vertical height. The patient's prosthodontic treatment may proceed similar to that in the SA-1 category. If inadequate bone is formed around the apical portion of an implant after initial healing, the progressive loading protocol for D4 bone is suggested.

Some authors have used the SA-2 sinus lift procedure to gain more than 2 mm of implant vertical height or place bone graft materials in the osteotomy site before implant insertion. These blind surgical techniques increase the risk of sinus membrane perforation. When the sinus mucosa is perforated, the graft material may extrude into the antrum and increase the risk of postoperative

Figure 18-12 Treatment plan SA-2 calls for elevation of 0 to 2 mm of the floor of the maxillary sinus at the same time as implant placement. During the treatment plan phase, a computed tomography scan with implant software can be used to visualize the sinus lift and final implant relationship with surrounding bone. *(Courtesy S. Caldwell, El Paso, Tex.)*

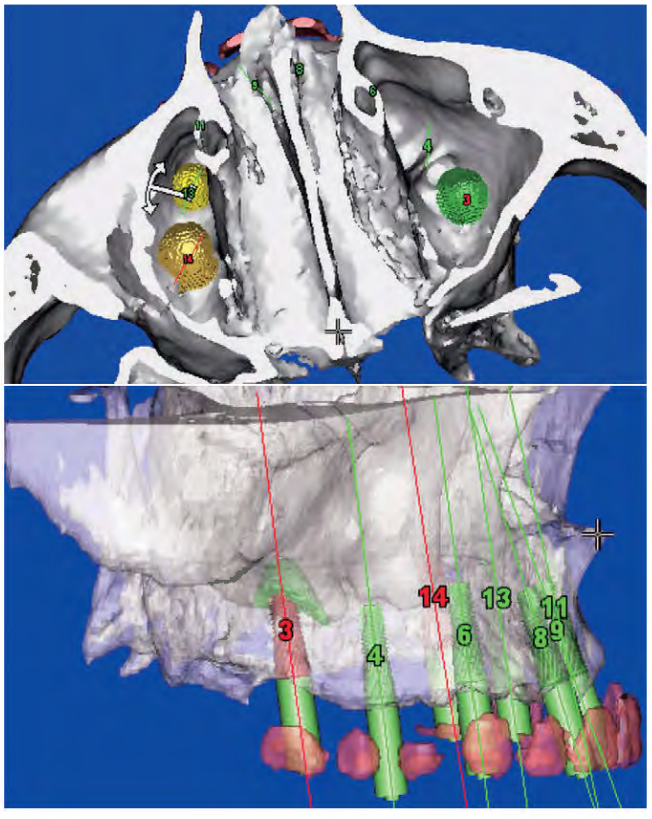

Figure 18-13 **A,** A three-dimensional (3D) view of the maxillary sinus illustrates the membrane being elevated only in the vicinity of the implant apex, creating a halolike image. **B,** A 3D view of the maxillary sinus illustrating implant placement during the treatment planning phase along with the proposed final level of t he sinus floor after SA-2. *(Courtesy S. Caldwell, El Paso, Tex.)*

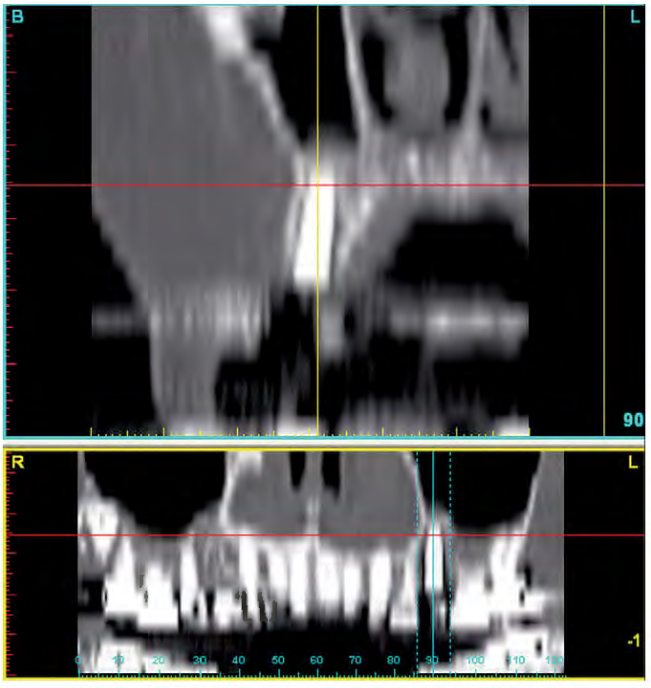

Figure 18-14 After healing, the halo effect at the apex of the implant can be visualized on postoperative imaging. *(Courtesy S. Caldwell, El Paso, Tex.)*

WWW.HIGHDENT.IR

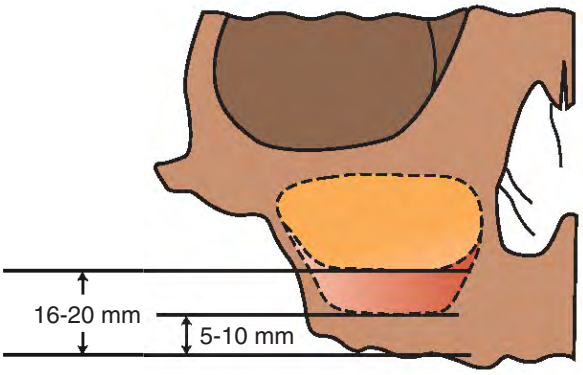

Figure 18-15 A posterior maxilla with 5 to 10 mm between the crest of the ridge and sinus floor is placed in subantral option 3. A Tatum sinus graft is indicated before implant insertion. When greater than 5 mm of width is present, the sinus graft converts the ridge to Division A. When 2.5 to 5 mm of width is present, the Division B ridge should be augmented in width.

infection. If a sinus infection occurs, a bacterial smear layer may accumulate on the implant apex. This prevents future bone-implant contact and may contribute to future sinus infections.

If sinus membrane perforation occurs during the initial implant placement procedure, increased bone height is not likely. This is the primary reason why no more than 2 mm of additional bone height is attempted with this technique. However, even when membrane perforation occurs or no bone grows around the apical end of the implant, the SA-2 technique is of benefit, because the apical end of the implant is surrounded by denser bone. This enhances rigid fixation during healing and increases bone-implant contact, leading to improved loading conditions. As a result of the less predictable outcome, one additional implant may be placed or a larger diameter is suggested in the SA-2 procedure.

Worth and Stoneman have reported a comparable phenomenon of bone growth under an elevated sinus membrane, called *halo formation.*[87] They observed the natural elevation of the sinus membrane around teeth with periapical disease. The elevation of the membrane resulted in new bone formation once the tooth infection was eliminated.

Subantral Option 3: Sinus Graft with Immediate or Delayed Endosteal Implant Placement

The third approach to the maxillary posterior edentulous region, SA-3, is indicated when at least 5 mm of vertical bone and sufficient width are present between the antral floor and the crest of the residual ridge in the area of a needed prosthodontic abutment (Figure 18-15). A Tatum lateral maxillary wall approach is performed just superior to the residual alveolar bone. After the lateral access window and membrane are rotated in and upward to a superior position, a mixture of autogenous bone, alloplast, or allograft material is placed in the space previously occupied by the sinus. When the original ridge is greater than 5 mm in width, the implant may be inserted at the same time as the sinus augmentation under ideal conditions or delayed for a period of 2 or more months before implant insertion[14,60-62,73-75,88-91] (Boxes 18-1 and 18-2). The short delay between graft placement and implant insertion ensures the graft is more stable and is healing without compromise related to postoperative sinus infection. When the original ridge width is Division B or C–w, an onlay graft in conjunction with the sinus augmentation is a possible treatment option.

The 5 to 10 mm of initial bone height in an SA-3 posterior maxilla may have cortical bone on the residual crest, and cortical-like bone on the original antral floor may stabilize an implant that is inserted at the time of the graft and permit its rigid fixation. Therefore an endosteal implant may be inserted at this appointment and has been advocated for some years by this author[7] and others.[14,17,61] However, several advantages tend toward the decision to delay implant placement for approximately 4 months, as follows:

1. The individual rate of healing of the graft may be assessed while the implant osteotomy is being prepared and the implant inserted. The healing time for the implant is no longer arbitrary, but more patient specific.
2. Postoperative sinus graft infection occurs in approximately 3% to 5% of patients, which is greater than the percentage for implant placement surgery.

Box 18-1 Implant Placement (SA-3I)

When the endosteal implants are inserted at the same time as the sinus graft, several conditions are suggested:
1. >5 mm bone height (D3 or better)
2. >6 mm bone width
3. No sinus pathology
4. No history of sinusitis
5. No relative contraindications
6. No parafunction on RPD transitional
7. No sinus membrane perforation

RPD, Removable partial denture.

Box 18-2 No Implant Placement (SA-3)

Implants should not be inserted at the same time as the sinus graft when the following conditions exist:
1. >5 mm bone height (D4)
2. <6 mm bone width
3. Treated sinus pathology
4. History of sinusitis
5. Relative contraindications (smoking, diabetes, periodontal disease)
6. Parafunction on RPD transitional
7. Sinus membrane perforation during surgery

RPD, Removable partial denture.

WWW.HIGHDENT.IR

If the sinus graft becomes infected with an implant in place, a bacterial smear layer may develop on the implant and make future bone contact with the implant less predictable. The infection is also more difficult to treat when the implants are in place, and may result in greater resorption of the graft as a consequence. If the infection can not be adequately treated, the graft and implant must be removed. Therefore there is also a decreased risk of losing the graft and implant if a postoperative infection occurs with a delayed implant insertion. Reports in the literature indeed indicate a higher failure rate of implants when inserted simultaneously compared with a delayed approach.[62,72,83,84]

3. Blood vessels are required to form and remodel bone. An implant in the middle of the sinus graft does not provide a source of blood vessels. It may even make vascular supply more troublesome.
4. Bone width augmentation may be indicated in conjunction with sinus grafts to restore proper maxillomandibular ridge relationships or increase the implant diameter in the molar region. Augmentation may be performed simultaneously with the sinus graft. As a result, larger-diameter implants may be placed with the delayed technique.
5. The bone in the sinus graft is denser with the delayed implant placement. As such, implant angulation and position may be improved because it is not dictated by existing anatomical limitations at the time of the sinus graft.
6. The surgeon may access the sinus graft before implant insertion. On occasion, the sinus graft underfills a region, and the lack of awareness of the condition during implant insertion at the same time results in an implant placed in the sinus proper, rather than the graft site.

The primary disadvantage of delaying the implant placement is the need for an additional surgery. If overall treatment time is a significant factor for the patient, the implant may be inserted after 2 months yet reduce considerably the risk of infection. Otherwise, 4 months or more is typical for implant insertion with the SA-3 technique (Figure 18-16).

Subantral Option 4: Sinus Graft Healing and Extended Delay of Implant Insertion

In the fourth option for implant treatment of the posterior maxilla, SA-4, the subantral region for future endosteal implant insertion is first augmented. This option is indicated when less than 5 mm remains between the residual crest of bone and the floor of the maxillary sinus. There is inadequate vertical bone in these conditions to predictably place an implant at the same time as the sinus graft and less recipient bone to act as a vascular bed for the graft (Figure 18-17). The SA-4 corresponds to a larger antrum and minimal host bone on the lateral, anterior, and distal regions of the graft, because the antrum generally has expanded more aggressively into these regions.

There is also less autologous bone to harvest in the tuberosity, which further delays the bone regeneration in the site. In addition, there are usually fewer septa or webs in the sinus, which increases the bone regeneration, and it typically exhibits longer mediodistal and latero-medial dimensions. Therefore the fewer bony walls, less favorable vascular bed, minimal local autologous bone, and larger graft volume all mandate a longer healing period and slightly altered surgical approach.

The Tatum lateral wall approach for sinus graft is performed as in the previous SA-3 procedure. Most SA-4 regions provide better surgical access than the SA-3 counterparts because the antrum floor is closer to the crest, compared with the SA-3 maxilla. The medial wall of the sinus membrane is elevated at least 16 mm from the crest so that adequate height is available for future endosteal implant placement (Figures 18-18 and 18-19). The combination of graft materials used and their placement are similar to those for the SA-3 technique. However, less autogenous bone is often harvested from the tuberosity, so an additional harvest site may be required, most often from the mandible (i.e., from the ascending ramus).

The augmented region matures for 6 to 10 months before reentry for placement of endosteal implants. The amount of initial healing is related to the antral size (including small, medium, or large lateral-medial size) and the amount of autologous bone used in the inferior one third of the antrum. Typically, the width of crestal bone is wide enough in SA-4 regions for the placement of root form implants after the graft matures.

The implant surgery at reentry for SA-3 or SA-4 is similar to SA-1 with one exception. The periosteal flap on the lateral side is elevated to directly allow inspection of the previous access window of the sinus graft. The previous access window may appear completely healed with bone; soft and filled with loose graft material; or with cone-shaped fibrous tissue ingrowth (with the base of the cone toward the lateral wall); or in any variation states. If the graft site appears clinically as bone, the implant osteotomy and placement follow the approach designated by the bone density.

A hydroxyapatite-coated or roughened surface condition, threaded implant does offer an advantage when the bone density is D4 at implant insertion. Additional time is then allowed until the Stage II implant uncovery is performed and the progressive loading started.

The time interval for stage II uncovery and prosthetic procedures after implant insertion is dependent on the density of bone at the reentry implant placement. The crest of the ridge and the original antral floor may be the only cortical bone in the region for implant fixation. The most common bone density observed is D4, and often it is softer than the region in general.

WWW.HIGHDENT.IR

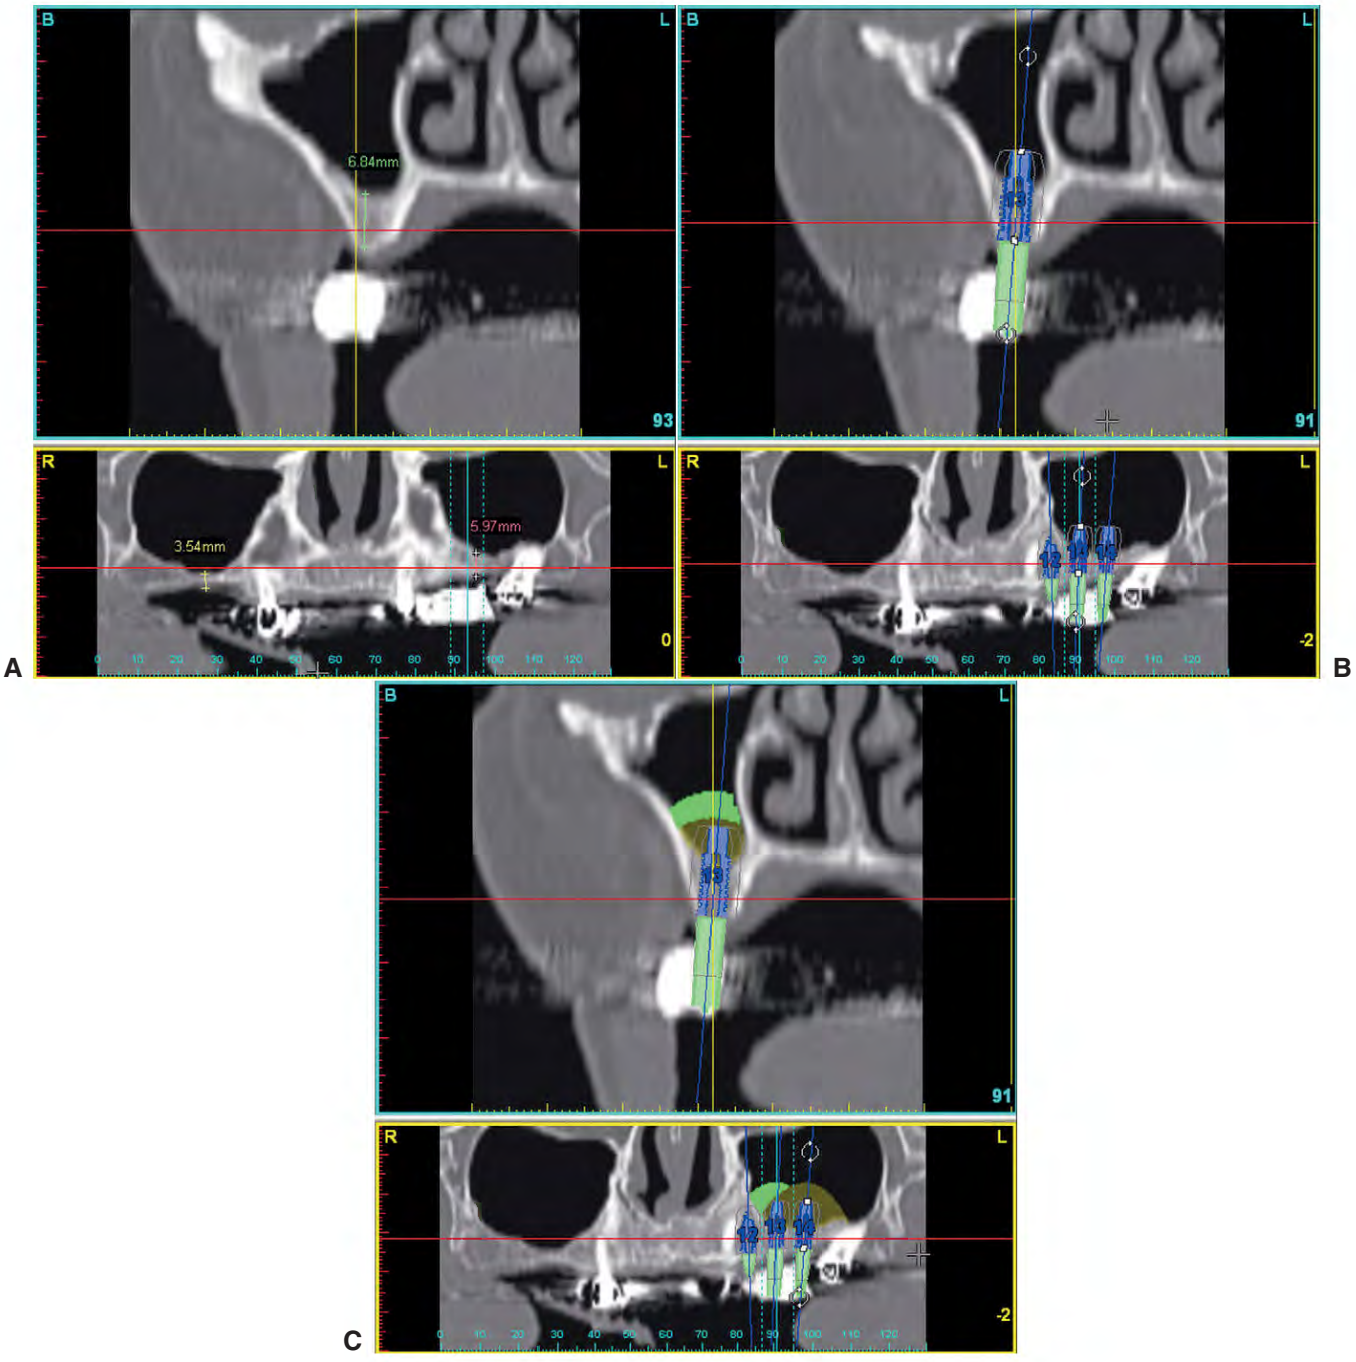

Figure 18-16 **A,** An SA-3 posterior maxilla exhibiting only 5 to 10 mm below the floor of the maxillary sinus. **B,** The implant length required in poor-quality bone such as the posterior maxilla is 12 mm or greater. Therefore a sinus graft to obtain the necessary bone height will be performed before implant placement. **C,** The amount of bone graft necessary can be assessed on computed tomography imaging assisted with a computerized surgery navigation software. *(Courtesy S. Caldwell, El Paso, Tex.)*

Progressive loading after uncovery is most important when the bone is particularly soft and less dense. Inadequate bone formation after the sinus graft healing period of SA-4 surgery is a possible, but uncommon, complication. When observed, the SA-3 technique may be used to place additional subantral graft before the implant placement surgery 4 months later.

The width of the host site for sinus grafts is most often Division A; however, when Division C–w to B exists, an onlay graft for width is indicated. When the graft cannot be secured to the host bone, it is often preferable to perform the sinus graft 6 to 9 months previous to the autogenous graft for width. Then after graft maturation, the implants may be inserted.

SUMMARY

In the past, the posterior maxilla has been reported as the least predictable area for implant survival. Causes cited

WWW.HIGHDENT.IR

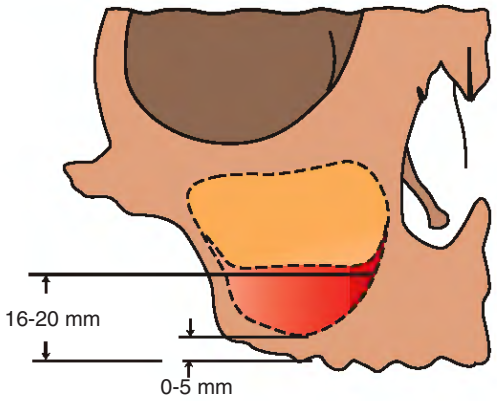

Figure 18-17 A posterior maxilla with 0 to 5 mm of bone below the antrum is subantral augmentation option 4. A Tatum sinus graft is placed and allowed to mature before implant placement. After the sinus graft, width of bone 5 mm or greater is placed into Division A, and 2.5 to 5 mm is placed into Division B and modified into Division A before implant placement.

include inadequate bone height, poor bone density, and high occlusal forces. Past implant modalities attempted to avoid this region, with approaches such as excessive cantilevers when posterior implants are not inserted or excess numbers of pontics when implants are placed posterior to the antrum.

The maxillary sinus may be elevated and subantral bone regenerated to improve implant height. Tatum began to develop these techniques as early as the mid 1970s. Misch developed four options for treatment of the posterior maxilla in 1987 based on the height of bone between the floor of the antrum and the crest of the residual bone. These options were further modified to reflect the width of available bone after adequate height was obtained. Root form implants are indicated under these conditions. When the ridge anatomy is too

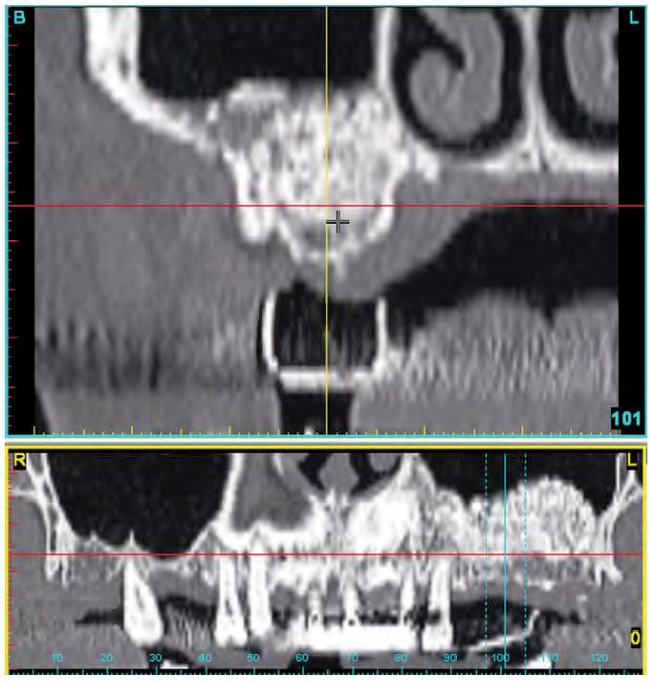

Figure 18-19 Computed tomography (CT) scans can be used after the sinus graft (SA-4) before implant placement to verify proper graft placement. (The medial wall was elevated to permit proper bone graft material placement.) narrow in width for root form implants, these ridges may be treated by osteoplasty or with autogenous grafts. The higher forces and less dense bone often require larger-diameter implants.

Chapter 19

Treatment Plans for Partially and Completely Edentulous Arches in Implant Dentistry

Carl E. Misch

PARTIALLY EDENTULOUS ARCHES

To organize treatment plans in a consistent approach, a classification of patient conditions is necessary. Because more than 65,000 possible combinations of teeth and edentulous spaces exist in a single arch, no universal agreement exists regarding the use of any one classification system. Numerous classifications have been proposed for partially edentulous arches. Their use allows the profession to visualize and communicate the relationship of hard and soft structures. This chapter reviews a classification for diagnosis and treatment planning for patients who are partially or completely edentulous and require implant prostheses. By using this classification, which the author first presented in 1985, the doctor is able to convey the dimensions of the bone available in the edentulous area and also indicate the strategic position of the segment to be restored.[15]

HISTORY

Cummer,[1] Kennedy,[2] and Bailyn[3] originally proposed the classifications of partially edentulous arches that are most familiar to the profession. These classifications were developed to organize removable partial denture (RPD) designs and concepts. Other classifications have also been proposed[4-14] (including one by the American College of Prosthodontists), none of which has been universally accepted. The Kennedy classification, however, has been taught in most American dental schools.

The Kennedy classification divides partially edentulous arches into four classes.[2] Class I has bilateral posterior edentulous spaces, Class II has a unilateral posterior edentulous space, Class III has an intradental edentulous area, and Class IV has an anterior edentulous area that crosses the midline.

The Kennedy classification is difficult to use in many situations without certain qualifying rules. The eight Applegate rules are used to help clarify the system.[11] They may be summarized in three general principles. The first principle is that the classification should include only natural teeth involved in the final prosthesis and follow rather than precede any extractions of teeth that might alter the original classification. This concept, for example, considers whether second or third molars are to be replaced in the final restoration. The second rule is that the most posterior edentulous area always determines the classification. The third principle is that edentulous areas, other than those determining the classification, are referred to as *modifications* and are designated only by their number. The extent of the modification is not considered.

CLASSIFICATION OF PARTIALLY EDENTULOUS ARCHES

The implant dentistry bone volume classification developed by Misch and Judy in 1985 may be used to build on the four classes of partial edentulism described in the Kennedy-Applegate system.[15,16] This facilitates communication of teeth positions and the primary edentulous sites among the large segment of practitioners already familiar with this classification, and it enables the use of common treatment methods and principles established for each class. The implant dentistry classification for partially edentulous patients by Misch and Judy also includes the same four available bone volume divisions previously presented for edentulous areas. Other intradental edentulous regions that are not responsible for the Kennedy-Applegate class determination are not specified within the available bone section, should implants not be considered in the modification region. However, if the modification segment is also included in the treatment plan, then it is listed, followed by the available bone division it characterizes (Box 19-1).

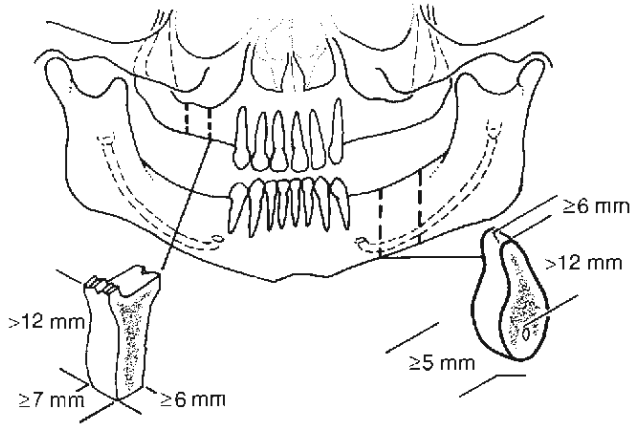
WWW.HIGHDENT.IR

Box 19-1 Implant Dentistry Classification of Partially Edentulous Arches

Class I: Partially Edentulous Arch with Bilateral Edentulous Areas Posterior to Remaining Natural Teeth

Division A

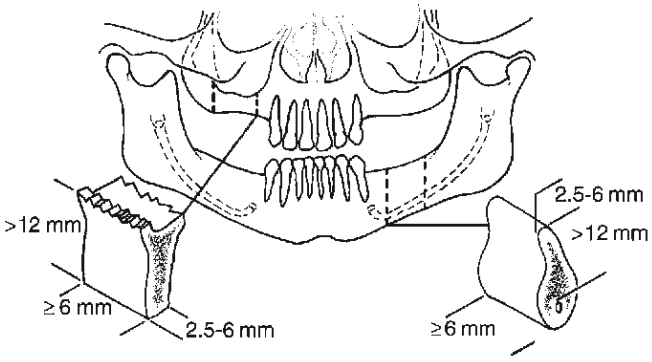
1. Edentulous areas have abundant bone width (>6 mm), height (>12 mm), and length (>7 mm) for endosteal implant(s).



2. Direction of load is within 30 degrees of implant body axis.
3. Crown height <15 mm.
4. Root form implants and independent prostheses often are indicated.

Division B

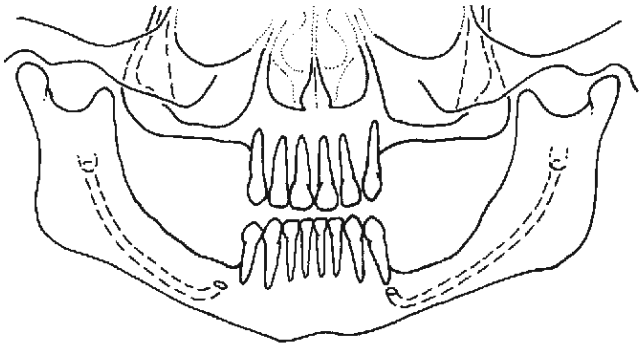
1. Edentulous areas have moderate available bone width (2.5 to 6 mm) and at least adequate bone height (>12 mm) and length (>6 mm).



2. Direction of load is within 30 degrees of implant body axis.
3. Crown height <15 mm.
4. Surgical options include osteoplasty, small-diameter implants, and/or augmentation.

Division C

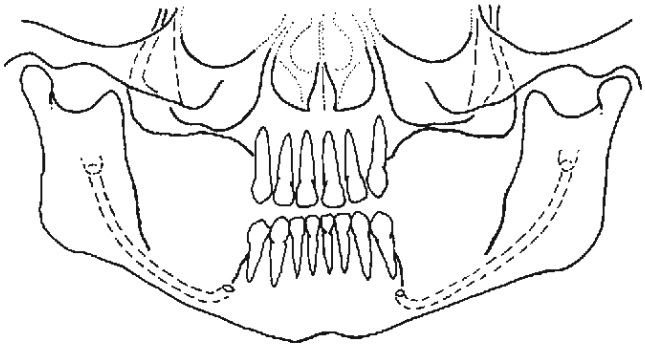
1. Edentulous areas have inadequate available bone for endosteal implant (or implants) with a predictable result, because of too little bone width (C–w), length, height (C–h), or angulation of load.



2. Crown height >15 mm.
3. Surgical options for C–w include osteoplasty or augmentation; for C–h, options include subperiosteal or disc implants or augmentation.
4. Root forms may be considered with augmentation and/or nerve repositioning.

Division D

1. Edentulous areas have severely resorbed ridges, involving a portion of the basal or cortical supporting bone.



2. Crown height >20 mm.
3. Surgical options usually require augmentation before implants can be inserted.

Note: If the bilateral edentulous areas are not within the same division, then the right side is described first (e.g., Class I, Division A, B).

Treatment Planning: Class I

In Class I patients, distal edentulous segments are bilateral and natural anterior teeth are present. The majority of these arches are only missing molars, and almost all have retained at least the anterior incisors and canines.[17] Therefore, once restored to proper occlusal vertical dimension, the natural anterior teeth contribute to the distribution of forces throughout the mouth in centric relation occlusion. More importantly, when opposing natural teeth or in fixed implant prosthesis, they also permit excursions during mandibular movement to disclude the posterior implant-supported prostheses and protect them from lateral forces. However, many of these mandibular Class I patients oppose a maxillary denture, in which case bilateral balance is more appropriate.

The Class I patient is more likely to wear a RPD than Class II or III patients because mastication and/or support of an opposing removable prosthesis is more difficult when not wearing a mandibular prosthesis. The posterior soft tissue–supported Class I partial dentures are designed to either primary load the edentulous regions or the natural anterior teeth. The clasp design, which places less force on the tooth (e.g., bar clasp including t, y rpi), will place more force on the bone. The RPDs, which place more force on the abutment teeth (e.g., precision partial dentures), will place less force on the bone. In either case, the removable prosthesis often accelerates the posterior bone loss. In addition, a partial denture that is not well designed or maintained distributes additional loads to abutment teeth and may even contribute to poor periodontal health. The combinations of these conditions lead to bone loss in the edentulous regions and poorer adjacent natural abutments.[18-20] As a result, it is this author's observation that long-term Class I patients who have been wearing an RPD often exhibit Division C ridges and mobile abutment teeth.

Class I patients often have mobile anterior teeth, because long-term lack of bilateral posterior support caused by the wearing of a poorly fitting RPD, or none at all, has resulted in an overload to the remaining dentition. Therefore these patients often require a posterior implant prosthesis to be independent from the mobile natural teeth. In addition, the occlusal scheme must accommodate the specific conditions of mobile anterior teeth. This requires increased implant support in the posterior segments when compared with most Class II or III patients, as well as greater attention and frequency for occlusal adjustments.

The treatment plan must consider the factors of force previously identified and relate them to the existing bilateral edentulous condition. Osteoplasty cannot be as aggressive in the Class I patient to increase bone width, compared with the Class IV or fully edentulous patient with implants primarily in the anterior regions, because of the opposing anatomical landmarks (maxillary sinus or mandibular canal). Augmentation procedures are often required to improve posterior bone volume, increase the implant surface area, and permit the fabrication of an independent implant restoration.

Financial concerns may require the staging of treatment over years. The posterior region with the greatest volume of bone usually is restored first, if no bone grafting is required. In this manner, implants of greater size and surface area can resist the unilateral posterior forces while the patient awaits future treatment. If many years pass before implants are to be inserted in the lesser available bone, then continued resorption may require augmentation before reconstruction.

If both posterior segments require bone grafting, the patient is encouraged to have both posterior segments augmented at the same time. In this way, the autologous portion of the graft may be harvested and distributed to both posterior regions, decreasing the number of surgical episodes for the patient.

Division A Treatment Plans

When patients are placed in a Class I, Division A category, an independent implant-supported fixed prosthesis is usually indicated. Two or more endosteal root form implants are required to replace molars with independent prostheses. The greater the number of teeth missing, the larger the size and/or number of implants required. Posterior available bone is limited in height by the mandibular canal in the mandible or the maxillary sinus in the maxilla. The first premolar-positioned implants must avoid encroachment on the apex of the canine root and yet avoid the anterior loop of the mandibular canal or maxillary sinus.

Division B Treatment Plans

Class I, Division B patients have narrow bone in posterior edentulous spaces and anterior natural teeth. A fixed prosthesis is also indicated in these categories. Available bone height is restricted by the mandibular canal or maxillary sinus. Therefore osteoplasty to increase bone width has limited applications. Endosteal small-diameter root form implants may be placed in the mandibular posterior Division B edentulous ridge. If narrow-diameter root forms are used, then a greater number than for the Division A ridge is indicated, and the use of one implant for every missing tooth root with no cantilever is recommended.

The patient missing molars and both premolars requires additional implant support. Four Division B root forms may be the foundation of an independent fixed partial denture (FPD) in the mandible , depending on the other stress factors. If stress factors are too great (as a result of parafunction) or bone density is poor (as in the maxilla), then the Division B bone should be augmented to Division A before larger-diameter implant insertion. The anterior teeth in Class I patients

WWW.HIGHDENT.IR

should provide disclusion of the posterior implants during all excursions when opposing natural teeth or a fixed prosthesis. Molar endosteal implants should not be rigidly cross-splinted to each other in the Class I patient. Flexure of the mandible during opening may cause a rigid splint to exert lateral forces on the posterior implants. Therefore independent restorations are indicated.

Division C Treatment Plans

When inadequate bone exists in height, width, length, or angulation, or if crown/implant ratios are equal to or greater than 1, the practitioner must consider several options. The first treatment option is to not use implant support, but rather to orient the patient toward a conventional removable partial prosthesis. However, although this condition is easiest to treat with a traditional soft tissue–borne restoration, bone loss will continue and can eventually compromise any restorative modality.

The second option is to use bone augmentation procedures. If the intent of the bone graft is to change a Division C to a Division A or B for endosteal implants, then at least some autogenous bone is indicated. Augmentation is used most often in the Class I maxilla, where sinus grafts with a combination of allografts and autogenous bone are a predictable modality. Implants may be placed after the graft has created a Division A ridge, and the treatment plan follows the options previously addressed.

In the mandible, the third option for the Class I, Division C patient is to place unilateral subperiosteal implants or disc implants above the canal (Figure 19-1). The disc implants support independent posterior fixed prostheses bilaterally.

The fourth treatment option in the mandible is nerve repositioning and endosteal implants in Class I patients who are poor candidates for bone augmentation or subperiosteal implants. Risks of long-term paresthesia exist that may include hyperesthesia and pain. Reports in the literature concern dysesthesia and fracture of the severely atrophic mandible.[21,22] In addition, the gain of height in the C–h mandible may only permit the placement of implants 10 mm high, still insufficient to compensate for the increased crown height and resultant unfavorable crown/implant ratio.

Division D Treatment Plans

Class I, Division D usually occurs most often in the long-term edentulous maxilla. A sinus graft is usually performed before implant placement. Class I, Division D ridges are rarely found in the mandibular partially edentulous patient. When observed, the most common causes are from trauma or surgical excision of neoplasms. These patients often need autogenous bone onlay grafts to improve implant success and prevent pathologic fracture before prosthodontic reconstruction. After the graft is mature and the available bone improved, the patient is evaluated and treated in a manner similar to other patients with favorable bone volume.

Treatment Planning: Class II

Kennedy-Applegate Class II partially edentulous patients are missing teeth in one posterior segment (see Box 19-1). These patients are often able to function without a removable restoration and are less likely to tolerate or overcome the minor complications of wearing the prosthesis. As a result, they are not as likely to wear a removable restoration. The available bone is therefore often adequate for endosteal implants, even when long-term edentulism has been present. However, the local bone density may be decreased. Endosteal implants with minimum osteoplasty are a common modality in these patients, who are more often Class II, Division A or B types.[23,24]

Because the patient is less likely to wear the RPD, the opposing natural teeth have often extruded into the posterior edentulous region. The occlusal plane and tipped or extruded teeth should be closely evaluated and restored as indicated to provide a favorable environment in terms of occlusion and forces distribution. It is not unusual to require extraction of the second molar, endodontics, crown lengthening and a crown of the first molar, and enameloplasty for the second premolar.

Division A Treatment Plans

When patients are placed in a Class II, Division A category, an independent implant-supported fixed prosthesis is usually indicated. Two or more endosteal root form

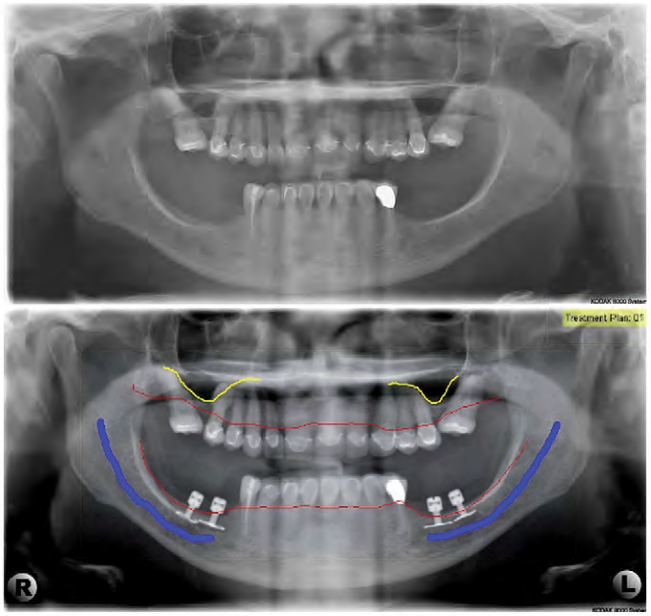

Figure 19-1 In Class I, Division C, options include small-dimension implants such as disc implants, which can be placed in minimal heights of bone above the mandibular canal. Two independent fixed prostheses are supported by implants.

WWW.HIGHDENT.IR

implants are required to replace molars with independent prostheses. The greater the number of teeth missing, the larger the size and/or number of implants required. Posterior available bone is limited in height by the mandibular canal in the mandible or the maxillary sinus in the maxilla. The first premolar-positioned implants must not encroach on the apex of the canine root while still avoiding the anterior loop of the mandibular canal or maxillary sinus (Figure 19-2).

Division B Treatment Plans

Class II, Division B patients have narrow bone in posterior edentulous spaces and anterior natural teeth. A fixed prosthesis is also indicated in these categories. Available bone height is restricted by the mandibular canal or maxillary sinus. Therefore osteoplasty to increase bone width has limited applications. Endosteal small-diameter root form implants may be placed in the mandibular posterior Division B edentulous ridge. If narrow-diameter root forms are used, then a greater number than for the Division A ridge is indicated, and the use of one implant for every missing tooth root with no cantilever is recommended.

The patient missing molars and both premolars requires additional implant support. Four Division B root forms may be the foundation of an independent FPD in the mandible, depending on the other stress factors. If stress factors are too great (as a result of parafunction) or bone density is poor (as in the maxilla), then the Division B bone should be augmented to Division A before larger-diameter implant insertion. The anterior teeth in Class II patients should provide disclusion of the posterior implants during all excursions.

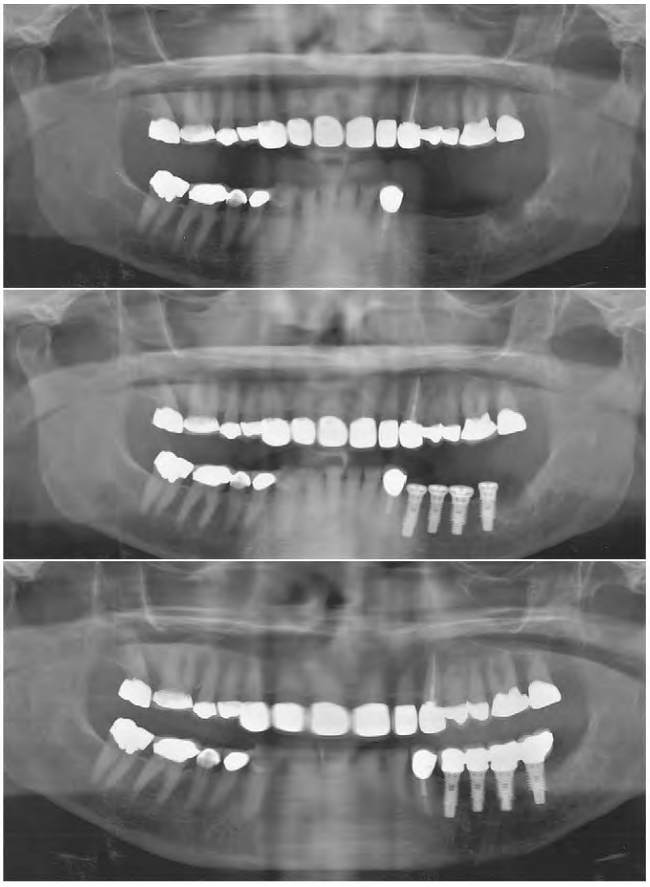

Figure 19-2 **A,** After socket grafting and ridge preservation in the posterior mandible, sufficient bone exists for the area to be classified Division A. **B,** Class II, Division A patients can be treated with endosteal implants (often one implant is treatment planned for each mandibular root). **C,** A final independent fixed cemented restoration is the treatment of choice.

Division C Treatment Plans

When inadequate bone exists in height, width, length, or angulation, or if crown/implant ratios are equal to or greater than 1, then the practitioner must consider several options. In the mandible, the first treatment option is to not use implant support but to consider a posterior cantilevered FPD replacing one premolar-sized crown, using two or three anterior teeth as abutment support. This is the easiest option and is strongly recommended when only molars are missing.

The second option is to use bone augmentation procedures. If the intent of the bone graft is to change a Division C to a Division A or B for endosteal implants in the mandible, then autogenous bone is indicated. Augmentation is used most often in the Class II maxilla as the first choice, where sinus grafts with a combination of allografts and autogenous bone are a predictable modality. Implants may be placed after the graft has created a Division A ridge, and the treatment plan follows the options previously addressed.

The third option for the Division C mandibular patient is to place a Class II unilateral subperiosteal implant or a disc implant above the canal.

The fourth treatment option in the mandible is nerve repositioning and endosteal implants in Class II patients who are poor candidates for bone augmentation. Risks of long-term paresthesia exist that may include hyperesthesia and pain. Reports in the literature concern dysesthesia and fracture of the severely atrophic mandible.[21,22] In addition, the gain of height in the C–h mandible may only permit the placement of implants 10 mm high, which is still insufficient to compensate for the increased crown height and resultant unfavorable crown/implant ratio.

Division D Treatment Plans

Class II, Division D usually occurs most often in the long-term edentulous maxilla. A sinus graft is usually performed before implant placement. Class II, Division D ridges are rarely found in the mandibular partially edentulous patient. When observed, the most common causes are from trauma or surgical excision of neoplasms. These patients often need autogenous bone onlay grafts to improve implant success and prevent pathologic fracture before prosthodontic reconstruction. After the

WWW.HIGHDENT.IR

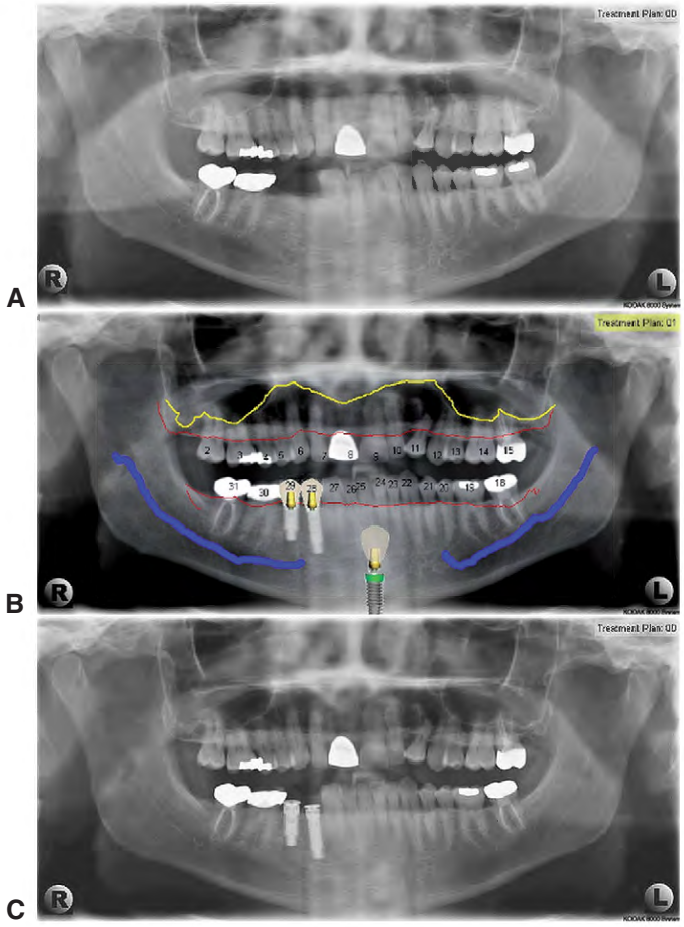

Figure 19-3 **A,** Typically, patients with Class III edentulous segments are missing a single tooth or a posterior space. **B,** The ideal treatment plan can be studied with computer-assisted programs that help visualize proper positioning and the contours of the final restoration (XCPT, Naples, Fla.). **C,** The implant surgical phase replicates the computer-assisted programmed surgery. (**B,** *Courtesy N. Levine, Chicago, Ill.)*

graft is mature and the available bone improved, the patient is evaluated and treated in a manner similar to other patients with favorable bone volume.

Treatment Planning: Class III

Typically, the two most common Class III patients consulting for implants are either missing a single tooth or have a long posterior edentulous span. A multiple-tooth posterior edentulous region most often can be restored as an independent restoration, but it may on occasion need to be joined to a posterior natural abutment. The posterior tooth usually exhibits less mobility compared with the anterior teeth, and disclusion of the posterior segments can be achieved. A review of the literature demonstrates joining implants in teeth in the same prosthesis under those conditions is possible. On the other hand, an anterior tooth abutment exhibits greater mobility and sustains greater lateral forces during excursions and should not be joined to an implant, unless it is a "living pontic" or a part of a restoration using a splinted arch concept to distribute lateral forces.

A single-tooth implant is the treatment of choice when the bone and soft tissues are within normal range before or during implant treatment. Fixed prostheses increase the risk of decay, pulpal involvement, and periodontal disease on the natural abutment teeth.[25] Both the traditional prosthesis and the abutment teeth have a poorer survival rate than implant prostheses. As a result, single-tooth implants are often indicated.[26,27]

Division A Treatment Plans

Class III, Division A patients are good candidates for endosteal root form implant placement in the edentulous space. This allows the restoration of natural teeth to be independent and allows the fabrication of shorter span restorations. It is easier to obtain maximum available height of bone for implant placement anterior to the mandibular foramen or maxillary sinus (Figure 19-3). As a general rule, the final prosthesis should be completely implant supported, and two implants should support each section of three missing tooth roots (not three missing crowns). Mobile natural teeth adjacent to the edentulous span cause greater loads on the implants; therefore one implant for each missing root may be indicated. If the adjacent teeth are mobile, then the implant must support both the missing teeth and mobile teeth during occlusion.

Division B Treatment Plans

In Class III, Division B patients, narrow-diameter endosteal implants may be placed in the mandibular long-span edentulous space. This treatment plan is primarily used for a fixed prosthesis when the span is too long or occlusal forces are too great for the natural abutments to act as sole support for the final prosthesis. The final implant prosthesis should be independent of these teeth.

Division C or Division D Treatment Plans

When Division C is found in Class III patients, the most common treatment plan in the maxilla is bone augmentation before implant insertion and an independent implant prosthesis. Sinus grafting in the posterior Division C ridge is very predictable. In the mandible, Division C bone volume for Class III patients should often consider a traditional fixed prosthesis, because bone grafting for height is less predictable than in the maxilla.

Treatment Planning: Class IV

In the Class IV patient, the anterior edentulous space crosses the midline. In the past, traditional FPDs were often the treatment of choice when the canines were present. Today, an independent implant prosthesis is often warranted. However, a lack of anterior bone volume in the maxilla is common, and bone grafts before

WWW.HIGHDENT.IR

implant placement are typically necessary to prevent the implants from being placed palatally in relation to the natural roots. A cantilever is often created off the implant bodies to place the maxillary incisor edge in proper position for esthetics and speech. The moment force generated is greater than when found in the mandibular counterpart. This, added to other factors, makes the premaxilla one of the more difficult regions of the mouth to treat successfully. As a general rule, one implant for each tooth is considered in the premaxilla; in the mandible, two implants can often be used to replace the four anterior incisors.

Division A Treatment Plans

Class IV, Division A patients are good candidates for endosteal root form implant placement in the edentulous space. This allows the restoration of teeth independently should they need it and allows the fabrication of shorter-span restorations. This situation is also indicated when occlusal forces are too great for the natural abutment teeth to act as support for a fixed prosthesis but are not mobile. If the adjacent teeth are mobile, then the implant must support both the missing teeth and the mobile teeth during occlusion. As a general rule, the final prosthesis should be completely implant supported, and two implants should support each section of three missing tooth roots (not three missing crowns). Mobile natural teeth adjacent to the edentulous span cause greater loads on the implants. Therefore one implant for each missing root may be indicated.

Division B Treatment Plans

The Class IV, Division B patient is most often treated with augmentation before implant placement. If the ridge is Division B and inadequate in width for Division A root form implants, then the narrow-diameter root forms compromise esthetics and oral hygiene procedures. Bone augmentation is more often used in anterior edentulous regions with narrow bone, and Division A implants are indicated to improve the final crown contour, esthetic appearance, and daily maintenance. Implant and tooth replacement should remain independent. The canine is an important natural abutment. When the canine and two adjacent teeth are missing, a fixed prosthesis is contraindicated. In other words, an implant should replace a canine whenever multiple teeth are missing, which includes the canine.[29] A hydroxyapatite (HA) graft is often placed on the labial aspect of the Division B edentulous ridge for enhanced soft tissue contour, proper emergence profile, and improved lip support for esthetics when pontics are used in the region.

Division C and D Treatment Plans

The first option for a Class IV patient is to use bone augmentation procedures. If the intent of the bone graft is to change a Division C or D to a Division A or B for endosteal implants, then autogenous bone is indicated. Implants may be placed after the graft has created a Division A ridge, and the treatment plan follows the options previously addressed.

CLASSIFICATION OF COMPLETELY EDENTULOUS ARCHES

Completely edentulous classifications include the classification of Kent and the Louisiana Dental School.[30] The classification was for ridge augmentation with HA and a conventional denture. This classification treats all regions of an edentulous arch in similar fashion and does not address regional variation. Likewise, the classification of Lekholm and Zarb only addressed the anterior maxilla and mandible, always resulted in root form implants without regard for bone grafting, and always used a fixed prosthesis, regardless of biomechanical considerations.[30a] The divisions of bone previously presented by Misch and Judy are the basis of the classification of the completely edentulous patient presented in this chapter.[15,16] Its purpose is to allow communication of not only the volume of bone but also its location. It organizes the most common implant options of prosthodontic support for the completely edentulous patient.

The edentulous jaw is divided into three regions and described according to the Misch-Judy classification.[30b] In the mandible, the right and left posterior sections extend from the mental foramen to the retromolar pad, and the anterior area is located between the mental foramina. The anterior section usually extends from first premolar to first premolar because of the foramen's most common location (i.e., between the two premolar teeth). The right and left posterior regions of the edentulous maxilla also start from the second premolar site, where the maxillary sinus most often determines the height of available bone. The anterior section of the maxilla consists of the region between the first premolars and is usually anterior to the maxillary sinus (Figure 19-4). The division of bone in each section of the edentulous arch then determines the classification of the edentulous jaw. The three areas of bone are evaluated independently from each other. Therefore one, two, or three different divisions of bone may exist. The term *type* is used in the completely edentulous classification, rather than *class*, as in the partially edentulous classification.

Type 1

In the Type 1 edentulous arch, the division of bone is similar in all three anatomical segments. Therefore four different categories of Type 1 edentulous arches are present. In the Type 1, Division A ridge, with abundant bone in all three sections, as many root forms as needed may be inserted (and the locations of implants are not

WWW.HIGHDENT.IR

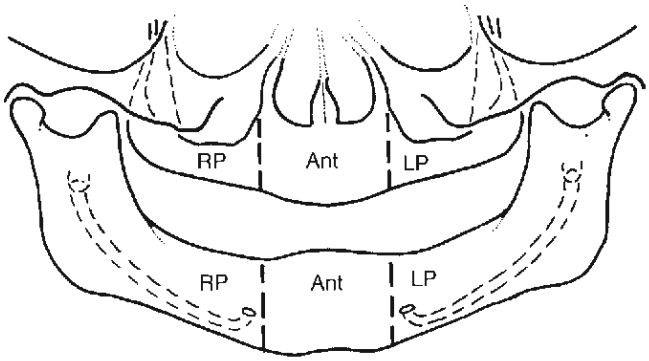

Figure 19-4 The completely edentulous jaw is divided into three segments. The anterior component *(Ant)* is between the mental foramina or in front of the maxillary sinus. Right *(RP)* and left *(LP)* posterior segments correspond to the patient's right and left sides.

limited) to support the final prosthesis. As a general rule, the range of five to nine implants may be used in the mandible and 7 to 10 implants in the maxilla for a fixed prosthesis.

The Type 1, Division B edentulous ridge presents adequate bone in all three sections in which to place narrow-diameter root form implants. It is common practice to modify the anterior section of bone in the mandible by osteoplasty to a Division A and to place full-size root form implants in this region. It is more unusual to have sufficient height in either the posterior maxilla or mandible to permit osteoplasty to improve the division. Therefore several narrower implants are often indicated in the mandible if posterior implants are inserted without grafting. One implant is used for every tooth root to compensate for the decrease in surface area of implant support. Augmentation by bone spreading may be indicated in the maxilla, if the patient desires a fixed prosthesis, especially when opposing natural teeth. If stress factors are great, then lateral augmentation may also be necessary in the posterior regions to increase implant diameter.

Type 1, Division C–w edentulous arches present adequate height of available bone but have inadequate width. If the patient desires an implant-supported removable prosthesis, then an osteoplasty may be used to convert the ridge to C–h. The treatment plan then follows a Type 1, Division C–h formula. When a fixed restoration is desired, an autogenous onlay graft in the C–w arch is usually warranted to restore the ridge to Division A before implant insertion.

Type 1, Division C–h edentulous arches often do not present all the essential requirements for predictable long-term implant support for fixed prostheses. An implant-supported RP-4 or RP-5 removable prosthesis is often indicated to reduce occlusal loads. The mandibular arch may be treated with a complete subperiosteal implant and/or root form implants in the anterior section. The prosthesis should be completely implant supported (RP-4) to halt the continued bone loss in the posterior regions of the mouth. When only Division C anterior root form implants are inserted, posterior soft tissue support (RP-5) may be required.

The edentulous maxilla is often treated with a conventional removable prosthesis until the mandible is completely restored. If this denture needs additional retention or stability, then HA can be used to augment the premaxilla. This squares the ridge shape and provides resistance to occlusal excursions during function. Intramucosal inserts may also be used to increase the retention of the removable complete denture. However, the patient and doctor should realize that bone loss will continue and will make future implant placement even more difficult.

The C–h maxilla should often consider subnasal augmentation combined with root form implants in the canine eminence region and sinus graft with root form implants with an RP-4 prosthesis.[31,32] Additional surgical training is required for these last two alternatives, and they have a greater incidence of complication.

Fixed prostheses may need autogenous iliac crest grafts to change the anterior division of bone and improve long-term success and esthetics. Sinus grafts are also indicated in these situations (Figure 19-5).

The edentulous arches classified as Type 1, Division D are the most challenging to traditional and implant dentistry. If an implant fails in a Type 1, Division D patient, then pathologic fractures or almost unrestorable conditions may result; yet these are the patients who need the most help for support of their prostheses. The benefits versus risks must be weighed carefully for each patient. Endosteal implants may be placed in the anterior mandible. However, the unfavorable crown height of greater than 20 mm and mandibular fracture during implant placement or after implant failure may result in significant complications.[33]

Often the best solution is to change the division with autogenous grafts, then reevaluate the improved conditions and appropriately alter the treatment plan. The Type 1, Division D ridges most often use autogenous iliac crest grafts. After 6 months a total of five to nine implants may be placed in the anterior and posterior regions.[34-35]

Type 2

In the Type 2 completely edentulous arch, the posterior sections of bone are similar but differ from the anterior segment. The most common arches in this category present less bone in the posterior regions, under the maxillary sinus, or over the mandibular canal than in the anterior segment. These edentulous ridges are described in the completely edentulous classification with two division letters following Type 2, with the anterior segment being listed first because it often determines the overall treatment plan. Therefore a mandible with Division A between the foramina and

WWW.HIGHDENT.IR

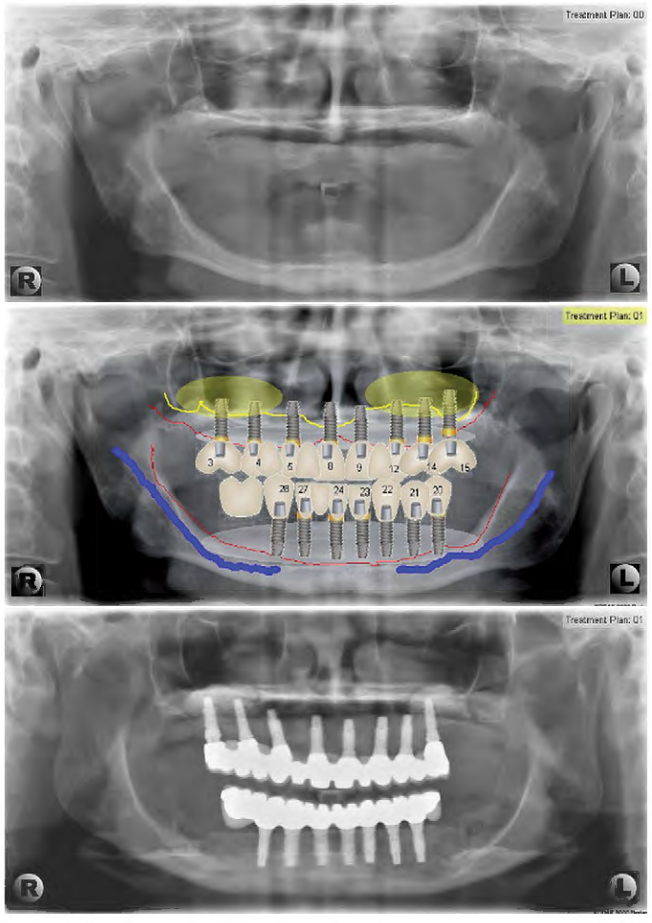

Figure 19-5 **A,** Type I division C–h mandible and maxilla should be restored to Division A with autogenous grafts when a fixed prosthesis is desired. **B,** Computer-assisted treatment plans with five to nine implants placed in the grafted bone volumes can be developed before treatment (XCPT, Naples, Fla.). **C,** Panoramic radiograph of a patient with Division C–h maxilla and in mandible—restored to Division A arches with iliac crest grafts, endosteal implants, and fixed maxilla and mandibular prostheses.

Division C distal to the mandibular foramen is a Type 2, Division A, C arch. This condition is common in the mandible, because the posterior regions resorb four times faster than the anterior regions. Because onlay grafts in the posterior mandible are more difficult to perform predictably, the anterior region is often the only segment used for implant support.

In the Type 2, Division A, B arch, the posterior segments may be treated with narrow-diameter implants, whereas the anterior section is adequate for larger-diameter root form implants to support the prosthesis (Figure 19-6). When possible, the posterior Division B section is changed into Division A. Synthetic onlay augmentation is not as predictable or timely as Division B endosteal implants, which may be used when stress factors are low. Autogenous grafts are more debilitating and require extended healing periods but may be indicated for the benefit of increased posterior bone width when stress factors and patient desires are high. Smaller segments can be augmented with intraorally harvested block grafts.

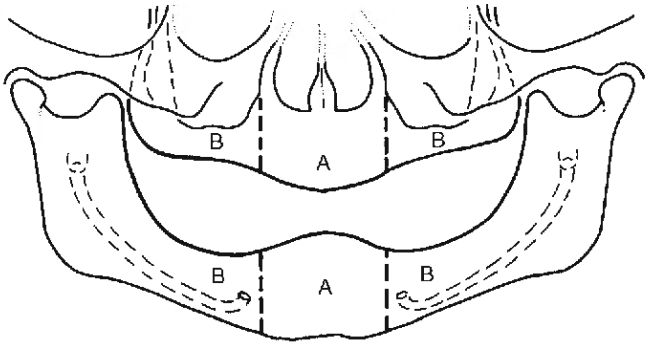

Figure 19-6 A Type 2, Division A, B arch has an anterior section classified as *Division A (A)* and posterior sections as *Division B (B)*. The anterior region dominates the overall treatment plan in all edentulous arches and usually has a greater volume of bone than the posterior.

In the posterior maxilla, bone spreading and Division A root forms should be considered. The softer the bone is, the easier it is to spread.

Two primary modules exist to restore the Type 2, Division A, C edentulous ridge. In the mandible, the most common option is the use of the anterior section only for implant-supported root form implants (Figure 19-7). The maxillary arch may be treated with a combination of sinus graft and endosteal implants if additional posterior support is required for the prosthesis. Because the bone density of the mandible is usually superior to that of the maxilla, and the moment forces remain directed within the arch form, rarely does the mandible require additional posterior support with grafts or circumferential subperiosteal implants. However, for a patient with a square arch form or high masticatory dynamics such as opposing natural teeth, posterior support may be required for an RP-4 or fixed prosthesis.

An edentulous ridge with severe posterior bone loss and abundant bone in the anterior region is uncommon and occurs more frequently in the maxilla. The Type 2, Division A, D patient is treated in a similar manner to the patient with a Type 2, Division A, C arch. Sinus grafts and endosteal implants in the maxilla or only anterior implants with or without an autogenous graft in the mandible are most often the treatment of choice.

The Type 2, Division B, C edentulous arch can be treated with two main treatment options. The anterior section may be changed to Division A by osteoplasty if anatomical conditions permit. These patients are then treated exactly as the previously described Type 2, Division A, C. When the ridge does not present sufficient height after osteoplasty to upgrade the division, the posterior segments may be improved by sinus grafts and the whole arch treated in the same manner as Type 1, Division B or Type 2, Division B, A. Onlay grafts are less predictable than sinus grafts; therefore the anterior mandible may be changed to a Division C by osteoplasty, and a mandibular complete subperiosteal implant and RP-4 restoration or anterior root forms and

WWW.HIGHDENT.IR

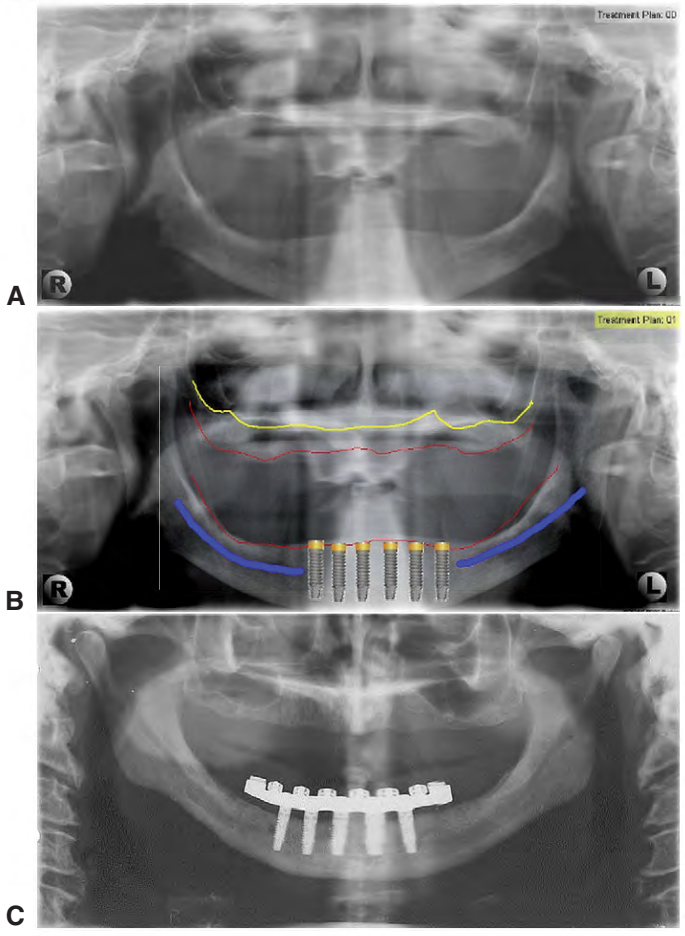

Figure 19-7 **A,** A treatment option for Type 2, Division A, C. **B,** A computer-generated treatment plan with favorable biomechanics places implants in the anterior section of the mandible and restore the arch with cantilevered posterior sections (XCPT, Naples, Fla.). **C,** In a situation with higher masticatory dynamics, this type of arch may mandate the fabrication of a RP-4 prosthesis.

RP-5 prosthesis may be selected for Type 1, Division C mandibular patients.

Patients who have advanced atrophy in the posterior segments and adequate ridge width and height in the anterior may be described as Type 2, Division B, D. This condition almost never occurs in the mandible, but it can be found on occasion in the maxilla. These patients are treated in a manner similar to patients with Type 2, Division B, C, as previously described. The primary difference is that the posterior graft is more extensive and requires additional months for healing before implant insertion and prosthodontic reconstruction. In the mandible, Type 2, Division C, D patients may be treated similar to a Type 1, Division D mandible with autogenous bone grafts before implant placement (Figure 19-8).

Type 3

In Type 3 edentulous arches, the posterior sections of the maxilla or mandible differ from each other. This condition is less common than the other two types and is found more frequently in the maxilla than the mandible. The anterior bone volume is listed first, then the right posterior, followed by the left posterior segment. Therefore the edentulous maxilla with no bone available for implants in the left posterior section, abundant bone in the anterior section, and adequate bone in the right posterior segment is a Type 3, Division A, B, D edentulous arch (Figure 19-9).

The patient with a mandible that has adequate bone in the right posterior segment and inadequate bone on the other side, but abundant bone in the anterior is a Type 3, Division A, B, C edentulous ridge. A narrow-diameter implant may be placed in the right posterior segment, as well as root forms in the anterior section as indicated by the prosthesis. If additional prosthetic support is needed in the left mandibular region, then in most cases additional anterior root forms are placed and splinted to the posterior implants and the teeth or bar cantilevered without implant support on the left posterior region. The Type 3, Division A, C, B patient is treated as a mirror image of Type 3, Division A, B, C.

The Type 3, Division A, D, C (or Type 3, Division A, C, D) patient receives a treatment plan similar to the plans discussed under Type 2, Division A, C. Endosteal root form implants are placed in the anterior section; if the prosthesis needs additional posterior support, then grafts are considered, especially in the posterior maxilla. Patients with Type 3 arches with anterior Division B or C are treated similar to the corresponding Type 2 patients with an anterior Division B or C. In the maxilla, it is not unusual that the premaxilla presents insufficient bone volume and one posterior quadrant requires a sinus graft (Type 3, Division C, A, D). In that case and if appropriate bone volume is present in the cuspid area with favorable force factors, then a full-arch fixed prosthesis can be fabricated after sinus graft and implant placement in the posterior regions, bypassing the premaxilla (Figure 19-10).

The arch is Type 3, even when the anterior region is similar to one of the posterior sections. For example, the Type 3, Division C, D, C ridge has Division C in the anterior, severe atrophy on the right section, and moderate atrophy in the left section. In a mandibular arch of this type, implant placement in the anterior section only may be sufficient to restore the patient, although a subperiosteal implant may be indicated. The maxilla usually requires sinus grafts and subnasal elevation because of the poor biomechanics and bone quality.

The anterior section usually determines the treatment plan. Rarely are posterior implants inserted without any anterior implant support. In traditional prosthetics, Kennedy-Applegate Class I, modification I patients with anterior missing teeth are often restored with an anterior FPD and posterior RPD. This limits rocking of the prosthesis and decreases the forces transmitted to the

WWW.HIGHDENT.IR

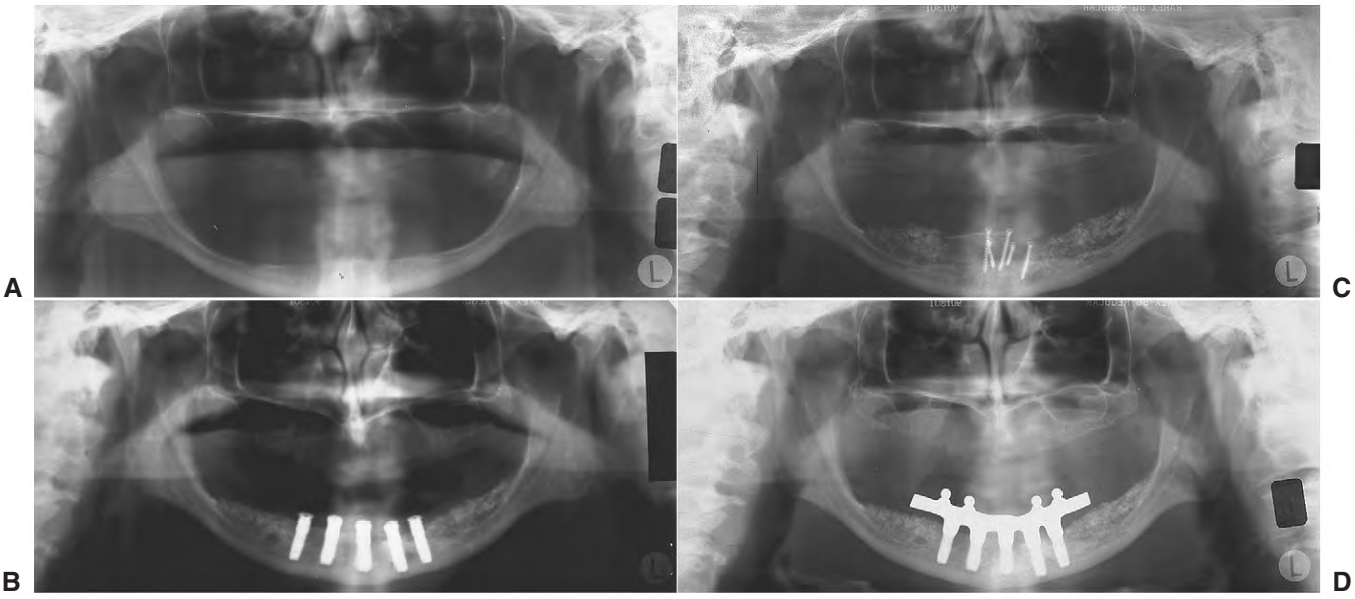

Figure 19-8 **A,** Patients with Type 2, Division C, D mandibles may be treated in a similar fashion as patients with Type I, Division D arches. Iliac crest bone grafting is necessary to restore proper volume of bone to Division A **(B)** before implant placement **(C)** and final restoration fabrication **(D)**.

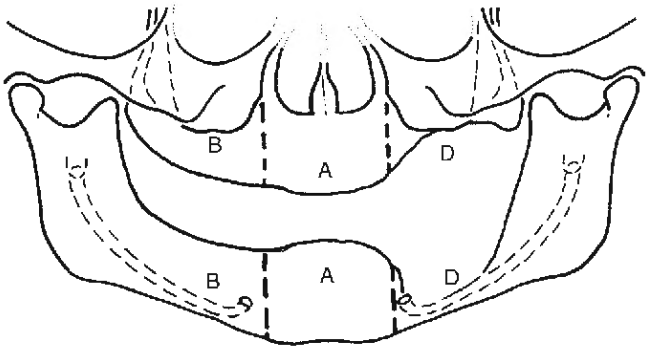

Figure 19-9 This Type 3, Division A, B, D arch has abundant anterior bone *(A)*, moderate bone in the posterior right *(B)*, and severe atrophy in the left posterior segment *(D)*. Sinus grafting is a common treatment if posterior implants are required in the maxilla. However, bone augmentation in the posterior mandible is more unusual, and additional anterior implants with a cantilever are more typical.

Figure 19-10 A maxilla with Type 3, Division C, D, E, may require bilateral sinus grafts and implants in the canine with nasal elevation to support a fixed prosthesis.

abutments. Conventional prosthetics also dictate that a FPD is not indicated when the canine and two adjacent teeth are missing. This applies also when the anterior six teeth are missing and implants cannot be inserted. These time-tested, traditional prosthodontic axioms indicate that posterior implants alone should not be placed without any anterior implant or natural tooth support. However, this concept is often ignored in the maxilla, where practitioners often rely solely on sinus grafts and implants in the posterior segments. If no canine implants are inserted, then the lack of anterior support can cause rotation of the prosthesis and accelerate posterior implant loss. The two posterior sections are not connected because the span between the first premolars is too great, and the posterior implants are placed almost in a straight line with little biomechanical advantage. Anterior rocking and posterior lateral forces on these straight-line implants increase implant failure. The patient's condition is then often worse than before any implant therapy. It is usually far more prudent to convince the patient to be treated with an anterior onlay graft and anterior implants so that a full-arch restoration (RP-4 or fixed) may be fabricated.

SUMMARY

An implant dentistry classification has been outlined that permits visualization of teeth and bone in partially edentulous arches. The foundation of this classification is the Kennedy-Applegate system, which is the most-used classification in prosthodontics. A classification for the completely edentulous arch based on available bone also has been developed.

Chapter 20

Medical Evaluation of the Dental Implant Patient

Carl E. Misch, Randolph R. Resnik

The medical evaluation of patients considering implant therapy is an important aspect to consider for every patient. A retrospective analysis of Veterans' Administration Registry data found that the medical status of patients (i.e., medical history, American Society of Anesthesiologists [ASA] category, and medication history) correlated with implant failure.[1] This chapter is specific for an implant candidate and is developed in three sections. The first section focuses on the importance of the patient interview, with primary emphasis on the medical history questionnaire and the physical examination. The medical history includes those medical conditions most likely to influence implant treatment decisions. The physical examination consists of a hands-on evaluation and recording of the patient's vital signs. The second section (Laboratory Evaluation) reviews those laboratory tests of interest to implant dentistry. The evaluation includes a complete blood cell count (CBC), basic metabolic panel (BMP), comprehensive metabolic panel (CMP), or bleeding disorder tests. The third section relates the medical and dental implications of the most common systemic diseases found in implant patients.

MEDICAL EVALUATION

The medical evaluation remains of paramount importance in implant dentistry, perhaps more so than in other disciplines of dentistry.[2] Implant treatment is primarily a surgical, prosthetic, and maintenance discipline for an older segment of the population. The need for implant-related treatment increases with the age of the patient; as a result, the implant dentist treats more elderly patients than do other specialists in dentistry.[3,4]

An estimated 12% of the U.S. population is 65 years of age or older; this number is expected to reach 21% (64.6 million) in the year 2030.[5] A 65-year-old person has a life expectancy of another 16.7 years, and an 80-year-old person can expect to live an additional 8 years.[6] These patients often request implant support for their failing fixed restorations or to improve the conditions of their removable prostheses. An increased life span means the number of elderly patients in the dental practice is likely to increase. Therefore it is important to design the medical and physical evaluations to accommodate the special conditions of these patients.

Physiologic Changes in the Elderly

Physiologic changes associated with aging and their pharmacologic counterparts modify the physical, social, and economic life of the patient. Although important individual variations exist, the biologic systems of the elderly patient must cope with a decrease in function and physiologic reserve. These physiologic changes may predispose or increase the aging patient's susceptibility to disorders.

In general, a healthy older person demonstrates only half the lung function of a healthy young adult. The blood flow of an older patient is 80% that of the healthy 30 year old, the cardiac output is only 70%, the renal plasma flow is only 50%, and the glomerular filtration is only 60%. A decrease in the elasticity of the arterial system is illustrated by an increase in systolic blood pressure. The vital capacity is reduced to 70% of a 17-year-old patient and corresponds to a decrease in the arterial partial pressure of oxygen.[7] Gastric motility and intestinal absorption are also decreased.

The total body weight of the patient is often reduced, especially if masticatory deficiency from lack of teeth and bone is present; however, there is an increase in body fat. Consequently, any medications administered will follow modified pharmacokinetics and dynamics. Drug kinetics are modified, especially in the distribution phase, as a result of the increased water weight, decreased plasma albumin, and decreased cardiac output. The decreased plasma albumin concentration causes a greater percentage of the drug to remain free and active. The decreased ability to metabolize drugs, related to the decreased renal function, is responsible

WWW.HIGHDENT.IR

for the decreased excretion of the drugs. Therefore the intervals between drug administration should be longer and dosages should be decreased, except for liposoluble drugs and antibiotics, to compensate for the increase in body fat and the reduced immune response.

The decreased gastric motility of the elderly patient affects the use of oral analgesics such as codeine. Pharmacodynamic alterations include an increased sensitivity to central nervous system (CNS) depressant drugs. The individual variations are greater than in other segments of the population; the dosage should be assessed for each patient.

Chronic illness and multiple disease states are characteristics of aging. Patient surveys indicate that 80% of the elderly have at least one chronic disease. Half of the people older than 65 years have arthritis, 42% have hypertension, 34% have other cardiovascular problems, and more than 40% have hearing impairments. Other conditions associated with aging are the increased frequency of diabetes (8.5%), immune response problems, orthopedic (osteoporosis) problems (17%), and sensory deficiencies as well as degenerative diseases.[8,9] The influence of chronic disease states doubles for people older than 65 years of age and affects pathologic processes; surgery may increase individuals' surgical risks and affect prognoses.

Medications and the number of drugs usually increase with age; women usually take more medications than men. At least 75% of patients 65 and older take medications.[10-12] Elderly patients receive 25% of all prescription drugs, although they represent only 12% of the total population. They receive an average of 13 prescriptions a year, in addition to numerous over-the-counter drugs, mainly analgesics. The drug categories most often prescribed among the top 50 drugs prescribed in 2004 include: (1) cardiovascular drugs (13 of the top 50), (2) central nervous system agents (10 of the top 50), (3) gastrointestinal and respiratory agents (7 of the top 50), and (4) endocrine agents (6 of the top 50).[13]

The cardiovascular drugs most prescribed are digitalis (digoxin; Lanoxin), anticoagulants (warfarin sodium; Coumadin), angiotensin-converting enzyme inhibitors (Vasotec, Zestril, Capoten, Prinivil), diuretics (triamterene, furosemide, Lasix), calcium channel blockers (Procardia, Cardizem, Norvasc), and cholesterol-reducing agents (Lipitor, Zocor). Psychotropics and anticonvulsants are mostly represented by benzodiazepines (Xanax), antidepressants (Prozac, Zoloft), and anticonvulsants (Dilantin, Klonopin). Among gastrointestinal and respiratory drugs are antacids (Zantac), beta bronchodilators (Proventil), and antihistamines (Claritin, Seldane).

Many of these drugs are often the cause of adverse drug reactions. A study showed that more than 70% of drugs taken by elderly patients have potential adverse effects in the dental practice. The most common side effects of prescription drugs are xerostomia (especially antidepressants and antianxiety drugs), gastroesophageal irritation and reflux, and abnormal bleeding.

Among the 13 broad categories of oral side effects of the 200 most frequently prescribed drugs reported, xerostomia was first. This may lead to frequent *Candida* spp. infections, increased periodontal and peri-implant diseases, caries, and bacterial infections caused by the loss of protection from saliva. Xerostomia also decreases the valve seal of soft tissue–borne removable prostheses and increases the risk of abrasions and sore spots. Suggested management includes saliva substitutes, salivary stimulants, frequent glasses of water throughout the day, strict control of the diet to decrease cariogenicity, and avoidance of tobacco or alcohol products.

Side effects of cardiovascular drugs depend on the drug category. Digitalis can cause nausea, anorexia, chromatopsia, and arrhythmias. Diuretics cause dehydration, xerostomia, electrolyte imbalance (potassium depletion), and hyperglycemia and predispose to sialoadenitis. Calcium channel blockers may be responsible for edema, constipation, and gingival hyperplasia. Nifedipine, a calcium channel blocker, is known to exacerbate gingival enlargement around both natural teeth and dental implants. To date, the best management is still frequent professional cleanings combined, if necessary, with surgical removal of the hyperplastic tissue to ease daily care and improve esthetics. Angiotensin-converting enzyme inhibitors may produce cough, angioedema, and taste alteration. Anticoagulants and potential risk of hemorrhage are well documented. Care should be taken not to administer erythromycin with terfenadine (Seldane) because of potential cardiotoxic drug interaction. The most common risk of patients on insulin is hypoglycemia.[14-17] Therefore dental practitioners may have to address a variety of drug-related adverse effects, the most common being:

- Abnormal bleeding (aspirin, nonsteroidal antiinflammatory drugs [NSAIDs])
- Altered hematopoiesis (barbiturates, phenothiazines)
- Altered host resistance (antibiotics, insulin)
- Systemic corticosteroids
- Decreased stress tolerance (beta blockers, calcium channel blockers)
- Gastrointestinal irritation (aspirin, antibiotics)
- Gingival hyperplasia (nifedipine, diltiazem, phenytoin, valproic acid, verapamil)
- Mucosal reaction (barbiturates)
- Respiratory depression (narcotics, barbiturates)
- Salivary gland swelling/pain (clonidine, insulin)
- Phenothiazines
- Sialorrhea (cholinergics, anticonvulsants, antianxiety)
- Taste alteration (ACE inhibitors, benzodiazepines, metronidazole)
- Xerostomia (nearly all drugs)

In older patients, 30% of drug-induced illnesses are due to interactions between medications. Antimicrobials and

WWW.HIGHDENT.IR

analgesics accounted for 40% of these.[17] These interactions account for 20% of hospital admissions of senior citizens. Notably, asthmatic patients taking NSAIDs may experience acute bronchospasm. Terfenadine (Seldane) may cause life-threatening ventricular arrhythmias in patients taking ketoconazole or erythromycin.[18] Erythromycin can cause nausea, vomiting, and cardiac dysrhythmias in patients on carbamazepine treatment. Patients receiving antiparkinsonian treatment with selegiline (Eldepryl)[18-20] may suffer fatal interaction if used with opioids (especially meperidine).[18-20] Patients following antihypertensive therapy should not receive long-term NSAIDs therapy because the latter may significantly lower the efficacy of the antihypertensive agents.

Management of Elderly Implant Patients

The elderly patient's compliance is often decreased. Aging patients have a tendency to forget to take medications or to mistake dosage and frequency. Because of impaired hearing and vision, they may become confused more easily. Many follow an inadequate diet that can impair their condition and slow healing after surgery.

Even healthy older implant candidates (older than 60 years) should be considered as patients with mild systemic disease, just because of their age.[21] As a result of a decrease in physiologic adaptability, the aged patient has less reserve to react to stress. If the limits of homeostatic reserve are reached, the patient can reach a critical condition.[22] The elderly patient can follow regular implant therapy provided a typical stress reduction protocol is implemented. Monitoring of vital signs, modified dosage of medications, and special care during sedation because of an increased sensitivity to CNS depressants are indicated. An increased dosage of antibiotics compensates for the less competent immune system and the increased susceptibility to viral and bacterial diseases. An increased dosage of liposoluble drugs is also suggested. Elderly patients are reportedly less sensitive to pain, so a reduced dosage of narcotic analgesics is recommended, especially because gastric motility is reduced in these patients. The doctor should be aware of the eventual adverse drug reactions to the medications already taken by these patients when combined with those later prescribed for implant surgical procedures.

MEDICAL HISTORY

A written medical history should be obtained for every implant candidate. The review of the patient's medical history is the first opportunity for the dentist to talk with the patient. The time and consideration taken at the onset will set the tone for the entire subsequent treatment. This first impression should reflect a warm, caring practitioner who is highly trained to help patients with complex treatments. A sincere interest and active note-taking process are beneficial. The practitioner should not underestimate the value of the medical history interview. Asking questions that show an understanding of listed medical conditions and related common problems offer several benefits.

The two basic categories of information addressed during the review of the medical history include the medical history and a review of the patient's systemic health. The dental office uses a medical evaluation form to obtain most of this information (Figure 20-1).[23] Of particular note is medication usage within the preceding 6 months, allergies, and a review of the systems of the body. The pathophysiology of the systems, the degree of involvement, and the medications being used to treat the conditions are evaluated. It is important to review this form with the patient to ensure that comprehension is adequate to answer all questions. The form should include all medical areas of interest to the implant dentist.

Extraoral and Intraoral Examinations

After the medical history is reviewed, the medical physical examination begins. This is the first physical contact the office staff has with the patient. A gentle, caring approach should continue throughout the examination. A complete evaluation of the head and neck is important initially and at all subsequent preventive maintenance (recall) appointments. The patient is informed of the need for periodic examination for cysts and benign or malignant tumors, because 26,000 cases of cancer are diagnosed in the head and neck region each year.

The extraoral and intraoral examinations are similar to those addressed in any oral diagnosis textbook. A few specific areas are mentioned because complications specific to implant treatment have been observed. The extraoral examination is performed first. Features and facial symmetry are observed, including the ears, nose, and eyes. If the midline, occlusal plane, or smile line of the natural teeth or existing prosthesis is not harmonious, the cause should be determined. Patients are very receptive to critical evaluation and treatment limitations relating to facial esthetics before reconstruction begins. However, a similar discussion at the end of treatment is considered an excuse.

The submental, submandibular, parotid, and cervical areas are palpated for lymphadenopathy or unusual swelling. Sialoliths may be blamed on implant surgery, when they were actually previously present. The area between the cricoid notch and the suprasternal notch is palpated for hypertrophy of the thyroid gland because its physiology influences bone metabolism and implant management.

Intraoral examination of the lips, labial and buccal mucosa, hard and soft palate, tongue, and oral pharynx is then performed. Any lesions or disease states must be further evaluated before implant procedures commence.

General Dental Responsibility And Consent Statement

I hereby authorize and request the performance of dental services for myself or for: _____

I also give my consent to ANY advisable and necessary dental procedures, medications or anesthetics to be administered by the attending dentist or his supervised staff for diagnostic purposes or dental treatment. These records may include study models, photographs, x-rays and blood studies. I understand and acknowledge that I am financially responsible for the services provided for myself and or the above named, regardless of insurance coverage. Treatment plans involving extended credit circumstances are subject to a credit check. I also understand that the treatment estimate presented to me is only an estimate. Occasionally, the need may arise to modify treatment. In such a case, I will be informed of the need for additional treatment, and any fee modification.

To the best of my knowledge the information in this form is accurate.

Vital Signs

The recording of vital signs (blood pressure, pulse, temperature, respiration, weight, and height) is also part of the physical examination. This information can often be gathered by trained dental auxiliary personnel before the patient's history is reviewed by the dentist. If any findings are unusual, the doctor can repeat the evaluation as needed.

Blood Pressure

Approximately 10% of dental offices record the patient's blood pressure.[24] This proves worthwhile for the implant dentist because surgery and long prosthodontic procedures are frequently required. The importance of obtaining and recording the blood pressure in every implant patient is twofold. First, the initial recording may serve as a baseline measurement, which if too high may contraindicate a surgical procedure. Second, when in an acceptable range, the initial blood pressure acts as a baseline measurement specific for that patient. If the patient has a future problem during treatment, the blood pressure difference between baseline and the current situation may alter the medical risk of the patient.

The blood pressure is measured within the arterial system. The maximum pressure is the systolic, and the minimum pressure is the diastolic. Blood pressure is influenced by the cardiac output, blood volume, viscosity of the blood, condition of blood vessels (especially the arterioles), and heart rate. There is a direct and an indirect determination of blood pressure. The dentist will use only the indirect method. This technique was first developed by the Italian physician Riva-Rocca in the nineteenth century.[25] The sphygmomanometer consists of an inflatable bag covered by a cuff and a manometer to register the force and rate of air within the bag. The two most common manometer systems use mercury gravity or aneroid gauges. The mercury system is more accurate in changing climates; after it is calibrated, it is consistent for many years. The aneroid manometer is as accurate as the gravity type, but requires regular calibration.

Blood pressure monitoring should only be completed by trained medical personnel. The operator should be trained and retrained on a regular basis in the standardized technique. Patients should ideally be seated for 5 minutes, with their feet on the floor and arm supported at the level of the heart. Caffeine intake, smoking, and strenuous exercise should be avoided for at least 30 minutes before measurement. At least two measurements should be taken, with the average recorded. An appropriately sized cuff (cuff bladder encircling 80% of the arm) should be used for accuracy.[26] The inflatable cuff is positioned over the bare upper arm at the level of the patient's heart, with the patient's palm supine. The brachial or radial artery is palpated and the bag is inflated to obliterate the vessel, about 30 mm Hg above the estimated systolic pressure. The cuff is deflated 2 to 4 mm Hg at every heartbeat. Using a stethoscope over the brachial artery, the systolic pressure is recorded at the first tapping sound heard. When the sounds become muffled or inaudible the diastolic pressure is noted.

Pulse

Only 3% of dentists record the pulse of their patients, yet much pertinent information is available from this simple procedure. The pulse represents the force of the blood against the aortic walls for each contraction of the left ventricle. The pulse wave travels through the arteries and reaches the wrist 0.1 to 0.2 seconds after each contraction. The actual blood flow takes longer to travel this distance. The usual location to record pulse is the radial artery in the wrist. However, other locations such as the carotid artery in the neck and the temporal artery in the temporal region are convenient to use during implant surgery or dental treatment. Pulse monitors are easy to use and are beneficial during surgery or long prosthetic appointments.

Pulse Rate

The pulse rate should be evaluated for a minimum of 30 seconds, and 1 minute is suggested. The normal pulse rate varies from 60 to 90 beats/min in a relaxed, nonanxious patient. The beats are both strong and regular. The normal cardiac rhythm originates in the sinoatrial node; the pulse reflects the ventricular contractions. The upper limit of normal is considered 100 beats/min; people in excellent physical condition may have a pulse rate of 40 to 60 beats/min. A pulse rate less than 60 beats/min or higher than 110 beats/min in the nonathlete is suspect and warrants a medical consultation.

A decreased pulse rate of normal rhythm (less than 60 beats/min) signals sinus bradycardia. It is natural for some patients and may reach as low as 40 beats/min, although most patients become unconscious below this rate. An adult pulse rate lower than 60 beats/min in a nonathlete mandates medical evaluation before surgery. During implant surgery, inappropriate bradycardia may indicate impending sudden death. If the pulse rate of the patient decreases to less than 60 beats/min and is accompanied by sweating, weakness, chest pain, or dyspnea, the implant procedure should be stopped, oxygen administered, and immediate medical assistance obtained.

An increased pulse rate of regular rhythm (more than 100 beats/min) is called *sinus tachycardia*. This rate is normal if experienced during exercise or anxiety. However, a medical consultation is suggested when a nonanxious patient has a resting pulse rate higher than 100 beats/min. In patients with anemia or severe hemorrhage, the heart rate increases to compensate for the depletion of oxygen in the tissues. Therefore, when increased bleeding during surgery is observed, evaluate

WWW.HIGHDENT.IR

the pulse rate and blood pressure. When elevated, an increase in bleeding is readily observed.

Pulse rate and temperature are also related, with the pulse rate increasing 5 beats/min for each degree that the body temperature rises. Hyperthyroidism and acute or chronic heart disease also may result in sinus tachycardia. A condition called *paroxysmal atrial tachycardia* is characterized by episodes of very fast heartbeats that may last a few minutes or several weeks. All of these conditions affect the surgery or may increase postoperative swelling. The increased swelling favors the occurrence of infections and complications during the first critical weeks after implant placement. This can compromise the subsequent years of implant service to the patient.

Pulse Rhythm

Two types of abnormal pulse rhythm are noted: regular and irregular. A regular irregularity increasing during exercise can signal atrial fibrillation. This may be a consequence of hyperthyroidism, mitral stenosis, or hypertensive heart disease and should be evaluated before implant surgery. Stress-reduction protocols can be implemented and implants may even be contraindicated if the causal conditions are severe.

An irregular abnormal pulse rhythm includes premature ventricular contractions (PVCs), which are noticed as a distinct pause in an otherwise normal rhythm. This condition may be associated with fatigue, stress, or excessive use of tobacco or coffee, but it is also observed during myocardial infarction and as a precursor to cardiac arrest. If during implant surgery, five or more PVCs are recorded within 1 minute, especially when accompanied by dyspnea or pain, the surgery should be stopped, oxygen administered, the patient placed in a supine position, and immediate medical assistance obtained. If the health history includes cardiovascular disease, including hypertension, the pulse rhythm should be recorded. Sudden death in persons older than 30 years with PVC is six times more frequent than in younger persons.[22]

Pulse Strength

The patient's pulse rate and rhythm may be normal, yet the blood volume can affect the character of the pulse. The pulse may alternate between strong and weak beats that can indicate pulsus alternans, which is frequently observed in left ventricular failure, severe arterial high blood pressure, and advanced coronary disease. Implant surgery is contraindicated, and medical consultation with an electrocardiographic examination is needed to obtain a diagnosis. After a diagnosis of pulsus alternans, a patient may have less than 2 years to live.

Temperature

The thermometer was first used clinically by Santorio of Padua, Italy, in the seventeenth century. Normal body temperature ranges from 96.8° to 99.4° F in a healthy individual. It is usually lowest in the morning and highest during late afternoon or evening. An oral temperature of 99.5° F or higher is considered in the febrile range. For every degree of fever, the pulse rate rises 5 beats/min and the respiratory rate increases 4 beats/min. If the patient's temperature is 104° F or higher, medical consultation is suggested.

The usual cause of elevated body temperature is bacterial infection and its toxic by-products. Other causes can be exercise, hyperthyroidism, myocardial infarction, congestive heart failure, and tissue injury from trauma or surgery. Dental conditions causing an elevated temperature include severe dental abscess, cellulitis, and acute herpetic stomatitis. Elective dental treatment (such as implant surgery or bone grafting) is contraindicated when the patient is febrile. The cause of the fever may complicate the postsurgical phase of healing. In addition, because elevated temperature increases the patient's pulse rate, the risks of hemorrhage, edema, infection, and postoperative discomfort are greater. Special attention must be given to a prolonged, sustained fever after surgery because sepsis or possible brain abscess could be present. Low body temperature can be found in hypothyroidism.

Respiration

Respiration is noted while the patient is at rest. The normal rate in the adult varies between 16 and 20 breaths per minute and is regular in rate and rhythm. If the patient uses accessory muscles in the neck or shoulders for inspiration, whether before or during surgery, dyspnea is suspected. Many intravenous drugs, including narcotics, cause dyspnea. Congestive heart failure, bronchial asthma, and advanced pulmonary emphysema also impair breathing. If dyspnea occurs during surgery, the pulse should immediately be evaluated to rule out the presence of PVC or myocardial infarction.

Hyperventilation is the result of both an increased rate and depth of respiration and may be preceded by frequent sighs such as is seen in the anxious patient. A respiratory rate greater than 20 breaths per minute requires investigation. Anxiety may increase this rate, in which case sedatives or stress-reduction protocols are indicated before implant surgery. Other causes for an increased respiration rate are severe anemia, advanced bronchopulmonary disease, and congestive heart failure. All three can affect the surgical procedure or healing response of the implant candidate.

LABORATORY EVALUATION

Routine laboratory screening of patients in a general dental setting who previously reported a normal health history have found that 12% to 18% have undiagnosed systemic diseases.[27,28] Many of these disorders may influence implant surgery protocol or long-term success rates. The percentage of implant patients with unreported systemic illnesses is most likely higher because

WWW.HIGHDENT.IR

Table 20-1 Normal Laboratory Values

Hemoglobin	12-18 g/100 mL
Hematocrit	35%-50%
Red blood cell count	4-6 million/mm^3
White blood cell count	4500-13,500/mm^3
Neutrophils	54%-62%
Lymphocytes	25%-30%
Eosinophils	1%-3%
Basophils	1%
Monocytes	0%-9%
Prothrombin time	1-18 sec
Partial thromboplastin time	By laboratory control
Platelets	140,000-340,000/mL
Bleeding time	1-6 min
International normalized ratio	Without anticoagulant therapy: 1 Anticoagulant therapy range: 2–3
Sodium	135-147 mEq
Potassium	3.5-5 mEq
Bicarbonate	24-30 mEq
Chloride	100-106 mEq
A1c (glycosylated hemoglobin)	6% controlled diabetic
Fasting blood sugar	70-100 mg/dL
Oral glucose tolerance test	<140 mg/dL

the average implant patient is older than those in these general studies. Implant therapy comprises an elective surgery that involves a considerable investment of time and money by the patient. Therefore clinical laboratory tests are often used to supplement diagnosis and treatment planning. Laboratory screening is also of benefit in recognizing oral manifestations of systemic diseases. However, preoperative testing should not be considered mandatory for all patients. Justification of laboratory procedures should relate to the specific type of surgery and the patient's condition. On the other hand, any patient older than age 50 years should have laboratory evaluations as part of a routine physical every 3 years or less. If the patient older than 50 years of age has not had a physical and laboratory tests, a physician referral is warranted before advanced implant surgery.

The most common clinical laboratory evaluation for implant dentistry is obtained from venous blood samples and may include a CBC, BMP, CMP, and bleeding disorder tests.[29] The dentist should select the tests needed in the diagnosis of systemic diseases affecting implant treatment.

Urinalysis

In the healthy adult, approximately 180 L of fluid is filtered through the glomeruli of the kidneys each day. The glomeruli filter the plasma, and the tubules selectively reabsorb water and substances useful to the body. They leave undesirable substances behind or secrete them into the urine. The urinary constituents can be altered in the presence of systemic disease, infection, or focal urinary tract infection.

Urinalysis has more qualitative than quantitative information. It is not indicated as a routine procedure for all dental patients and is rarely used in implant dentistry. It is primarily a screening test for diabetes (glucose/ketone), deficiencies or irregularities in metabolism, renal disease, protein in blood, liver function (bilirubin), or suspected infection. The most frequent use of urinalysis by the dentist concerns suspicion of or screening for diabetes mellitus, which is the most common cause of glucosuria. However, other conditions such as pregnancy, Cushing's disease, Graves' disease, intracranial tumor, and coronary thrombosis can modify this level. In addition, a diabetic patient with high glucose blood levels may not spill glucose into the urine. Examination of the blood, on the other hand, indicates more precisely the patient's glucose metabolism and is a more reliable test. Therefore urinalysis is rarely indicated specifically for oral implant surgery.

Complete Blood Cell Count

The CBC is one of the most common blood tests and consists of the calculation of the cellular components of blood. These calculations are determined by specifically designed machines that analyze the different components of blood in a very short period. These include testing the number of erythrocytes (red blood cells) and leukocytes (white blood cells), leukocytic differential, cellular morphology and maturity, hemoglobin determination, hematocrit, and platelet count (Table 20-1). Indications for a CBC are suspected dyscrasia, glucocorticoid therapy within 1 year, chemotherapy, renal diseases, or expected major blood loss. Asymptomatic patients do not require a CBC unless major blood loss is possible with surgery. Evaluation of the CBC can be limited to three clinical situations for implant dentistry: erythrocytic disorders, leukocytic disorders, and bleeding disorders.[30]

White Blood Cell Count

The normal total white blood cell (WBC) count ranges from 4500 to 13,500 per mm^3 and often varies with each disease. An increase in WBCs, or leukocytosis, is not specific to one white blood cell type. A decrease in number of WBCs is referred to as *leukopenia*. One or all the WBC elements may be decreased.

The determination of an inflammatory process is important for the implant dentist and may occur without leukocytosis. An increased count of band neutrophils indicates inflammation. Segmented neutrophils phagocytize bacteria and increase in times of infection. Therefore if a WBC count is ordered to determine whether infection around an implant is affecting the patient's overall health, a differential of WBC types is evaluated, not

WWW.HIGHDENT.IR

just the number of leukocytes present. WBC counts are critical to the dental outpatient, particularly for patients with immune diseases or undergoing chemotherapy. The counts can indicate infections, leukemic disease (myoproliferative), immune diseases, and toxicity of drugs (especially chemotherapeutic drugs). The two most critical groups are granulocytes (e.g., neutrophils, which fight infection) and lymphocytes (immune response). Absolute neutrophil count includes segs and bands and must be greater than 2000 for normal dental treatment without antibiotic prophylaxis. Levels of 1000 to 2000 need antibiotic coverage. Levels lower than 1000 mandate physician referral. Lymphocytes are necessary to evaluate the immune response potential of the patient. Many immunodeficient patients, including those with human immunodeficiency virus (HIV), may have no systemic symptoms, yet have deficient lymphocytes.[31]

Red Blood Cell Count

Red blood cells (RBCs) are responsible for the transport of oxygen and carbon dioxide throughout the body and for control of the blood pH. The cells represent the largest segment of the formed elements of the blood. The normal RBC count is higher in men than in women. Increases may result from polycythemia, congenital heart disease, or Cushing's syndrome. The most common finding is a decreased cell count usually indicating anemia.

Hemoglobin

Almost 95% of the dry weight of an RBC is hemoglobin. It is responsible for the oxygen-carrying capacity of the blood. The normal level of hemoglobin is 13.5 to 18 g/dL in men and 12 to 16 g/dL in women. The preoperative threshold of 10 g/dL is often used as a minimum baseline for surgery. However, many patients can undergo surgical procedures safely at 8 g/dL. The threshold is related to the underlying condition of the patient and the anticipated blood loss.[25]

Hematocrit

The hematocrit represents the packed cell volume and indicates the percentage of RBCs in a given volume of whole blood (RBCs/100 mL of blood). It is the prime indicator of anemia or blood loss. Therefore the hematocrit is evaluated if one of these conditions is suggested. Values within 75% to 80% of normal are required before sedation or general anesthesia.

Bleeding Tests

Bleeding disorders are one of the most critical conditions encountered in surgery. The platelet count may reflect this complication, but it does not provide enough information to determine potential bleeding disorders. The patient's medical history is a better detector (see Figure 20-1).

Understanding the normal clotting process determines which bleeding test to evaluate. Whenever the integrity of a vessel wall is altered surgically, hemostasis is achieved by vascular spasm, blood coagulation, and, finally, growth of fibrous tissue to close the defect in the vessel. For hemostasis to be maintained or achieved, the blood vessels must be normal, functional platelets must be present in sufficient number, and the coagulation mechanism of the blood must be intact. The three phases necessary for hemostasis involve the vessels, the platelets, and coagulation—both extrinsic (outside blood vessels) and intrinsic (inside blood vessels).

In a normal, healthy individual, coagulation is initiated within 20 seconds of blood vessel damage. This is accomplished by two phases of hemostasis: primary and secondary. Primary hemostasis is initiated when platelets adhere to collagen fibers in the vascular endothelium. The platelets are then activated, which results in additional platelet activation. The platelets undergo a change in shape, which exposes a phospholipid surface for platelets to link together via glycoprotein. The secondary phase consists of a coagulation cascade that has two pathways (Figure 20-2): contact activation pathway (formerly the intrinsic pathway) and the tissue factor pathway (formerly the extrinsic pathway). These pathways involve a series of enzymatic reactions in which an inactive coagulation factor is converted to an active form, which then activates the next coagulation factor in the series. The process involves a series of reactions in which the enzyme and substrate are localized on the activated platelet surface. In addition to the clotting factors, cofactors such as calcium and vitamin

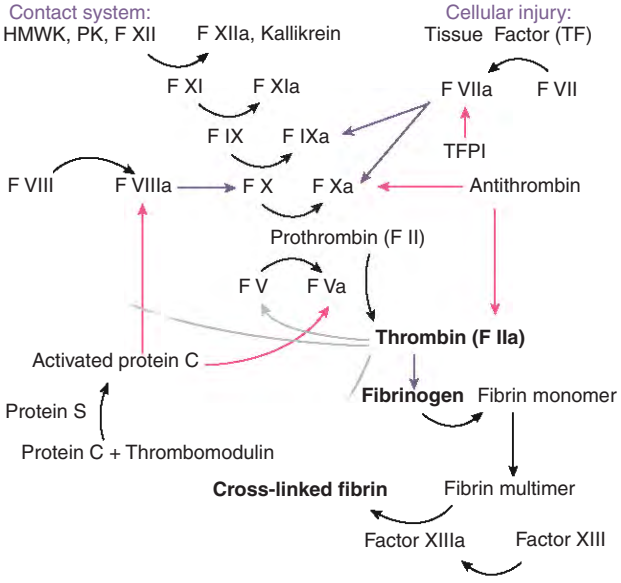

Figure 20-2 The secondary phase of hemostasis is a coagulation cascade.

WWW.HIGHDENT.IR

K are involved that are necessary for the synthesis of additional clotting factors. The tissue factor pathway main role is for the generation of thrombin via various reactions precipitated by various coagulation factors. The contact activation pathway uses various coagulation factors that form the primary complex on collagen. The end result is the formation of thrombin, which helps to convert fibrinogen to fibrin, which is the building block of the hemostatic plug.[32]

The tissue factor pathway (extrinsic system) and the contact activation pathway (intrinsic system) lead to completion of hemostasis along a common pathway. Both systems are necessary for normal coagulation. The extrinsic system is activated outside the blood vessels; the intrinsic system is activated within the blood vessels.

Three ways to detect potential bleeding problems are: (1) check the medical history, (2) review the physical examination, and (3) screen the clinical laboratory tests.[33] More than 90% of bleeding disorders can be diagnosed on the basis of the medical history alone. The history should include the following questions covering five topics entered on the medical history form:

1. Familial history of bleeding disorders
2. Spontaneous bleeding from the nose, mouth, or other apertures
3. Bleeding problems/bruising after operations, tooth extractions, or trauma
4. Use of medications that may cause bleeding disorders
5. Past or present illness associated with bleeding disorders

Medical History

Bleeding problems in relatives are significant because they indicate inherited coagulation disorders. Hemophilia and Christmas factor disease are the most common. Spontaneous bleeding from the nose, gingiva, or joints may indicate either inherited disease or illness with bleeding disorders (e.g., acute leukemia). If there were no bleeding problems in a previous surgery, no acquired disorders were present at that time, and no significant inherited disorder is present now. Medications that cause increased bleeding usually do so because of platelet disorders. These iatrogenic factors are seen primarily with three types of drugs: anticoagulants, aspirin, and long-term antibiotics. Past or present illnesses that may present associated bleeding disorders include leukemia, anemia, thrombocytopenia, hemophilia, and hepatic diseases. Approximately half of the patients with liver disease have a decrease in platelets secondary to hypersplenism, and therefore have potential bleeding disorders.[34]

Physical Examination

The second method by which the implant dentist can detect a patient with a bleeding disorder is the physical examination. The exposed skin and oral mucosa must be examined for objective signs. Petechiae, ecchymoses, spider angioma, or jaundice may be observed in liver disease patients with bleeding complications. Intraoral petechiae, bleeding gingiva, ecchymoses, hemarthroses, and hematomas may be present in patients with genetic bleeding disorders. Patients with acute or chronic leukemia show signs of oral mucosa ulceration, hyperplasia of the gingiva, petechiae or ecchymoses of the skin or oral mucosa, or lymphadenopathy.

Clinical Laboratory Testing

The third option to detect a bleeding disorder is clinical laboratory testing. If a patient's health history and physical examination do not reveal potential bleeding disorders, routine screening with a coagulation profile is not indicated. However, if extensive surgical procedures are expected, a coagulation profile is indicated. Four tests are used to screen patients for bleeding disorders and measure both pathways of the coagulation cascade as well as platelet function and capillary fragility. These include the platelet count, bleeding time, partial thromboplastin time (PTT), and international normalized ratio (INR) (formerly prothrombin time [PT]). A thrombin clotting time and fibrinogen level may be added on occasion.

International Normalized Ratio and Prothrombin Time

The most appropriate tests to evaluate patients that are on anticoagulant therapy are the INR and PT. These tests measure the effectiveness of the tissue factor pathway (extrinsic system) and common pathways of coagulation. In the past, PT values were used exclusively; however, because of the variability in laboratory reporting, the World Health Organization developed a more standardized system, the INR. In a normal individual, the INR value should be 1.0. The recommended therapeutic range of continuous anticoagulation is an INR between 2.0 and 3.0 for all conditions except artificial heart valves, for which the INR should be between 2.5 and 3.5 (Table 20-2).[35]

Partial Thromboplastin Time

Another test for coagulation is the PTT, which measures the contact activation pathway (intrinsic system) and

Table 20-2 Target International Normalized Values for Specific Medical Conditions

PATIENT CONDITION	INR VALUE
Normal	1.0
Prevention of myocardial infarction	2.0-3.0
Treatment of pulmonary embolism	2.0-3.0
Treatment of atrial fibrillation	2.0-3.0
Pulmonary embolism	2.0-3.0
Prosthetic heart valves	2.5-3.5
Prevention of venous thrombosis	2.5-3.5

INR, International normalized ratio.

WWW.HIGHDENT.IR

common pathways. A normal test time is 25 to 40 seconds. This test is usually used to measure the effectiveness of the anticoagulant heparin. It may also be used to evaluate the long-term affects of daily aspirin ingestion.

Bleeding Time

The bleeding time test is used to evaluate platelet function. The Ivy method is the standardized test usually used. In this test, a blood pressure cuff is placed on the upper arm and inflated to 40 mm Hg. A lancet or scalpel blade is used to make a cut on the underside of the forearm, and the time is measured until bleeding has stopped. Normal values fall between 1 and 6 minutes depending on the method used. The bleeding time measures both coagulation pathways and platelet function and capillary activity.

Platelet Count

The platelet count is part of the CBC and is usually in range of 140,000 to 340,000/µL of blood. This test identifies the number of platelets (thrombocytes), which are vital to the formation of the blood clot. If the count falls below 100,000/µL, the patient is said to have thrombocytopenia, which can be significant for bleeding problems in implant patients. If the count level is below 20,000/µL, spontaneous bleeding may occur, which can be life-threatening. Low blood counts may be caused by stomach ulcers, autoimmune diseases, alcohol, and chemotherapeutic medications.[36]

The PTT is used to determine the ability of the blood to coagulate within the vessels. Therefore it tests the intrinsic and common pathways of coagulation (factors VII through XII). The PT/INR determines the ability of the blood to coagulate outside the vessels and therefore tests the extrinsic and common pathways of coagulation. Both systems are necessary for normal coagulation. The patient's history and physical examination can now be related to the appropriate clinical laboratory tests.[37,38]

Heparin is the anticoagulant usually prescribed for renal dialysis. A PTT test should be scheduled for the day of surgery. Heparin is a short-acting anticoagulant; therefore this test and the surgery should be scheduled 24 hours or more after heparin administration. Four to six hours without heparin are usually adequate to return coagulation to near normal levels. Kidney dialysis patients often experience healing and maintenance complications with their natural teeth; implants are usually contraindicated in these patients. However, the dentist may have to treat a dialysis patient who has previously had implant therapy. If the PTT is more than 1.5 times the normal value, surgery should be postponed.

Long-term antibiotic therapy can affect the intestinal bacteria that produce the vitamin K necessary for prothrombin production in the liver. Therefore if long-term administration of antibiotics has been used by the implant patient, a PT should be obtained to evaluate possible bleeding complications.

Bleeding disorders should be suspected in a patient who is an alcoholic or shows signs of liver dysfunction. The liver is the primary site of synthesis of the vitamin K–dependent clotting factors II, VII, IX, and X. Alcoholism, independent of liver disease, has been shown to decrease platelet production by megakaryocytes and increased platelet destruction. Most coagulation factors are produced in the liver; 50% of patients with liver disease have hypersplenism resulting from the destruction of platelets. The PT is the single most useful test used to evaluate impaired hepatocyte synthesis of prothrombin complex factors and to assess hemostasis in patients with liver disease. Factor VII has the shortest half-life and is the first to decrease. Factor VIII and von Willebrand factor have a tendency to increase in chronic hepatic disease patients. The bleeding time and PT therefore should be evaluated.

The PT and PTT may be used together to determine coagulation factor defects. A normal PT and abnormal PTT suggest hemophilia. An abnormal PT and a normal PTT suggest factor VII deficiency. If both PT and PTT are longer, a deficiency of factors II, V, or X or fibrinogen are considered.

No surgical procedures should be performed on a patient suspected of having a bleeding problem based on history, examination, and clinical laboratory tests without proper preparation, understanding, and concerted management by the dentist and the physician. If the bleeding disorder has been previously undiagnosed, the underlying cause should be addressed before the elective implant surgical procedures begin.

Biochemical Profiles (Serum Chemistry)

The tenets of laboratory diagnosis should be understood, particularly as they relate to implant dentistry. The interpretation of biochemical profiles and the ability to communicate effectively with medical consultants will enhance the treatment of many patients.

The decision to proceed with oral implant treatment may be affected by the results of biochemical profiles by contraindicating the procedure completely, altering the type of implant surgery and reconstruction, postponing the treatment until therapy controls the disease entity, or simply changing the sequence of medications normally used during treatment. Biochemical sanguine profiles are a more necessary part of the medical evaluation for an implant candidate in the presence of systemic diseases or advanced surgical procedures.[39] They are not indicated for every potential implant patient.

1. The BMP, which has replaced the tests SMA 7 and Chem 7, is a group of seven to eight tests that gives the current status of the kidneys, electrolyte and acid/base balance, blood sugar, calcium levels, and monitoring of hypertension.

WWW.HIGHDENT.IR

Table 20-3 Laboratory Evaluation of Disease Indicators

CHEMISTRY	DISEASE
Glucose	Diabetes, steroid dysfunction
Calcium	Renal disease, diet, bone diseases, (carcinoma, parathyroid disease, Paget's disease)
Inorganic phosphorus	Renal disease, endocrine (parathyroid, thyroid, steroids), antacids
Alkaline phosphatase	Liver disease, bone diseases (Paget's disease, metastases, fractures, hyperparathyroidism)
Lactic dehydrogenase	Hemolytic disorders, liver disorders, myocardial infarction
Creatinine	Renal function
Bilirubin	Liver disease

2. The CMP (also Chem 12, SMA 12, or SMA 20) is a group of 14 specific tests that is used as a broad screening tool to evaluate organ function and conditions such as diabetes, liver disease, kidney disease, and hypertension.

Dentists have been trained to take a careful medical history, perform a thorough dental examination, and, on occasion, order laboratory tests that will either confirm or exclude a provisional diagnosis. However, with biochemical profiles such as the BMP and CMP, there is the opportunity to evaluate different biochemical parameters reflecting the patient's health.

To be comfortable in interpreting the biochemical profile, some time must be spent in learning the BMP/CMP pattern of systemic diseases. This pattern recognition is similar to the tissue patterns a pathologist looks at during a biopsy. The BMP/CMP profile has been described as a "biochemical biopsy" of the blood. It includes normal and abnormal values that have interrelationships in the diagnosis of systemic diseases. It is not wise to single out one value to establish a diagnosis. The data should be related with other values obtained in the profile before further determinations are rendered.

More than 20 different tests are available for the selection of this profile from which each laboratory and its referring physicians choose. Therefore the use of different laboratories makes it difficult to develop interpretative skills. The dentist should use the same laboratory consistently, highlighting the abnormal values for an individual test. The dentist is not responsible for treating the many systemic diseases that the biochemical profile reveals. However, it is necessary to know the effects of a disease on the implant treatment.

Normal Range

The normal values found on the BMP/CMP represent a statistical norm. Any population characteristically shows a bell-shaped curve for a particular measurement. It has been shown that 56% of a sample fall within one standard deviation of the mean and 95% are within two standard deviations. The normal value in the biochemical profile represents two standard deviations. Thus "normal" in the statistical sense does not necessarily mean healthy; the word merely describes the typical range of values expected in any given population. Approximately 1 in 20 results will be outside the two standard deviation ranges. The further from the average value a particular value falls, the more certain its clinical significance. Different laboratories can have different normal results.

As biochemical profiles are compiled for an individual patient over several years, the deviation in a given test may indicate a radical change for that individual, although the result never deviates from the normal population range. The implant dentist should remember that the healthy patient of today may have a systemic disease in the future. Therefore when evaluating long-term complications, it is of interest to relate a recent biochemical profile to the one first reviewed before the initial surgery.

The patient should fast before the blood is collected to avoid artificial elevations of blood glucose and depressed inorganic phosphorus. Most of the other elements of the profile will not be affected. This chapter will limit discussion to the factors of most benefit to the implant dentist (Table 20-3): glucose, calcium, inorganic phosphorus, alkaline phosphatase, lactic dehydrogenase, creatinine, and bilirubin.

Serum Glucose

The normal range of glucose found in the blood, 70 to 100 mg/mL, is maintained within fairly narrow limits. Hyperglycemia is a relatively common finding; the most common cause of this condition is diabetes mellitus. If high glucose values are found, referral to a physician for glucose tolerance tests after a glucose loading dose is recommended, except when inorganic phosphorus values are depressed. Depressed inorganic phosphorus usually indicates the patient has eaten before the blood was drawn and the elevated glucose is then related to digestion. Cushing's disease and other conditions related to excess production of adrenal corticoids are also considered in the differential diagnosis with hyperglycemia. Hypoglycemia is unusual and is related to varied causes (e.g., Addison's disease, bacterial sepsis, excessive insulin administration).

Serum Calcium

The implant dentist may be the first to detect diseases affecting the bones. Chemical confirmation is dependent on the patient's serum levels of calcium, phosphorus,

WWW.HIGHDENT.IR

and alkaline phosphatase. In the body, more than 98% of the calcium is stored in the skeleton and teeth. Calcium ions are responsible for neuromuscular excitability, normal blood coagulation, and the activation of several enzymes. Serum calcium levels are influenced by the parathyroid hormone and calcitonin. Serum calcium levels are increased by bone resorption, intestinal absorption, and renal reabsorption of calcium.

Decreased levels of calcium are primarily seen in hypoproteinemic conditions and in renal disease. Renal disease is much more common, but the diet of the potential implant patient may be severely affected by the lack of denture comfort and stability. The cause and treatment of hypocalcemic serum levels should be addressed before implant reconstruction.

Elevated levels of serum calcium are associated with carcinoma in bones, dietary or absorptive disturbances, and hyperparathyroidism. The osteoporosis that accompanies this disorder has been observed in the mandible. Hyperparathyroidism also causes hypophosphatemia. Hypercalcemia associated with a significant elevation of alkaline phosphatase suggests Paget's disease of bone. All other biochemical values being normal, an elevated calcium value may be the result of laboratory error.[40] If phosphorus or alkaline phosphatase levels are also affected, medical evaluation and treatment are indicated before implant surgery.

Inorganic Phosphorus

Inorganic phosphorus levels maintain a ratio of 4:10 compared with calcium, and there is usually a reciprocal relationship. When the level of one increases, the other decreases. The common cause of elevated phosphorus is chronic glomerular disease, indicated by elevated blood urea nitrogen (BUN) and creatinine values.

In the absence of significant glomerular disease (normal BUN and creatinine values), phosphorus level abnormalities are usually associated with the endocrine system or bone metabolism. If an increase in phosphorus is associated with a decrease in calcium and normal renal function, hypoparathyroidism is suspected. Other endocrine disorders associated with an increased phosphorus level include hyperthyroidism, increased growth hormone secretion, and Cushing's syndrome.

Decreased levels of phosphorus may appear in hyperparathyroidism patients, especially when it is associated with hypercalcemia. The chronic use of antacids containing aluminum hydroxide also may induce hypophosphatemia and warrants investigation for a peptic ulcer.

Alkaline Phosphatase

Serum alkaline phosphatase determination helps evaluate hepatobiliary and bone diseases. The normal levels for this enzyme in adults are derived primarily from the liver; extremely high levels of alkaline phosphatase are often associated with hepatic disease.

In the absence of liver disease, elevations of alkaline phosphatase are often a sign of osteoblastic activity in the skeletal system. Therefore bone metastases, fractures, Paget's disease, and hyperparathyroidism increase the level of this serum enzyme. Serum alkaline phosphatase is normal in patients with adult osteoporosis. Low levels of alkaline phosphatase are usually not of clinical significance for the dentist.

Lactic Dehydrogenase

Lactic dehydrogenase (LDH) is an intracellular enzyme present in all tissues (normal 0 to 625 U/L). False elevated LDH levels occur as a result of hemolyzed blood specimens. Therefore if all other blood values are normal, LDH testing should be repeated before further investigation. The highest elevations of this enzyme are seen in patients with myocardial infarction, hemolytic disorders such as pernicious anemia, and liver disorders. Lactic dehydrogenase, aspartate aminotransferase (AST), bilirubin, uric acid, and total protein are indicators of hematologic and reticuloendothelial disorders. Blood disorders are particularly important to the implant surgeon. When LDH values are elevated, the complete blood count is evaluated for blood abnormalities.

Creatinine

Creatinine is an anhydride of creatine used in muscle metabolism (normal 0.7 to 1.5 mg/dL). It is freely filtered by the glomeruli and not reabsorbed. The constancy of formation and excretion permits creatinine levels to be an index of renal function. This important system should not be impaired during implant surgery. Kidney dysfunction may lead to osteoporosis and decreased bone healing because the kidney is required for complete formation of vitamin D. Medications can alter pharmacokinetics, and normal healing can also be affected by kidney disease.

Bilirubin

Within the CMP, seven tests are indicative of liver function (total protein, albumin, cholesterol, bilirubin, LDH, alkaline phosphatase, and AST). Primary hepatic disease is reflected in elevations of bilirubin and enzymes such as serum glutamic-oxaloacetic transaminase. Therefore for the evaluation of liver disease, bilirubin measurement is of primary importance. Approximately 80% of the bilirubin comes from the degradation of red blood cells. The liver is responsible for hundreds of chemicals and proper body functions. The function of this organ should be adequate for proper healing, drug pharmacokinetics, and long-term health.

Glycosylated Hemoglobin

Glycosylated hemoglobin, also termed hemoglobin A1c or HbA1c, is a test to monitor the control of the diabetic patient over the previous 2 to 3 months. This test measures the percentage of hemoglobin bound to glucose.

WWW.HIGHDENT.IR

Table 20-4 HbA1c Values versus Blood Glucose Levels

HBA1C (%)	AVERAGE BLOOD SUGAR (mg/dL)
6	120
7	150
8	180
9	210
10	240
11	270
12	300

Hemoglobin, a protein in red blood cells, binds to the HbA1c form of hemoglobin by a process termed *glycosylation*. The percent HbA1c reflects how much glucose is bound to the blood during the past 120-day life span of the RBCs. Glycosylated hemoglobin helps to minimize complications in patients exhibiting chronically elevated glucose levels. For nondiabetic patients, normal values are approximately 4.0% to 6.0%. Ideally, a diabetic patients will have their HbA1c at approximately 6%, which corresponds to an average glucose of 135 mg/dL (7.5 mmol/L). For every 1% change in the HbA1c, a resultant change of about 30 mg/dL (1.67 mmol/L) will be seen (Table 20-4).

SYSTEMIC DISEASE AND ORAL IMPLANTS

Systemic diseases play a vital role in treatment planning and implant therapy for patients. There are specific systemic diseases and conditions that undeniably affect bone metabolism, wound healing, and ultimately the success of implant therapy. The implant dentist should use this information on systemic conditions, which have a significant impact on patient selection and management. Some conservative surgery and prosthetic implant procedures are rarely contraindicated based on systemic conditions; other complex treatments must be excluded for the same condition. It is the responsibility of the implant dentist to understand the interrelationship of systemic diseases and implant dentistry. Common conditions that may affect the implant treatment are discussed in three steps. The first section describes the entity in general. The second section discusses dental implant treatment implications. The last section reviews dental implant management.

American Society of Anesthesiologists Physical Status Classification

Systemic diseases have a wide range of effects on a patient, depending on the severity of the disease. There are relatively few systemic diseases that always contraindicate implant surgery or prosthetics. However, several metabolic disorders have contraindications when the conditions are out of control or severe. In 1962 the American Society of Anesthesiologists (ASA) adopted a classification system for the severity of disease, and the system is widely used. It was designed to estimate the medical risk presented by a patient receiving general anesthesia for a surgical procedure. The classification system is valuable for determining any medical risk regardless of the method of anesthesia or type of surgery (Box 20-1).

Box 20-1 American Society of Anesthesiologists (ASA) Classifications

ASA I: A normal, healthy patient, without systemic disease.
ASA II: A patient with mild to moderate systemic disease.
ASA III: A patient with severe systemic disease, which limits or alters activity but is not incapacitating.
ASA IV: A patient with severe systemic disease, which is incapacitating and is a constant threat to life.
ASA V: A moribund patient not expected to live more than 24 hours without an operation.

Elective implant surgeries are not indicated for ASA IV or V patients.

The systemic conditions listed in this chapter are the most commonly observed in an implant practice; it is not intended that all conditions be included. The diseases discussed are classified as mild, moderate, or severe. A disease entity affects the host with varied intensity. Therefore mild diabetes may permit implant treatment, but the same disease in the severe form may contraindicate most implant therapy. As a result, a mild diabetic patient should be treated differently than the severe diabetic patient. A general sedation and treatment format may be established with most expressions of systemic diseases.

In addition to the range of disease expression, Misch has presented a variety of implant treatments delivered to a patient.[39,39a] In Table 20-5, four levels of surgical and prosthetic dental treatments are established. A systemic condition may contraindicate one class of treatment, yet a more simple implant procedure can still be performed. The four levels of treatment range from noninvasive procedures with little or no risk of gingival bleeding to those that are most complicated and invasive.

Type 1 procedures can be performed on most patients regardless of systemic condition. Type 2 procedures are more likely to cause gingival bleeding or bacterial invasion of the bony structures. Type 3 procedures are surgical procedures that require more time and technique. Type 4 procedures are advanced surgical procedures with more bleeding and greater risk of postoperative infection and complications.

WWW.HIGHDENT.IR

Table 20-5 Classifications of Dental Treatment

CLASSIFICATION	TREATMENT
Type 1	Examinations, radiographs, study model impressions, oral hygiene instruction, simple extractions, single-tooth implants, stage 2 uncovery with minimum tissue reflection, simple restorative dentistry
Type 2	Multiple simple extractions, multiple implants with minimum tissue reflection
Type 3	Difficult extractions, multiple root forms, ridge augmentation, unilateral sinus graft, unilateral subperiosteal implants with quadrant periosteal reflections
Type 4	Full-arch implant (complete subperiosteal implants, ramus frame implants, full-arch endosteal implants), orthognathic surgery, autogenous block bone augmentation, bilateral sinus graft

A relationship can be established between the severity of the disease (mild to severe) and the maximum involvement of the dental implant procedure (Table 20-6). For the more extensive procedure, the patient should be healthier; for a more severe form of the disease, the surgical procedure should be less invasive.

Cardiovascular Diseases

Hypertension

Hypertension is the most common primary diagnosis in the United States and accounts for more than 35 million health care visits per year. It affects 50 million Americans and approximately 1 billion people worldwide.[26,41] There are an estimated 7.1 million deaths per year attributable to hypertension, along with 62% of cerebrovascular disease and 49% of ischemic heart disease.[42] Approximately 30% of adults with hypertension are unaware that they have hypertension, and two thirds of patients treated are not controlled to blood pressure less than 140/90 mm Hg. Untreated, undiagnosed, and uncontrolled hypertension is a serious problem in society today.

Table 20-7 Blood Pressure Classification for Adults*

BLOOD PRESSURE CLASSIFICATION	SYSTOLIC BLOOD PRESSURE (mm Hg)	DIASTOLIC BLOOD PRESSURE (mm Hg)
Normal	< 120	and <80
Prehypertension	120-139	or 80-90
Stage 1 hypertension	140-159	or 90-99
Stage 2 hypertension	≥160	or ≥100

Adapted from Chobanian AV, Bakris GL, Black HR et al: Seventh report of the National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, *Hypertension* 42:1206, 2003.
*Treatment determined by highest blood pressure category.

With increasing age, the prevalence of hypertension increases. More than half of people aged 60 to 69 years and approximately three quarters of those age 70 and older are affected with hypertension.[2] A recent study showed that the lifetime risk of hypertension is 90% for men and women who were nonhypertensive at age 55 to 65 and live to age 80.[43] Because implant dentists treat a high percentage of elderly patients, coupled with the high prevalence in the general population, prevalence of patients that have uncontrolled or undiagnosed hypertension is very high. Failure to diagnose and detect hypertensive patients can result in life-threatening conditions such as stroke or myocardial infarction.

Recently, the Joint National Committee on Hypertension published an updated classification of blood pressure for adults.[44] This classification is based on the average of two or more seated blood pressure readings on each of two or more office visits (Table 20-7).

The Joint National Committee on Hypertension introduced a new category termed *prehypertension*. Patients in this category are at risk of developing

Table 20-6 Evaluation of Risk in Systemic Diseases

RISK	ASA CATEGORY	TYPE 1	TYPE 2	TYPE 3	TYPE 4
Normal	I	+	Sedation, SRP	Intravenous sedation	SRP
	II	+			
Mild	II	+	Sedation, SRP	Intravenous sedation	SRP
Moderate	II	+	Intravenous sedation, SRP, physician consultation	Hospitalization	Hospitalization
Severe	III	+	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures

ASA, American Society of Anesthesiologists; *SRP,* stress-reduction protocol; +, procedure may be performed with regular protocol after physician consultation.

WWW.HIGHDENT.IR

hypertension and are encouraged to make a lifestyle modification to reduce this risk. Additionally, the previous stage 2 and stage 3 have been combined to form Stage 2 hypertension. In patients younger than 50 years of age, diastolic hypertension predominates as a leading indicator. However, in patients older than age 50, the systolic is a better indicator of hypertension as systolic pressure rises with age. Contrary to past knowledge that diastolic pressure is more important than systolic pressure, studies have shown that with the aging population, uncontrolled systolic hypertension causes increased rates of cardiovascular and renal diseases.[44] Risk factors for hypertension include obesity, high sodium intake, poor diet, lack of exercise, alcohol consumption, and smoking. Special attention should be given to patients with a history of obstructive sleep apnea. Sleep apnea has been associated with a number of cardiovascular diseases including dysthymias, myocardial infarction, and stroke.[45] Greater than 50% of patients with sleep apnea also have hypertension.[46]

Hypertension is usually asymptomatic and is the major risk factor for coronary heart disease and cerebrovascular accidents leading to cardiovascular morbidity and mortality for people older than 50 years of age. Patients with stage 1 and stage 2 hypertension are susceptible to three times as much coronary disease, four times as much cardiac failure, and seven times as many strokes as normotensive patients. The medical history should focus on predisposing factors such as excessive alcohol intake, history of renal disease, stroke, other cardiovascular diseases, diabetes, obesity, and smoking.

Stage 1 and stage 2 hypertension is usually treated with antihypertensive medications, many of which have an impact on implant therapy because of their numerous side effects. These include orthostatic hypotension, dehydration, sedation, xerostomia, and depression. The side effects may alter treatment or require special precautions. For example, orthostatic hypotension affects a patient brought from a supine to an upright position, which can result in syncope and falling with possible injuries. The patient may feel lightheaded or even faint; these symptoms can be avoided by allowing patients to sit upright for several minutes after the completion of their dental procedure. Patients at high risk include the elderly, those with anxiety, patients taking multiple medications, and those who have undergone lengthy dental procedures.

Box 20-2 Supplements Associated with Increased Swelling and Increased Blood Pressure

Calcium channel blockers used to treat hypertension or congestive heart failure can cause gingival hyperplasia around teeth or implants (similar to Dilantin) and have been linked to erythema multiforme and other types of oral ulceration.[47] Gingival overgrowth can result in pain, gingival bleeding, and difficulty in mastication. The incidence is approximately 1.7% to 3.8% of patients taking calcium channel blockers.[48] A newer agent blocking angiotensin II seems to exhibit no dental implications.[49]

The use of NSAIDs has been shown to lessen the effectiveness of various antihypertensive medications. Of the 50 million patients being treated with antihypertensive therapy, 12 million use NSAIDs concomitantly.[50,51] However, short-term use of NSAIDs has not been shown to have a clinically significant effect.[52]

In addition, severe hypertension can lead to angina pectoris, congestive heart failure, or even a cerebrovascular episode, which can be precipitated by a rapid increase in blood pressure during an injection or surgery. Myocardial infarction, retinal hemorrhage, and kidney failure are other serious complications.

When a patient indicates hypertension on the medical history form, the date of the diagnosis, the complications, and the medications should be reviewed. The former guidelines for hypertension therapy followed a stepped-care approach that permitted the patient to use the medications as a good indicator of the severity of the disease; single diuretic drugs are usually used to treat mild hypertension, whereas combination drugs indicate a more severe hypertension. Patients taking additional drugs such as clonidine exhibit more severe hypertension[53] and require a medical consultation before undergoing complicated implant surgery procedures.

Dental Implant Management

Because a high percentage of patients have hypertension, the dentist and staff members must be knowledgeable about the measurement, detection, and treatment of hypertension. The accurate measurement of blood pressure, along with a review of all medications including herbal and over-the-counter medications, should be an integral part of the implant consultation and examination (Table 20-8; Box 20-2).[54]

An increased blood pressure is not uncommon in the dental office setting, because stress associated with treatment (also termed *white coat syndrome*) leads to increased levels of catecholamine, which causes an increase in blood pressure and heart rate. Two important steps to decrease the stress in the dental office are a well-monitored stress reduction protocol and proper management of pain and discomfort. Stress reduction protocol may include premedication on the night before the appointment (flurazepam [Dalmane] 30 mg or diazepam [Valium] 5 to 10 mg), setting an early morning appointment, minimizing waiting room time, and

Table 20-8 Recommendation for Blood Pressure Evaluation

INITIAL BLOOD PRESSURE	RECOMMENDATION	IMPLANT THERAPY
Normal	Recheck yearly	No contraindications
Prehypertension	Recheck every 6 months	No contraindications
Stage 1 hypertension	Recheck at next visit	If blood pressure remains high, patient is receiving antihypertensives, or there is previous organ damage, initiate medical consultation; stress reduction protocol
Stage 2 hypertension	Recheck at next visit; if unchanged, initiate medical consultation	Medical consultation Stress reduction protocol

Table 20-9 Dental Implant Management in Hypertensive Patients

RISK	SYSTOLIC (mm Hg)	DIASTOLIC (mm Hg)	TYPE 1	TYPE 2	TYPE 3	TYPE 4
Normal	<120	<80	+	+	Sedation	Sedation
Prehypertension	120-139	80-89	+	+	Sedation	Sedation
Hypertension						
Stage I	140-159	90-99	+	Sedation	Sedation	Sedation
Stage II	≥160	≥100	+	Sedation after physician consultation	Postpone all elective procedures	Postpone all elective procedures
	>180	>110	Refer and postpone all elective procedures			

+, May be performed with regular protocol after physician consultation.

ensuring the duration of treatment does not exceed the patient's limits. Adequate pain control is also important including preemptive analgesia, profound anesthesia during the procedure, and sufficient postoperative pain control including long-acting anesthetics (Table 20-9). A resting systolic pressure greater than 180 or a diastolic pressure greater than 110 should indicate that all elective procedures be delayed until blood pressure may be reduced to a safer level.

Angina Pectoris

Angina is defined as chest pain as a consequence of exertion and alleviated by rest. Angina pectoris is a form of coronary heart disease that is usually caused by arteriosclerotic heart disease; however, it may be caused by coronary artery spasm, severe aortic stenosis, aortic insufficiency, anemia, emboli, and hereditary connective tissue disease. The cause of angina is a discrepancy between the myocardial oxygen demand and the amount of oxygen being delivered through the coronary arteries.

The risk category for the typical angina patient is ASA III, and unstable angina or a recent onset may represent ASA IV risks. The classical symptom of retrosternal pain often develops during stress or physical exertion, radiates to the shoulders, left arm, or mandible or to the right arm, neck, palate, and tongue; these symptoms are relieved by rest.[55] Episodes of stable angina (exertional angina) last 3 to 5 minutes after the stress or exercise is halted. Intensity may vary from mild to severe.

Patients with a history of angina may be taking long-acting nitrates to prevent the occurrence of acute episodes. Sublingual or spray nitroglycerin is recommended for the treatment of acute episodes. When retrosternal pain occurs, myocardial infarction is part of the differential diagnosis. This pain is similar in region, but is more intense, does not cease within 3 to 5 minutes, and is not relieved by nitroglycerin. Risk factors for angina pectoris are smoking, hypertension, high cholesterol, obesity, and diabetes.

If a patient reports a history of angina, the severity of the disease is evaluated by the last attack, change in frequency, frequency and severity of attacks, and the medications prescribed. As with hypertension, the disease may be classified as mild, moderate, or severe (Table 20-10). The patient with mild angina may have one or fewer attacks each month; the patient with moderate angina may suffer infrequent but predictable attacks, even in the absence of excessive stress or exertion; patients with severe unstable angina have almost daily attacks, often with increasing severity. Recent-onset angina (less than 60 days) is classified as unstable (ASA IV).

The major concern for the implant dentist is the precipitation or management of the actual angina attack.

WWW.HIGHDENT.IR

Table 20-10 Dental Implant Management in Patients with Angina Pectoris

RISK		TYPE 1	TYPE 2	TYPE 3	TYPE 4
Mild	≤1/month; ASA II	+	+	Sedation supplemental oxygen	
Moderate	≤1/week; ASA III	+	Sedation, premedication, nitrates, supplemental oxygen	Sedation, premedication, nitrates, supplemental oxygen	Premedication, sedation, outpatient hospitalization
Severe	Daily/more; ASA IV; unstable	+	Physician consultation	Elective procedures contraindicated	Elective procedures contraindicated

ASA, American Society of Anesthesiologists, +, may be performed with regular protocol after physician consultation.

Precipitating factors are exertion, cold, heat, large meals, humidity, psychological stress, and dental-related stress. All of these factors cause catecholamine release, which in turn increases the heart rate, blood pressure, and myocardial oxygen demand.[56]

Dental Implant Management

The dental emergency kit should include nitroglycerin tablets (0.3 to 0.4 mg) or sublingual nitroglycerine spray, which are replaced every 6 months because of their short shelf life. During an angina attack, all dental treatment should be stopped immediately. Nitroglycerin is then administered sublingually and 100% oxygen is given at 6 L/min, with the patient in a semisupine or 45-degree position.

Vital signs should be monitored after nitroglycerin is administered because transient hypotension may occur. If the systolic blood pressure falls below 100 mm Hg, the patient's feet should be elevated. If the pain is not relieved in 8 to 10 minutes with the use of nitroglycerin at 5-minute intervals, emergency medical assistance should be initiated.

Patients with mild angina (up to one attack per month) may undergo most nonsurgical dental procedures performed with normal protocol (type 1). General cardiac precautions are advised, such as vital signs monitoring, and patients are instructed to bring their own nitroglycerin. Advanced restorative procedures and minor implant surgery (type 2) are performed with nitrous oxide or oral sedation. For more advanced implant procedures (types 3 and 4), appropriate sedation techniques should be used. Appointments should be as short as possible. This may require more than one surgical or restorative appointment. Use of vasoconstrictors should be limited to a maximum of 0.04 to 0.05 mg epinephrine, and concentrations greater than 1/100,000 should be avoided.

Patients with moderate angina (up to one attack per week) tolerate examination and most simple operative procedures (type 1). Prophylactic nitroglycerin (0.3 to 0.4 mg) or long-acting nitrates are given sublingually just before advanced operative or simple to moderate implant surgery (types 2 and 3). Antianxiety sedation with supplemental oxygen is required. The use of even small amounts of vasoconstrictor is debatable; many claim it is contraindicated. Advanced surgical procedures may require a hospital setting (type 4).

Patients with unstable angina (daily episodes) are limited to examination procedures performed under normal protocol. Medical consultation is recommended for any additional treatment. This form of angina has been represented as an absolute contraindication for elective dental surgery (ASA IV).

The side effects of nitroglycerin are important to recognize because prophylactic administration is in order for the patient with moderate to severe angina. There is a decrease in blood pressure, which causes a decrease of the blood flow to the brain. Fainting is possible. Therefore the patient should be sitting or lying down during nitroglycerin administration. The heart attempts to compensate for the decreased blood pressure; the pulse rate may increase to as much as 160 beats/min. Blushing of the face and shoulders is common after administration of nitroglycerin. If the patient has been taking long-acting nitrates, tolerance to the drug may occur; therefore two tablets may be needed at a time. A headache may occur after administration, which may be treated with analgesics.

Myocardial Infarction

Myocardial infarction (MI) is a prolonged ischemia or lack of oxygen resulting from a deficiency in the coronary arterial blood supply that causes injury to the myocardium. The end result is cellular death and necrosis of the heart muscle. Approximately 1.3% of patients older than 30 and 10% of patients 40 years or older undergoing noncardiac surgery in a hospital setting indicate a history of previous MI.[57,58] An acute MI may be precipitated when the patient undergoes unusual stress, either physical (painful stimuli) or emotional (anxiety). The patient usually has severe chest pain in the substernal or left precordial area during an MI episode. It may radiate to the left arm or mandible. The pain is similar to angina pectoris, but more severe. Cyanosis, cold sweat, weakness, nausea or vomiting, and irregular and increased pulse rate are all signs and symptoms of MI.

The complications of MI include arrhythmias and congestive heart failure (CHF). The larger the ischemic

WWW.HIGHDENT.IR

Table 20-11 Dental Implant Management in Patients with Myocardial Infarction

RISK	TYPE 1	TYPE 2	TYPE 3	TYPE 4
Mild (>12 mo)	+	+	Physician	Physician Hospitalization if general anesthesia required
Moderate (6-12 mo; ASA III)	+	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures
Severe (<6 mo; ASA IV)	+	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures

ASA, American Society of Anesthesiologists; +, may be performed with regular protocol after physician consultation.

area, the greater the risk of heart failure or life-threatening arrhythmias. Any history of MI indicates significant problems in the coronary vessels. Recent infarctions correspond to higher morbidity and death rates with even simple elective surgery. The risk of MI is less than 1% in the general population in a perioperative setting. Approximately 18% to 20% of patients with a recent history of MI will have an increase of complications, which have a high mortality rate of 40% to 70%. If general anesthesia and surgery are performed within 3 months of MI, the risk of another MI is 30%; if within 3 to 6 months, it is 15%. After 12 months, the incidence of recurrent MI stabilizes at about 5%.[59]

Dental Implant Management

The dental evaluation should include the dates of all episodes of MI, especially the latest, and any complications. Medical consultation should preclude any extensive restorative or surgical procedure. Patients with an MI in the preceding 6 months may have dental examinations without any special protocol. Any surgical treatment should be postponed if possible for 6 months. Patients who experienced an MI 6 to 12 months preceding consultation may have examinations, nonsurgical procedures, and simple emergency surgical procedures performed after medical consultation. Longer procedures should be segmented into several shorter appointments whenever possible. Stress reduction protocol is indicated. Elective implant procedures should be postponed for at least 12 months after MI[60] and only performed after physician consultation. Elective hospitalization is an accepted modality for all advanced surgical procedures, regardless of the time elapsed after an MI; it is mandatory if general anesthesia is performed (Table 20-11).

Congestive Heart Failure

Congestive heart failure is a pathophysiologic state in which an abnormality in cardiac function is responsible for failure of the heart to pump blood in adequate volume to meet the needs of the metabolizing tissues.[61] More than 3 million people in the United States suffer from CHF, with approximately 400,000 new patients being diagnosed each year. Every year, 30% to 40% of patients with CHF are hospitalized, which accounts for the leading diagnosis-related group of hospitalized patients older than age 65.[62]

The heart pumps about 2000 gallons of blood per day to the other organs and body tissues. It coordinates the function of two pumps simultaneously: the left side, the larger of the two sides, pushes the blood out into the body; the right side sends the blood to the lungs for oxygenation. When the heart has been damaged, the blood begins to back up in the lungs or body. The heart will attempt to compensate by increasing the rate of contraction and stretching the muscle to accommodate a larger volume of blood to contract with a greater force and eject more blood (Starling's law). Both of these compensation attempts of the heart maintain circulatory needs in the short term, but they exact a long-term price. Less blood is circulated because, in beating faster, the heart is left with less time to refill while the extra effort increases the heart muscle's demand for oxygen. When this need is not met, the heart rhythms can become dangerously abnormal (arrhythmic) and lead to death.

Compensatory measures are taken by other parts of the body to counteract the insufficient blood circulation. The kidneys retain water and salt. In the case of heart failure, this only further strains the heart by increasing the amount of blood it must pump. At the same time, the retained fluid may seep into the body tissue. The patient's medical history (e.g., questions about the patient's ability to climb stairs) will give clues along with observation of signs and symptoms to congestive heart failure.

Symptoms of CHF are listed in Box 20-3; they include abnormal tiredness or shortness of breath (dyspnea) brought on by slight activity or even occurring at rest (these symptoms are due to excess fluid in the lungs and partly to the excess work required of the heart); wheezing caused by fluid in the lungs (pulmonary edema); peripheral edema or swelling of the ankles (pedal edema) and lower legs; frequent urination at night; jugular venous distension; sounds at auscultation (S_3 gallop); and paroxysmal nocturnal dyspnea (the

- Paroxysmal nocturnal dyspnea
- Excessive weight gain
- Orthopnea
- Pulmonary edema
- Jugular venous distention
- S_3 gallop

Box 20-4 Classification of Congestive Heart Failure (New York Heart Association)

I. No symptoms and no limitation in ordinary physical activity.
II. Mild symptoms and slight limitation during ordinary activity. Comfortable at rest.
III. Marked limitation in activity due to symptoms, even during less-than-ordinary activity. Comfortable only at rest.
IV. Severe limitations. Experiences symptoms even while at rest.

sensation of being unable to breath), which may interrupt sleep. This symptom is due to the effect of gravity on fluid that has spent the day down at the feet. As the fluid flows back up, it may pool in the lungs, causing a feeling of suffocation. Excessive weight gain, as much as 20 to 30 lb, with no change in diet is also a symptom. This increase, purely from fluid retention, gives some indication of how poorly the heart is pumping.

Although heart failure affects both sides of the heart, one side tends to be more weakened, so the condition is often referred to as left-sided or right-sided failure. Left-sided failure is most common. The fluid backs up into the lungs and brings on the symptom of breathlessness. Right-sided heart failure causes fluid backup in the veins that return blood to the heart, leading to swelling of the extremities and the liver.

Patients with CHF may be classified as to the progression of their disease. The New York Heart Association (NYHA) provides a simple way to classify the extent of heart failure. This classification places patients in one of four categories based on limitation during physical activity (Box 20-4).[63]

Medications prescribed for CHF are loosely classified as the *three Ds:* digitalis, diuretics, and dilators. Digitalis (digoxin; Lanoxin) increases the heart's pumping action (positive inotropic); diuretics (furosemide; Lasix) eliminate excess salt and water; and vasodilators (e.g., angiotensin-converting enzyme) expand the blood vessels so that pressure decreases and blood can flow more readily. Because digitalis is such a common drug for treating CHF, the doctor should be familiar with its common side effects.

A lethal dose of digitalis is only twice the treatment dose. A dentist recognizing the more common side effects (i.e., nausea, vomiting, anorexia) should report them to the treating physician. The heart rate is decreased (negative chronotropic) because the drug decreases the effect of the atrioventricular node (negative dromotropic) and stimulates the vagus nerve. Premature ventricular contractions are more common because the heart rate is decreased. Less common side effects (e.g., chromatopsia, spots, a halo around objects) may be reported. Trigeminal neuralgia symptoms may occur with use of digitalis. Although very uncommon, this condition has been reported to the author; a decrease of the medication dose partially relieves the symptoms.

Calcium channel blockers are also used to treat congestive heart failure and hypertension. Calcium is needed for atrial contraction. By blocking calcium, sodium remains available for ventricle contraction. Gingival hyperplasia (similar to that caused by Dilantin) has been reported to occur around teeth, implants, or superstructure bars of overdentures, especially with nifedipine. Other side effects such as edema and constipation have also been reported.

Dental Implant Management

In patients classified as NYHA I and II, no medical consultation is indicated unless there exist additional systemic diseases. In NYHA III and IV, medical consultation is highly recommended for all implant type 3 and 4 procedures. A comprehensive stress reduction protocol is indicated for all patients with CHF. Intraoperatively and postoperatively, pain and anxiety control is important because increased stress can produce an increased myocardial workload with an increase in the degree of heart failure.

Positioning of patients may require modification from the standard supine position. Patients with CHF may exhibit orthopnea, which may prevent the supine position. Patients should be placed in the most recumbent position in which they may breathe comfortably and efficiently.[52] Oxygen supplementation during implant procedures is highly recommended so as to minimize the possibility of hypoxia.

Subacute Bacterial Endocarditis and Valvular Heart Disease

Bacterial endocarditis is an infection of the heart valves or the endothelial surfaces of the heart. It is the result of the growth of bacteria on damaged or altered cardiac surfaces. The microorganisms most often associated with endocarditis following dental treatment are alpha-hemolytic *Streptococcus viridans* and less frequently

WWW.HIGHDENT.IR

staphylococci and anaerobes. The disorder is serious, with a mortality rate of about 10%.[53] Dental procedures causing transient bacteremia are a major cause of bacterial endocarditis. As a result, the implant dentist should identify the patient at risk and implement prophylactic procedures (Box 20-5).

The American Heart Association recently revised its recommendations of antibiotic prophylaxis for dental procedures in the prevention of infectious endocarditis. The new guidelines are based on the scientific studies showing that the risks of taking antibiotics outweigh the benefits for most patients. Adverse risks of taking antibiotics range from mild to sever allergic reactions along with development of drug-resistant bacteria. In addition, published studies have verified that the majority of patients are more at risk of developing infectious endocarditis from everyday activities than from dental procedures.[63a]

The recommendation states that patients who have routinely taken prophylactic antibiotics in the past are no longer required to do so. The new guidelines, however, are aimed at patients who are considered to be at a high risk of developing infection endocarditis (see Box 20-5).[63b] Acquired valvular lesions, roughened areas of the heart from septal defects, and prosthetic heart valves also increase the risk of endocarditis. Patients with prosthetic heart valves develop endocarditis with an incidence rate of 4% per year. Patients with a history of infectious endocarditis have an increased chance of recurrence. The risk of a second infection of any patient with one previous episode of endocarditis is 10% per year. After the second infection, the risk of recurrence increases to 25%.

The risk of bacterial endocarditis increases with the amount of intraoral soft tissue trauma. There is a correlation between the incidence of endocarditis and the number of teeth extracted or the degree of a pre-existing inflammatory disease of the mouth.[64] A incidence of bacteremia is six times higher in patients with severe periodontal disease.[65] However, if scaling and root planing are performed before subsequent soft tissue surgery, the risk of endocarditis is greatly reduced. Bacteremia after traumatic tooth brushing, endodontic treatment, and paraffin chewing has also been reported.[66] Endocarditis may even occur in an edentulous patient with denture sores.[67] Chlorhexidine painted on isolated gingiva or irrigation of the sulcus 3 to 5 minutes before tooth extraction reduces postextraction bacteremia.

Box 20-5 American Heart Association Recommended Antibiotic Prophylaxis Guideline

Prophylactic Antibiotics No Longer Recommended for Patients with These Conditions

- Mitral valve prolapse
- Rheumatic heart disease
- Bicuspid valve disease
- Calcified aortic stenosis
- Congential heart conditions such as ventricular septal defect, atrial septal defect, and hypertrophic cardiomyopathy

Phrophylactic Antibiotics Indicated for Patients with These Conditions (High Risk)

- Artificial (prosthetic) heart valves
- History of infectious endocarditis
- Unrepaired or incompletely repaired cyanotic congential heart disease including shunts and conduits
- Congenital heart defects repaired with prosthetic material or device
- Repaired congential heart defects with residual defect at the site or adjacent to a prosthetic device
- Cardiac transplantation recipients who develop cardiac valvulopathy

Dental Implant Management

The implant dentist must be familiar with the antibiotic regimens for heart conditions requiring prophylaxis. A similar regimen is suggested for any person requiring antibiotic coverage. The standard regimen established by the American Heart Association in 1997 may be administered orally or parenterally (Table 20-12).[68] The oral regimen in adults is 2 g amoxicillin orally, 60 minutes before the procedure. A second dose is not necessary because of the prolonged serum levels above the minimal inhibitory concentration of most oral streptococci[69] and the prolonged serum inhibitory activity induced by amoxicillin against such strains (6 to 14 hours).[70] For patients unable to take oral medications, 2 g ampicillin is administered intramuscularly (IM) or intravenously (IV) 30 minutes before the procedure.

If the patient is allergic to penicillin, clindamycin 600 mg or cephalexin (or cefadroxil) 2 g are administered orally 1 hour before the procedure. For patients allergic to penicillin and not able to take oral medications, clindamycin 600 mg IV within 30 minutes of the procedure or cefazolin 1 g IM or IV 30 minutes before the procedure are the recommended regimens for oral procedures.[68] Erythromycin is no longer included because gastrointestinal upset and complicated pharmacokinetics of various formulations[68] make its use problematic.

In patients who are classified in the high-risk category for development of endocarditis, elective implant therapy may be contraindicated. Edentulous patients restored with implants must contend with transient bacteremia from chewing, brushing, or peri-implant disease. Endosteal implants, with an adequate width of attached gingiva, are the implants of choice for patients

WWW.HIGHDENT.IR

Table 20-12 Antibiotic Regimens for Heart Conditions Requiring Prophylaxis

SITUATION OF PATIENT	AGENT	REGIMEN
Standard general prophylaxis	Amoxicillin	Adults: 2.0 g, 1 hr before procedure
Unable to take oral medications	Ampicillin	Adults: 2.0 g IM or IV
Allergic to penicillin	Clindamycin	Adults: 600 mg, 1 hr before procedure
	Cephalexin* or cefadroxil*	Adults: 2.0 g, 1 hr before procedure
	Azithromycin or clarithromycin	Adults: 500 mg, 1 hr before procedure
Allergic to penicillin and unable to take oral medication	Clindamycin	Adults: 600 mg IV within 30 min before procedure
	Cefazolin*	Adults: 1.0 g IM or IV within 30 min before procedure

IM, Intramuscularly; *IV*, intravenously.
* Cephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (urticaria, angioedema, or anaphylaxis) to penicillins.

in this group who need implant-supported prostheses. Implants may be contraindicated for patients with a limited oral hygiene potential and for those with a history of multiple endocarditis events. In addition, intramucosal inserts may be contraindicated for many of these patients because a slight bleeding can occur on a routine basis for several weeks during the initial healing process.

Implant surgery in patients with aortic stenosis is contraindicated until after aortic valve replacement.[71] It has been recommended that patients with valve replacements postpone any elective implant surgery until 15 to 18 months after surgical completion. This is because these patients are at high risk for bacterial endocarditis and because of the use of high doses of anticoagulants.[72] Special precautions should always be adhered to in valve replacement patients, as their therapeutic bleeding times are usually high (INR 2.5 to 3.5).

Endocrine Disorders

Diabetes Mellitus

Diabetes mellitus is a major endocrine disorder that affects approximately 7% of the population with another 2% to 3% undiagnosed.[73] In patients age 60 years or older, 20.9% of all people in this age group suffer from diabetes (approximately 1 in 5).[74] Approximately 20.8 million children and adults suffer from diabetes and contribute to 225,000 deaths per year. Diabetes ranks as the sixth leading cause of death in the United States.

Over the years, the classification of diabetes has included "juvenile-onset" and "adult-onset" diabetes as well as "insulin-dependent" and "non–insulin-dependent" diabetes. The most current classification includes three general clinical categories; type 1 diabetes, type 2 diabetes, and gestational diabetes (pregnancy).[75,76]

In type 1 diabetes, insulin is not produced from the pancreas. This type of diabetes develops most frequently in children; however, the incidence in an older population is increasing. Type 2 diabetes is much more common and accounts for approximately 95% of the diabetic cases. This type of diabetes almost always occurs in adults and results from the body's inability to respond properly to the action of insulin, which is produced from the pancreas. The incidence of type 2 diabetes is estimated to double by the year 2025 because of aging, unhealthy diets, and obesity.[77]

The major symptoms of diabetes are polyuria, polydipsia, polyphagia, and weight loss. Therefore the patient's medical history should include questions concerning increased thirst, urination, appetite, or recent weight loss. Almost every cell membrane needs insulin to enable glucose penetration to occur, with the exception of those cells in the brain and spinal cord. With insulin deficiency, the glucose remains in the bloodstream and increases the blood glucose level. Diabetic patients are prone to develop infections and vascular complications. The healing process is affected by impaired vascular function, chemotaxis, impaired neutrophil function, and an anaerobic milieu. Protein metabolism is decreased, and healing of soft and hard tissue is delayed. Nerve regeneration is altered, and angiogenesis is impaired.

Many studies both in animals and humans have been conducted with respect to diabetes. Animal studies have shown a significant reduction in bone-implant contact[78] and a reduction of osseointegration in trabecular bone but not cortical bone.[79] Clinical human data include the recommendation that no contraindications exist for diet and orally controlled diabetes; however, for insulin-controlled patients, implants may be contraindicated.[80] Some studies have shown that insulin-controlled diabetic patients are implant candidates if they have antibiotic coverage, and other studies have seen no differences with success rates.[81,82] Additionally, researchers have concluded that

Table 20-13 Dental Implant Management in Patients with Diabetes Mellitus

RISK	MEAN BLOOD GLUCOSE (mg/dL)	HBA1c (%)	TYPE 1	TYPE 2	TYPE 3	TYPE 4
Mild	≤150	≤7	+	+	Sedation; premedication; diet/insulin adjustment	Sedation; premedication; diet/insulin adjustment
Moderate	150-240	7-10	+	+	Sedation; premedication; diet/insulin adjustment; consultation	Diet/insulin adjustment; hospital consultation
Severe	Uncontrolled, >240	>10+	+	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures

+, May be performed with regular protocol after physician consultation.

implants are usually successful in patients with diabetes, provided the diabetes is controlled (patients should monitor HbA_{1C}). Uncontrolled diabetes should be treated and controlled during the implant surgery healing period.[83-86]

Dental Implant Management

The most serious complication for diabetic patients during dental procedures is hypoglycemia, which usually occurs as a result of excessive insulin level, hypoglycemic drugs, or inadequate food intake. Weakness, nervousness, tremor, palpitations, or sweating are all signs of hypoglycemia. Mild symptoms can be treated with sugar in the form of orange juice or candy. If the symptoms are not addressed, they may evolve from confusion and agitation to seizure, coma, and death.

The stress of surgery may provoke the release of counterregulatory hormones that will impair insulin regulation and may result in hyperglycemia and a catabolic state.

A stress reduction protocol is recommended on all patients including early morning appointments, adequate breakfast, pain and anxiety reduction, treatment breaks, and possible sedation.

Patients at low risk of complications related to diabetes are those who are asymptomatic and have good metabolic control. Their blood glucose levels are less than 150 mg/dL (average 100 mg/dL) with HbA1C 7.0 test scores. These patients may be treated with a normal protocol for all nonsurgical appointments (type 1). For surgical procedures, these patients need a little more care and attention. Need for a stress reduction protocol, diet evaluation before and after surgery, and control of the risk of infection are all addressed. Sedative procedures and antibiotics are often used for implant or advanced surgical procedures (types 3 or 4). Intravenous conscious sedation and infusion of glucose and saline solution (D_5W) can be used for lengthy procedures (Table 20-13).

Patients at moderate risk show periodic manifestations of the disease but are in metabolic balance because few complications of diabetes are present. Their blood glucose levels are around 200 mg/dL (HbA1C test scores at 8.0 to 9.0). Diet control, stress reduction protocol, aseptic technique, and antibiotics are more important for these individuals than for those in the low-risk group. Most nonsurgical procedures can follow a normal protocol (type 1). Oral or IV sedation should be considered for many surgical or restorative type 2 procedures. For all patients who have a moderate or high risk to uncontrolled diabetes, corticosteroids should not be prescribed as they may adversely affect blood sugar levels. Patients after surgery or prosthetic appointment who require long-lasting anesthetics may not eat until sensation returns to their oral structures, especially in the mandible. This may require a modification of their insulin doses, because normal food intake is not present. However, the dentist usually should not alter the patient's insulin without physician consultation and recommendation. Medical consultation should precede moderate or advanced surgical procedures (types 3 and 4). Sedative techniques and hospitalization should be considered for advanced surgical procedures (type 4).

Patients at high risk with uncontrolled diabetes report a history of frequent hypoglycemia and show multiple complications of diabetes. Their fasting blood sugar fluctuates widely, often exceeding 250 mg/dL (HbA1C test scores 10.0 or higher). These patients can follow type 1 procedures when a conscious effort is made to decrease stress. All other procedures, whether nonsurgical or surgical, require medical consultation. If possible, any treatment should be deferred until the medical condition is stabilized. Postoperatively, the patient's diet requires careful attention in relationship to insulin doses.

All diabetic patients are subject to a greater incidence and severity of periodontal disease, dental caries from xerostomia, candidiasis, burning mouth, and lichenoid reactions. Approximately 75% of these patients suffer from periodontal disease and exhibit increased alveolar bone loss and inflammatory gingival changes. Tissue abrasions are more likely in denture wearers because the depletion in oxygen tension decreases the rate of

epithelial growth and decreases tissue thickness. Burning mouth syndrome is associated with neuropathies, microangiopathy, and salivary gland dysfunction.

Thyroid Disorders

Thyroid disorders are the second most common endocrine problem, affecting approximately 1% of the general population, principally women. This is reflected in the rank held by Synthroid, the fourth most common drug prescribed in the United States.[52,87] Because the majority of patients in implant dentistry are women, a slightly higher prevalence of this disorder is seen in the dental implant practice.

The thyroid gland is one of the larger endocrine glands in the body and is situated at the level of C5 and T1 vertebral bodies, just below the laryngeal prominence. The main function of the thyroid gland is to produce hormones, the most common being thyroxine (T4) and triiodothyronine (T3). Thyroxine is responsible for the regulation of carbohydrate, protein, and lipid metabolism. In addition the hormone potentiates the action of other hormones such as catecholamines and growth hormones.

Abnormalities in the anterior pituitary gland or the thyroid can result in disorders of thyroxine production. Excessive production of thyroxine results in hyperthyroidism. Symptoms of this disorder include increased pulse rate, nervousness, intolerance to heat, excessive sweating, weakness of muscles, diarrhea, increased appetite, increased metabolism, and weight loss. Excessive thyroxine may also cause atrial fibrillation, angina, and CHF. Palpation of the patient's neck often reveals an enlarged thyroid gland (goiter) between the cricoid cartilage and the suprasternal notch.

The most common form of hypothyroidism is Hashimoto's thyroiditis, which is an autoimmune disease in which there is insufficient production of thyroxine. The related symptoms are a result of a decrease in metabolic rate. The patient complains of cold intolerance, fatigue, and weight gain. Eventually hoarseness and decreased mental activity occur, which may lead to coma. Thyroid function tests are used to confirm the diagnosis of hypothyroidism.

Dental Implant Management

Patients with hyperthyroidism are especially sensitive to catecholamines such as epinephrine in local anesthetics and gingival retraction cords. When exposure to catecholamines is coupled with stress (often related to dental procedures) and tissue damage (dental implant surgery), an exacerbation of the symptoms of hyperthyroidism may occur. The result is termed *thyrotoxicosis* or *thyroid storm*. This acute, life-threatening hypermetabolic state clinically presents with symptoms of fever, tachycardia, hypertension, and neurologic and gastrointestinal abnormalities. If left untreated, these symptoms may result in CHF and life-threatening arrhythmias.

The hypothyroid patient is particularly sensitive to CNS-depressant drugs, especially narcotics and sedative drugs such as diazepam or barbiturates. The risk of respiratory depression or cardiovascular depression or collapse must be considered.

Undiagnosed thyroid disease is rare, and the thyroid problems usually are related to previously treated thyroid disease. Therefore a patient with a history of thyroid disorders should be asked about temperature sensitivity, recent weight gain or loss, tremors, or changes in appetite. The pulse and respiration are carefully noted. The most common thyroid disorder patient seen by the implant dentist is the one with known and treated thyroid disease. Any patient with a thyroid disorder and a medical examination in the preceding 6 months who reports normal thyroid function and has no symptoms of the disease is at low risk. A euthyroid patient most often is an ASA II. A normal protocol can be followed for all dental implant surgery and restorative appointments (types 1 to 4) (Table 20-14). Studies have shown that medically controlled hypothyroid patients are not at a higher risk of implant failure and are not a contraindication for implant therapy.[88]

The patient with thyroid disorder who has no symptoms related to thyroid disorders, but has not had a physical or thyroid function test recently, is placed in the moderate-risk category. This patient may follow a normal protocol for type 1 procedures. Stress reduction protocol with or without sedation is suggested for

WWW.HIGHDENT.IR

simple to advanced operative appointments and simple surgical procedures (type 2). The use of epinephrine and of CNS depressants such as narcotic analgesics, barbiturates, and diazepam should be limited. For moderate to advanced implant procedures or surgery (types 3 and 4), medical reexaminations are often indicated. After thyroid control is established, these patients are placed in the low-risk category and normal protocol is adopted.

A symptomatic patient is at high risk and is usually classified as an ASA III risk, regardless of when the last medical evaluation was performed.[89] Such patients should have only examination procedures performed (type 1); all other treatment is deferred until a medical and laboratory evaluation confirms control of the disorder.

Adrenal Gland Disorders

The adrenal glands are endocrine organs located just above the kidneys. Epinephrine and norepinephrine are produced by chromaffin cells in the adrenal medulla, which forms the central portion of the gland. These hormones are largely responsible for the control of blood pressure, myocardial contractility and excitability, and general metabolism.[90] The outer portion of the gland or adrenal cortex produces three different types of hormones. Glucocorticoids regulate carbohydrate, fat, and protein metabolism and also help decrease inflammation. Synthetic glucocorticoid medications may be used by the implant dentist to decrease swelling and pain.[91] The mineralocorticoids maintain sodium and potassium balance, and the third category consists of the sex hormones. The hypothalamus, the anterior pituitary gland, and the adrenal glands interact to regulate glucocorticoid production. The mineralocorticoids are regulated by renin angiotensin hormone, the anterior pituitary gland, and serum potassium levels.

Cortisol is one of the most important glucocorticoids secreted by the adrenal cortex. Insufficient production and secretion of cortisol leads to primary adrenocortical insufficiency, also termed *Addison's disease*. A patient with Addison's disease shows symptoms of weakness, weight loss, orthostatic hypotension, nausea, and vomiting. The physical signs of primary insufficiency do not manifest until 90% of the gland is destroyed. Signs and symptoms develop insidiously over months. When these signs are noted, the implant dentist should require a medical consultation. These patients cannot increase their steroid production in response to stress and in the midst of surgery or long restorative procedures may have cardiovascular collapse. During the physical examination, the dentist can notice hyperpigmented areas on the face, lips, and gingiva.[92] An increase in serum potassium level (hyperkalemia) and decrease in serum glucose level are characteristic of Addison's disease.

When adrenal hypersecretion of cortisol is present, patients will show signs of Cushing's syndrome. The characteristic changes associated with this disease are moon facies, truncal obesity or "buffalo hump," muscle wasting, and hirsutism. Patients are hypertensive and long-term excess function of the cortex decreases collagen production. These patients bruise easily, have poor wound healing, experience osteoporosis, and are also at increased risk for infection. These elements are especially noteworthy to the implant dentist. Laboratory studies show an increase in blood glucose related to an interference with carbohydrate metabolism. The CBC often shows a slight decrease in eosinophil and lymphocyte counts.

Corticosteroids are potent anti-inflammatory drugs used to treat a number of systemic diseases and are one of the most prescribed drugs in medicine. Steroids are used for more than 80 conditions such as arthritis, collagen and vascular disorders, kidney diseases, asthma, and dermatologic disorders. However, the continued administration of exogenous steroids suppresses the natural function of the adrenal glands and cause a condition equivalent to Cushing's disease. As a result, patients under long-term steroid therapy are placed on the same protocol as patients with hypofunction of the adrenal glands.

Dental Implant Management

Patients with a history of adrenal gland disease, whether hyperfunctioning or hypofunctioning, face similar problems related to dentistry and stress. The body is unable to produce increased levels of steroids during stressful situations, and cardiovascular collapse may occur. As a result, additional steroids are prescribed for the patient just before the stressful situation. These doses are stopped within 3 days. The healthy patient will accelerate steroid production three to five times higher than regular levels to respond to the stress of surgery or dental procedures. Therefore for patients with known adrenal disorders, the physician should be contacted for consultation. The nature of the disorder and the recommended treatment should be evaluated.

The patient on regular maintenance doses of steroid in excess of prednisone 5 mg/day is at high risk of adrenal suppression. Adrenocortical suppression should be suspected if a patient has received a dose of 20 mg or more of cortisone or equivalent daily via the oral or parenteral route for a continuous period of 2 weeks or longer within 2 years of dental treatment (Table 20-15).[93] Consultation with the patient's physician is indicated. For simple to advanced operative procedures and simple extractions, and for periodontal or implant surgery (types 1 and 2), the steroid dose should be doubled up to 60 mg prednisone or equivalent (10 mg dexamethasone). The day after the procedure, the maintenance dose is returned to normal. Oral or intravenous conscious sedation is used to reduce stress. For moderate to advanced implant surgery or the very anxious patient, general anesthesia may be indicated. The day of the procedure, 60 mg prednisone is administered. This dose is reduced by 50% each day over a 2- to 3-day period to the maintenance dose. Antibiotics are also administered for 3 to 5 days.

WWW.HIGHDENT.IR

Table 20-15 Dental Implant Management in Patients with Adrenal Disorders

RISK		TYPE 1	TYPE 2	TYPES 3 AND 4
Mild	Equivalent of prednisone on alternate days for >1 year	+	Surgery on day of steroids	Sedation and antibiotics Steroids <60 mg prednisone on day 1 Dose ×/2 on day 2 Maintenance dose on day 3
Moderate	Equivalent of prednisone >20 mg or >7 days in past year	+	Sedation and antibiotics: 20-40 mg day 1 Dose × 2 on day 2 Dose × 4 on day 3	Sedation and antiobiotics: 60 mg day 1 Dose × 2 on day 2 Dose × 4 on day 3
Severe	Equivalent of prednisone 5 mg/day	+	Elective procedures contraindicated	Elective procedures contraindicated

+, May be performed with regular protocol.

Patients at significant or moderate risk for adrenal suppression are those formerly on steroid therapy of 20 mg prednisone or more for longer than 7 days within the preceding year. Simple to complex restorative procedures or simple surgery (types 1 and 2) suggest administration of 20 to 40 mg prednisone the day of the procedure. Sedation techniques and antibiotics for 3 to 5 days are suggested. The following day the steroid dose is reduced by 50%, and the third day the dosage is reduced by an additional 50% or returned to normal. For types 3 and 4, moderate to advanced surgical procedures, the protocol is further modified. Prednisone 60 mg or equivalent is administered the day of the surgery. This dose is reduced 50% the following day, and another 50% on the third day. General anesthesia may be used to reduce anxiety in the apprehensive patient.

Patients at low risk for adrenal suppression are those on alternate-day steroid therapy or those whose steroid therapy ended 1 year or more before the implant procedure. For these, dental procedures are scheduled the day steroids are taken or up to 60 mg prednisone is administered. On the second day the dose is reduced 50%; on the third day, the patient resumes the alternate-day schedule. Sedation and antibiotics are also used.

Steroids act in three different ways that affect implant surgery. They decrease inflammation and are useful in decreasing swelling and related pain. However, steroids also decrease protein synthesis and therefore delay healing. In addition, they decrease leukocytes and thereby reduce the patient's ability to fight infection. Therefore whenever steroids are given to patients for surgery, it is reasonable to prescribe antibiotics. After a loading dose, amoxicillin or clindamycin are given three times per day for 3 to 5 days.

Pregnancy

Implant surgery procedures are contraindicated for the pregnant patient. Not only is the mother the responsibility of the dentist, but so is the fetus. The radiographs or medications that may be needed for implant therapy and the increased stress are all reasons the elective implant surgical procedure should be postponed until after childbirth. However, after implant surgery has occurred, the patient may become pregnant while waiting for the restorative procedures, especially as modalities may require 3 months to 1 year of healing. Periodontal disease is often exacerbated during pregnancy. All elective dental care, with the exception of dental prophylaxis, should be deferred until after the birth. The only exceptions to this are caries control or emergency dental procedures. In these instances, medical clearance should be given for all drugs, including anesthetics, analgesics, and antibiotics. Usually lidocaine, penicillin, erythromycin, and acetaminophen (Tylenol) are approved. Aspirin, vasoconstrictors (epinephrine), and drugs that cause respiratory depression (e.g., narcotic analgesics) are usually contraindicated. Diazepam (Valium), nitrous oxide, and tetracycline are almost always contraindicated.

Dental Implant Management

Almost 15% of pregnancies are terminated by spontaneous abortion or miscarriage during the first trimester. Dental prophylactic appointments are suggested in the second or third trimester. The hygienist and dentist should realize that in the middle to late third trimester, hypotension can occur in a supine mother as a result of pressure of the fetus on the inferior vena cava.

Hematologic Diseases

Erythrocytic Disorders

In a healthy patient, 4 to 6 million RBCs per milliliter of blood are in circulation. Red blood cells make up the largest portion of the formed elements in blood. There are two main categories of erythrocyte disorders: polycythemia (increased erythrocyte count) and anemia (decrease in hemoglobin).

Polycythemia

Polycythemia is a rather rare chronic disorder characterized by splenic enlargement, hemorrhages,

WWW.HIGHDENT.IR

and thrombosis of peripheral veins. Death usually occurs within 6 to 10 years and complicated implant or reconstruction procedures are usually contraindicated.

Anemia

Anemia is the most common hematologic disorder. Almost all blood dyscrasias may at one time or another be associated with anemia. Anemia is not a disease entity; rather, it is a symptom complex that results from a decreased production of erythrocytes, an increased rate of their destruction, or a deficiency in iron. It is defined as a reduction in the oxygen-carrying capacity of the blood and results from a decrease in the number of erythrocytes or the abnormality of hemoglobin. There are a number of different types of anemia, the most common being iron deficiency anemia and relative bone marrow failure. Iron deficiency anemia may be caused by a decreased intake of iron, a decreased absorption of iron, or an increase in bleeding. Vitamin C increases the absorption of iron. The female patient may normally be anemic in menses or pregnancy. Mild anemia in a man, however, may indicate a serious underlying medical problem. The most common causes of anemia in men are peptic ulcers or carcinoma of the colon. These serious complications warrant medical evaluation of any male patient found to be anemic.

The general symptoms and signs are all a consequence of either a reduction of oxygen reaching the tissues or alterations of the red blood cell count. The symptoms of mild anemia include fatigue, anxiety, and sleeplessness. Chronic anemia is characterized by shortness of breath, abdominal pain, bone pain, tingling of extremities, muscular weakness, headaches, fainting, change in heart rhythm, and nausea. The general signs of anemia may include jaundice, pallor, spooning or cracking of the nails, hepatomegaly and splenomegaly, and lymphadenopathy. The oral signs of anemia affect the tongue; symptoms include a sore, painful, smooth tongue; loss of papillae; redness; loss of taste sensation; and paresthesia of the oral tissues.

Complications in the implant patient may affect both short-term and long-term prognoses. Bone maturation and development are often impaired in the long-term anemic patient. A faint, large trabecular pattern of bone may even appear radiographically, which indicates a 25% to 40% loss in trabecular pattern. Therefore the initial character of the bone needed to support the implant can be affected significantly. The decreased bone density affects the initial placement and may influence the initial amount of mature lamellar bone forming at the interface of an osteointegrated implant. The time needed for a proper interface formation is longer in poor-density bone.[94] However, after the implant is loaded successfully, the local strain environment will improve the bone density at the interface.

Abnormal bleeding is also a common complication of anemia; during extensive surgery, a decreased field vision from the hemorrhage may occur. Increased edema and subsequent increased discomfort postsurgically are common consequences. In addition, the excess edema increases the risk of postoperative infection and its consequences. Not only are anemic patients prone to more immediate infection from surgery, they are also more sensitive to chronic infection throughout their lives. This may affect the long-term maintenance of the proposed implant or abutment teeth.

Approximately 0.15% of the African American population has sickle cell anemia.[95] Patients with such a disorder usually show marked clinical manifestations and often die before the age of 40. Secondary infections are a common consequence with frequent history of osteomyelitis and bone infection. Because of these complications, implants are contraindicated in patients with sickle cell anemia.

The laboratory tests that diagnose anemia or polycythemia are in the CBC (see Table 20-1). An accurate test for anemia is the hematocrit, followed by the hemoglobin; the least accurate is the RBC count. The hematocrit indicates the percentage of a given volume of whole blood composed of erythrocytes. The normal values for men range from 40% to 50%; those for women from 35% to 45%. Hemoglobin composes almost 95% of the dry weight of red blood cells. Abnormal hemoglobin may result from its combination with substances other than oxygen (e.g., carbon monoxide) or genetic diseases (e.g., sickle cell diseases). Normal values for men are 13.5 to 18 g/dL; those for women are 12 to 16 g/dL. The minimum baseline recommended for surgery is 10 mg/dL, especially for elective implant surgery. For the majority of anemic patients, implant procedures are not contraindicated. However, preoperative and postoperative antibiotics should be administered and the risk of bleeding in anemic patients should not be potentiated by the prescription/use of aspirin. Hygiene appointments should be scheduled more frequently for these patients.

Leukocytic Disorders

Leukocyte disorders are an important consideration in hematologic diseases. The WBC count normally ranges from 4500 to 13,500/mm^3 in the adult. Leukocytosis is defined as an increase in circulating WBCs in excess of 13,500/mm^3. The most common cause of leukocytosis is infection. Leukemia, neoplasms, acute hemorrhage, and diseases associated with acute inflammation or necrosis (e.g., infarction, collagen diseases) are more serious causes of leukocytosis. Physiologic conditions such as exercise, pregnancy, and emotional stress can also lead to leukocytosis.

Leukopenia is a reduction in the number of circulating WBCs to less than 4500/mm^3. A decreased leukocyte count may accompany certain infections (e.g., infectious hepatitis), bone marrow damage (from radiation therapy), nutritional deficiency (e.g., vitamin B_{12}, folic acid), and blood diseases (e.g., anemia).

WWW.HIGHDENT.IR

Table 20-16 Dental Implant Management in Patients with Chronic Obstructive Pulmonary Disease

RISK	TYPE 1	TYPE 2	TYPE 3	TYPE 4
Mild (ASA II)	+	+	+	+
Moderate (ASA III)	+	Physician	Physician/moderate treatment	Physician/moderate treatment
Severe (ASA IV)	+	Postpone (hospitalization)	Elective procedures contraindicated	Elective procedures contraindicated

ASA, American Society of Anesthesiologists; +, may be performed with regular protocol.

In the potential implant candidate with leukocytosis or leukopenia, many complications can compromise the success of the implants and prosthesis. The most common is infection, not only during the initial healing phase but also long term. Delayed healing is also a consequence of WBC disorders. For most implant procedures, the first few months are critical for long-term success. Delayed healing may increase the risk of secondary infection.

Thrombocytopenia is caused by decreased production, increased destruction, or sequestration of platelets in the spleen, which results in potential bleeding complications during surgery. A platelet count should always be obtained, and a value lower than 50,000 U/L contraindicates elective dental surgery because of a significant risk of postoperative bleeding.[96]

Most oral implant procedures are contraindicated for the patient with acute or chronic leukemia. Acute leukemia is an inevitably fatal disease. These patients experience serious oral problems, either secondary to the disease process or as complications after chemotherapy. The patient with chronic leukemia will experience anemia and thrombocytopenia. Although the infection is less severe than in acute leukemia, radiolucent lesions of the jaws, oral ulcerations, hyperplastic gingiva, and bleeding complications develop in these patients.

Treatment planning modifications should shift toward a conservative approach when dealing with leukocyte disorders. Complications are more common than in erythrocyte disorders. If the condition is temporary, such as an acute infection, surgical procedures should be delayed until the infection has been controlled and the patient has returned to a normal condition.

Chronic Obstructive Pulmonary Diseases

Two common forms of chronic obstructive pulmonary disease (COPD) are emphysema and chronic bronchitis. COPD is the fourth most common cause of death after cardiovascular disease and accounts for more than 125,000 deaths per year in the United States.

The death rate of COPD is higher in women than men, and 80% to 90% of deaths occur in smokers. A smoker has a tenfold greater chance of dying from COPD than does a nonsmoker.[97] The usual course of COPD is progressive, resulting in a decline in pulmonary function over many years. Respiratory failure is usually precipitated by pulmonary infection, which eventually leads to death.[98]

Patients with COPD may have a combination of symptoms including chronic cough, sputum production, and shortness of breath. The examination evaluates tachycardia, tachypnea, wheezing, use of accessory respiratory muscles, cyanosis, an increase in the anteroposterior diameter of the chest (barrel chest), prolonged expiration, and failure of the right side of the heart.

Dental Implant Management

Patients with difficulty breathing only on significant exertion and normal laboratory blood gases are at minimal risk and may follow all restorative or surgical procedures with normal protocols (types 1 to 4) (Table 20-16). Dental management of COPD patients may require repositioning the patient from the normal supine position. Depending on the severity of the disease, orthopnea may result. The patient can be placed in the most recumbent position so that breathing is comfortable. Supplemental oxygen (2 to 3 L) should be administered throughout the dental procedures.

Patients with difficulty breathing on exertion in general are at moderate risk, as are patients on chronic bronchodilator therapy or who have recently used corticosteroids. These patients may follow examination procedures with normal protocol (type 1). A recent medical examination is recommended for all other procedures. Type 2 procedures should be performed in a hospital setting. If the patient is on bronchodilators, no epinephrine or vasoconstrictors should be added to the anesthetics or gingival retraction cord. Adrenal suppression should be evaluated for any patient on steroid therapy within the past year.

Patients at high risk are those with previously unrecognized COPD, acute exacerbation (e.g., respiratory infection), dyspnea at rest, or a history of carbon dioxide retention. Dental management of patients with COPD is staged according to the severity of the disease. If a patient has been hospitalized for respiratory difficulties, a medical consultation is warranted. The dentist should inquire regarding the carbon dioxide retention capability of these patients. Patients who retain carbon dioxide have a severe condition and are prone to respiratory

WWW.HIGHDENT.IR

failure when given sedatives, oxygen or nitrous oxide, and oxygen analgesia.

Examination procedures may be performed under normal protocol (type 1). Elective moderate procedures or advanced surgical or prosthetic procedures are usually contraindicated. However, if surgery or prosthetic procedures are needed to repair a previously inserted implant, they should be performed in the hospital. The use of epinephrine should be limited. Drugs that depress respiratory function, such as sedatives (including nitrous oxide), tranquilizers, and narcotics, should be discussed with the physician.

Liver Disease (Cirrhosis)

Cirrhosis is the third leading cause of death in young men between the ages of 35 and 54 years. It occurs as a result of injury to the liver with resultant loss of liver cells and progressive scarring. The major cause of cirrhosis is alcoholic liver disease.[99] In 1992 more than 7% of all adults met the diagnostic criteria for alcohol abuse and alcohol dependence, but as many as 15 to 20 million may be considered alcoholics. More than 25 million Americans have alcohol-related liver or gallbladder disease, and an estimated 900,000 Americans have cirrhosis.[100-102]

Two of the more important functions to the implant dentist are the synthesis of clotting factors and the ability to detoxify drugs. Hemostatic defects of liver disease are not only the reduced synthesis of clotting factors, but also an abnormal synthesis of fibrinogen and clotting proteins, Vitamin K deficiency, enhanced fibrinolytic activity, and quantitative and qualitative platelet defects. Of patients with liver disease, 50% have a prolonged PT and clinical bleeding. The inability to detoxify drugs may result in oversedation or respiratory depression. The laboratory evaluation of the implant candidate gives much insight to hepatic function. Many CMP tests are associated with the liver; however, the tests that relate most specifically to liver disorders are those for bilirubin and albumin. In addition, the CBC, PT, and even PTT tests may be affected. Therefore a history of abnormal bleeding may indicate liver dysfunction.

Dental Implant Management

Patients with no abnormal laboratory values for CMP, CBC, PTT, and PT are at low risk. A normal protocol is indicated for all procedures (types 1 to 4). Patients with an elevated PT of less than 1.5 times the control value, or bilirubin slightly affected, are at moderate risk. These patients should be referred to their physician. The use of sedatives and tranquilizers may need physician clearance. Nonsurgical and simple surgical procedures may follow normal protocols (types 1 and 2). However, strict attention to hemostasis is indicated. Bovine collagen such as CollaTape, topical thrombin, or additional sutures may be indicated. Moderate to advanced surgical procedures may require hospitalization (types 3 and 4). Postsurgical close surveillance is indicated. Elective implant therapy is a relative contraindication in the patient with symptoms of active alcoholism.

Patients with a PT greater than 1.5 times the control value, mild to severe thrombocytopenia (platelets lower than 140,000/mL), or several liver-related enzymes or chemicals affected (bilirubin, albumin, alkaline phosphatase, serum glutamic-oxaloacetic transaminase, and serum glutamic pyruvic transaminase) are at high risk. Elective dental procedures such as implants are usually contraindicated. If surgical procedures must be performed on a preexisting implant, hospitalization is recommended. Platelet transfusion may be required for even scaling procedures and administration of mandibular nerve blocks. Fresh frozen plasma may be used to correct PT to under half the control value.

Bone Diseases

Diseases of the skeletal system and specifically the jaws often influence decisions regarding treatment in the field of oral implants. Bone and calcium metabolism are directly related. Approximately 99% of the calcium in the body is held in the bones and teeth. Calcium equilibrium is decided by the calcium metabolism of the body, and this affects the bones. Alveolar bone responds to systemic bone-active agents.[103]

The parathyroid hormone is the most important regulator of extracellular calcium concentrations. Vitamin D, prostaglandins, lymphocytes (through osteoclast-activating factors), insulin, glucocorticoids, and estrogen also are involved in this complex balance. Prostaglandins act as a local factor and may cause osteolysis and hypercalcemia, leading to bone resorption.

Osteoporosis

The most common disease of bone metabolism the implant dentist will encounter is osteoporosis, an age-related disorder characterized by a decrease in bone mass, increased microarchitectural deterioration, and susceptibility to fractures. The World Health Organization defines *osteoporosis* as a bone mineral density level more than 2.5 standard deviations below the mean of normal young women.[104] Forty percent of postmenopausal women in the United States have bone mineral density levels denoting osteopenia, and 7% have scores correlated with osteoporosis.[105]

After age 60, almost one third of the population has this disorder; it occurs in twice as many women as men.[53] This condition is common in postmenopausal women or those with a history of ovariectomy. The lack of estrogen increases the likelihood of osteoporosis; the addition of estrogen is the single most effective treatment to increase calcium absorption in these women.

Half of all women present bone mineral density below the normal fracture threshold of a 20-year-old woman

WWW.HIGHDENT.IR

by the age of 65 years. It is estimated that 1.3 million fractures and 133,000 hip fractures occur every year as a result of osteoporosis. Most patients fail to recover normal activity; 24% die from complications related to the fracture within the first year.[106]

Risk factors for the development of osteoporosis are classified as nonmodifiable (sex, age, early menopause, small body frame, race, heredity) or modifiable (low bone mass, lack of exercise, smoking, alcohol, hyperparathyroidism).[107]

The osteoporotic changes in the jaws are similar to other bones in the body. The structure of the bone is normal; however, because of the uncoupling of the bone resorption and formation processes with emphasis on resorption, the cortical plates become thinner, the trabecular bone pattern becomes more discrete, and advanced demineralization occurs.[108,109] The bone loss related to osteoporosis may be expressed in both the dentate and edentulous patient. In one study of osteoporotic women who had their teeth at age 50, 44% had a complete denture by the age of 60, whereas only 15% of nonosteoporotic women had dentures.[110] A strong correlation was shown between periodontal disease and skeletal osteoporotic changes. In addition, women represent a greater percentage of patients with residual ridge resorption than men.[111] The loss of trabecular bone is accelerated in the edentulous patient because the factors involved in resorption are already established. Osteoporosis affects the trabecular bone mass loss to a greater extent than it does cortical bone.[112] Implants in the jaws can decrease the resorption process and should be encouraged.

Bone remodeling is a continuous process; however, bone mass increases during youth and diminishes with aging. The peak bone mass is usually reached by the age of 35 to 40 years and is usually 30% higher in men than in women. In the first 3 to 10 years after menopause, bone loss is rapid. Trabecular bone loss in women 80 years old reaches 40%, but is only 27% in men of the same age. Persons most at risk of osteoporosis are thin, postmenopausal, Caucasian women with a history of poor dietary calcium intake, cigarette smoking, and British or Northern European ancestry. Estrogen therapy can halt or retard severe bone demineralization caused by osteoporosis and can reduce fractures by about 50% compared with the fracture rate of untreated women. Premarin (estrogen replacement therapy) is the most common drug prescribed in the United States for the last several years.[13] However, long-term estrogen therapy has been linked to a slight increase in endometrial cancer, and recently drug regimens have been altered. Studies have evaluated the effect of estrogen replacement therapy on dental implant failures. Osteoporotic patients not taking estrogen have nearly twice the failure rate of maxillary implants in comparison to patients who were receiving estrogen therapy.[113]

Recent advances in radiology, such as dual-energy x-ray absorptiometry, can measure as little as 1 mg of bone mass change at such sites as the hip, spine, and wrist. Such measurements may accurately predict future fracture risk and identify the patients at risk.[114,115] The actual diagnosis and treatment of osteoporosis should be accomplished by the physician. The implant dentist can benefit the patient by noting the loss of trabecular bone and by early referral. Treatment of osteoporosis remains controversial. Its management concentrates on prevention. Regular exercise has shown to help maintain bone mass and increase bone strength. Adequate dietary calcium intake is essential. The advanced demineralization and consequent increase in bone loss of the completely edentulous may become a vicious circle. The denture is less secure, and the patient may not be able to follow the diet needed to maintain proper calcium absorption levels.

The recommended calcium intake is 800 mg/day. The average person in the United States ingests 450 to 550 mg. In postmenopausal women, 1500 mg may be required to maintain a positive calcium balance.[116] Calcium supplements of 1 to 2 g of elemental calcium per day have been shown in several studies to reduce the rate of bone loss. However, there is no evidence that these supplements lead to recovery of bone mass. Plain calcium carbonate tablets contain the greatest fraction of elemental calcium and are relatively inexpensive. It is insoluble and is absorbed after conversion into calcium chloride by gastric hydrochloric acid. Patients with achlorhydria (lack of hydrochloric acid) should be given salts other than calcium carbonate. If the patient has a lactate deficiency, lactate salts are contraindicated. Several food-drug interactions have been reported. Tetracycline and iron do not work effectively with calcium doses. Patients should also avoid phosphate (found in some dairy products or diet soda) or oxalic acid (in spinach and rhubarb) and the phytic acid in bran and whole grains, because these decrease calcium absorption. Patients with a history of renal calculi should avoid calcium supplements. Patients with renal dysfunction need periodic serum and urine calcium level checks, and their serum pH should be monitored to avoid hypercalcemia and metabolic alkalosis.

For patients with established osteoporosis, treatment options include bisphosphonates and calcitonin. Bisphosphonates are inhibitors of bone resorption. Calcitonin, which is normally secreted by the thyroid gland, inhibits bone resorption and alters calcium metabolism.

Dental Implant Implications

Patients with osteoporosis present the implant dentist with many challenges. Although not contraindicated, immediate stabilization of dental implants is a common concern because of decreased trabecular bone mass. Healing periods and implant surface characteristics

WWW.HIGHDENT.IR

should be selected for poorer-quality bone. Additionally, a large percentage of these patients are being treated with bisphosphonates, which have been attributed to various surgical complications.

Although osteoporosis is a significant factor for bone volume and density, it is not a contraindication for dental implants. Clinical reports in postmenopausal women older than 50 years had failure rates similar to other patients, and hormone replacement therapy did not influence the failure rate.[113,117,118] The bone density does affect the treatment plan, surgical approach, length of healing, and need for progressive loading. Implant designs should be greater in width, and surface conditions of implant bodies should be designed to increase bone contact and density. Bone stimulation to the healed interface will increase bone density, even in advanced osteoporotic changes.

Vitamin D Disorders (Osteomalacia)

Vitamin D is a hormone synthesized by the body in several steps involving the skin, liver, kidney, and intestine. It is activated by the kidney in conjunction with parathyroid hormone. The deficiency of vitamin D in the adult leads to osteomalacia. With this deficiency, the intestinal uptake and mobilization of calcium from the bone is altered, thus resulting in hypocalcemia. This will lead to an increased parathyroid hormone secretion, which increases the clearance of phosphorus from the kidneys. This resultant decrease in the concentration of phosphorus prevents a normal mineralization process. Anticonvulsant drugs, especially diphenylhydantoin and phenobarbital, may cause drug-induced osteomalacia. Many gastrointestinal disorders also may result in osteomalacia.

The oral findings of osteomalacia are usually not dramatic. A decrease in trabecular bone, indistinct lamina dura, and an increase in chronic periodontal disease have been reported. The treatment for osteomalacia is supplemental oral vitamin D (50,000 IU).

Dental Implant Implications

Treatment for osteomalacia is usually successful with radiographic changes seen months after treatment. There are no known reports of implant complications in osteomalacia patients; however, there is no contraindication as long as the disease is not active and well controlled.

Hyperparathyroidism

The clinical manifestations of this disease vary widely, depending on the severity. Mild forms may be asymptomatic. Renal colic disorders often occur with moderate disease. Severe hyperparathyroidism can cause bone, renal, and gastric disturbance. It has been noted that when skeletal depletion occurs as a result of stimulation by the parathyroid gland, alveolar bone may be affected before that of the rib, vertebrae, or long bones.

Oral changes related to this disorder occur only with advanced disease. The loss of lamina dura is the most significant finding. Clinically, patients with this disorder develop loose teeth. Altered trabecular bone pattern with the appearance of ground glass may also occur. In animals, secondary hyperparathyroidism affects alveolar bone loss greater than any other bone of the skeleton.[119] Central or peripheral giant cell tumors may also develop.

Dental Implant Implications

Dental implants are contraindicated in areas of active bony lesions. However, implant placement may be initiated after treatment and healing of the affected areas.

Fibrous Dysplasia

Fibrous dysplasia is a disorder in which fibrous connective tissue replaces areas of normal bone in an unorganized arrangement. It is found twice as often in women than it is in men and may affect a single bone or multiple bones. The single-bone disorder is more common in adults and is present in the jaws about 20% of the time. The condition is twice as common in the maxilla as in the mandible. The monostotic (single-bone) fibrous dysplasia begins as a painless, progressive lesion. The facial plate usually expands. The teeth may move as a consequence of the progression. Roots of the teeth may be displaced, but external resorption is rare. Radiographically the appearance of fibrous dysplasia is a noted increase in trabeculation, which presents a "mottled appearance." A ground-glass appearance may also be noted.[120] The polyostotic (multiple-lesion) fibrous dysplasia may affect one or virtually all bones. A predisposition to fracture may occur with this entity. There exists an increased incidence of malignancy (osteosarcoma, chondrosarcoma) in bones affected with fibrous dysplasia. Healing after trauma in patients with fibrous dysplasia is much different than normal bone. The tissue is hypocellular, leading to slow healing and an increased incidence of infection.

Dental Implant Implications

Implant dentistry is contraindicated in the regions of this disorder. The lack of bone and increased fibrous tissue decrease rigid fixation of the implant and are more susceptible to local infection processes. These local infections may spread through the bone and result in more advanced complications. Excision of fibrous dysplasia areas is usually the treatment choice. After the condition is corrected long-term, the area may receive an implant. Radiation therapy has been used, but may be responsible for the transformation of fibrous dysplasia into osteosarcoma or chondrosarcoma.

WWW.HIGHDENT.IR

Osteitis Deformans (Paget's Disease)

Osteitis deformans, or Paget's disease, is a common metabolic disease characterized by slow, progressive, uncontrolled resorption and deposition of bone. This disease is usually seen in Caucasian men older than 40 years. The etiology is unknown and usually affects the maxillary alveolar ridge twice as frequently as the mandibular ridge. Because of the enlargement of the middle one third of the face, the appearance of a "lion-like" deformity is often noted. Diastemas, tooth mobility, and bone pain are additional characteristics. Radiographically, a decreased radiodensity, large circumscribed radiolucencies, patchy areas of coalesced sclerotic bone (cotton-wool appearance), and marrow spaces that are replaced by fibrous tissue are observed. During the active phases of this disease, bone is highly vascular with the possibility of arteriovenous shunts, which may cause hemorrhagic complications.

Paget's disease is marked by high elevations of serum alkaline phosphatase, normal or elevated calcium, and normal phosphate levels. Edentulous patients are often unable to wear their prostheses without discomfort.[121] There is no specific treatment for Paget's disease, and these patients are predisposed to develop osteosarcoma and possibly osteomyelitis.

Dental Implant Implications

Oral implants are contraindicated in the regions affected by this disorder.

Multiple Myeloma

Multiple myeloma is a plasma cell neoplasm that originates in the bone marrow and is characterized by the abnormal proliferation of B cells. It causes severe hypercalcemia, immune suppression, anemia, and thrombocytopenia because it causes widespread bone destruction. The disease is usually found in patients between 40 and 70 years of age. Usually it affects several bones in the body with symptoms of skeletal pain. Pathologic fractures may occur. Punched-out lesions appear radiographically. Oral manifestations of the disease are common (80%) and may affect both the maxilla and the mandible. Paresthesia, swelling, tooth mobility, and tooth movement may occur. Gingival enlargements are also possible. Plasma cell malignancy, Bence Jones proteins in the urine, and anemia are possible laboratory findings associated with this disorder. There is no treatment for multiple myeloma, and the condition is usually fatal 2 to 3 years after onset.

Dental Implant Implications

Dental implants are a relative contraindication in patients with multiple myeloma because of the severity of this disease; however, a case report has described successful implant placement in a patient with this disease.[122]

Osteomyelitis

Osteomyelitis is an acute or chronic inflammatory bone disease that is bacterial in nature. The radiographic appearance is a poorly defined, radiolucent area with isolated fragments of bone (sequestra) that can exfoliate or become surrounded by bone (involucrum). This disorder can be caused by odontogenic and periodontal infections, trauma, dental implants, immunocompromised states, and hypovascularized bone. The treatment includes aggressive surgical drainage, with possible intravenous antibiotic intervention. Osteomyelitis usually occurs in the mandible and is rarely seen in the maxilla, possibly due to the increased vascularization.

Dental Implant Intervention

Osteomyelitis is usually a contraindication unless the etiologic factors are removed and adequate blood supply to the affected area is restored.

Osteogenesis Imperfecta

Osteogenesis imperfecta is the most common inherited bone disease and is characterized by poor bone quality and fragility. Bone fractures along with skeletal deformities are common with very poor healing. Histologically, defective osteoblasts lead to a reduction in bone matrix and abnormal collagen. The quality of the bone is poor with very thin cortical bone and thin, fine trabeculae.

Dental Implant Implications

Dental implants are not contraindicated; however, caution should be given to the very poor bone quality and questionable osseous healing.

Cement-Osseous Dysplasia

This disease is the most common fibro-osseous lesion usually occurring in the mandibular anterior region. There are three types of this disease (i.e., focal, periapical cementoma, and florid) that can vary radiographically as radiolucent, radiopaque, or a combination. The lesions are usually associated with the mandibular anterior teeth. Cement-osseous dysplasia usually occurs in middle-aged women and has a high incidence in African Americans.

Dental Implant Implications

Dental implants are not contraindicated unless in the sclerotic phase of the disease in which the bone is hypovascular. This bone has the ability to become infected easily with questionable healing. Special attention must be given so that the disease does not progress to osteomyelitis.

Table 20-17 American Dental Association/American Academy of Orthopaedic Surgeons Suggested Antibiotic Prophylaxis Regimens

PATIENT TYPE	RECOMMENDED DRUG	SINGLE-DOSE REGIMEN
Patients not penicillin allergic	Amoxicillin, cephalexin, or cephradine	2 g PO 1 hr before dental procedure
Patients not penicillin allergic, unable to take oral medications	Ampicillin or cefazolin	Ampicillin 2 g IM or IV or cefazolin 1 g, 1 hr before dental procedure
Penicillin-allergic patients	Clindamycin	600 mg PO 1 hr before dental procedure
Penicillin-allergic patients, unable to take oral medications	Clindamycin	600 mg IV 1 hr before dental procedure

Data from American Dental Association, American Academy of Orthopedic Surgeons: Antibiotic prophylaxis for dental patients with total joint replacements, *J Am Dent Assoc* 134:895-899, 2003.
PO, By mouth; *IM*, intramuscularly; *IV*, intravenously.

Prosthetic Joints

Approximately 450,000 total joint arthroplasties are performed every year in the United States, and more than 60% are performed on patients older than age 65.[123,124] Dental implants may be used on patients with other prosthetic implants. Bacteremias can cause hematogenous seeding of total joint implants in the early and long term after implantation. The most critical period is up to 2 years after placement.[125,126] There appears to be no scientific evidence to support antibiotic prophylaxis in patients with total joint prosthesis to prevent hematogenous infections.[127] However, approximately 1% to 2% of these prosthetic joint prostheses will become infected each year. The literature reports an association between prosthetic joint infection and dental treatment. It is hypothesized that bacteria from the dental treatment may seed the prosthesis and produce infection. The evidence for this often seems circumstantial or coincidental because the anatomy, blood supply, microorganisms, and mechanisms of infection are all different.[128] Reported cases related to the mouth have involved regions of established suppuration such as a dental abscess or tonsillitis, rather than procedure-induced transient bacteremia.

The joint ADA/American Academy of Orthopaedic Surgeons advisory statement[123,124] recommends the aggressive treatment of acute orofacial infections in patients with total joint prosthesis because those bacteremias associated with acute infections can and do cause late implant infections. Antibiotic prophylaxis is not indicated for dental patients with pins, plates, and screws and is not routinely indicated for most dental patients with total joint replacement. The antibiotic prophylaxis regimen recommended is, however, indicated for patients with higher risk for hematogenous infections undergoing dental procedures with a higher bacteremic incidence (Table 20-17). In addition, it is recommended for dental procedures with higher bacteremic incidence performed on patients within 2 years of post-total joint implant surgery,[126] or those with a history of prosthetic joint infection or other conditions such as inflammatory arthropathies, immune suppression, type I diabetes, or hemophilia. Dental extractions, surgical placement of implants, periodontal surgery, and prophylactic cleaning of teeth and implants are examples of dental procedures with a higher risk of bacteremia.

Ectodermal Dysplasia

Ectodermal dysplasia (ED) is a genetically inherited disorder that occurs in 1 per 100,000 live births.[129] Clinically, ectodermal dysplasia has been divided into two broad categories: an X-linked hypohidrotic form (Christ-Siemens-Touraine syndrome) characterized by the classical triad of hypodontia, hypohidrosis, and hypotrichosis and by characteristic facial features such as prominent supraorbital ridges and a depressed nasal bridge,[130] and an autosomal inherited hydrotic form (Clouston's syndrome) that usually spares the sweat glands but affects teeth, hair, and nails.[131]

The most common intraoral feature off ED is hypodontia or anodontia. In these patients, conventional prosthodontic procedures often are not successful because of anatomical abnormalities that result in poor retention and stability. Because of this, dental implant therapy aimed at restoring function, esthetics, and psychological rehabilitation is an integral part in the management of adolescent patients with ED.[131] Numerous studies have been completed on dental implants in patients with ED. A 3-year study showed impressive success rates in preadolescents (ages 7 to 11, 87%), adolescents (ages 12 to 17, 90%), and in adults (older than 17, 97%).[132] Other positive case reports have shown dental implants as a successful adjunct to oral rehabilitation.[133,134]

Dental Implant Implications

Dental implants are not contraindicated in patients with ED. Although not ideal, implants may be placed in preadolescents with the advantage of function, esthetics, and psychological advantages. Alveolar bone has been shown to continue to grow after implants

WWW.HIGHDENT.IR

have been placed in edentulous ridges of children with ED. Transverse and sagittal growth is not restricted; however, vertical growth may result in submersion of the implants, necessitating prosthetic revision or possible use of longer abutments.[130]

SYSTEMIC AUTOIMMUNE DISEASES

Autoimmune diseases refers to a group of more than 80 serious, chronic illnesses that can affect almost any organ in the body. Approximately 75% of autoimmune diseases occur in women; these diseases are thought to have a genetic predisposition. However, autoimmune diseases are among the most poorly understood diseases, with symptoms extremely variable among individuals.

Sjögren's Syndrome

Sjögren's syndrome is an autoimmune disease in which immune cells attack and destroy exocrine glands that produce saliva and tears. This disorder affects an estimated 4 million people in the United States and 90% of females with an average age of onset in the late 40s. The classic symptoms of Sjögren's syndrome are xerostomia and xerophthalmia (dry eyes). Because of the xerostomia, patients are more susceptible to decay and the mucous membranes become atrophic and friable. Because of the lack of salivary secretions, complications may arise with the use of a tissue-borne prosthesis.

The healing response and integration of implants has been shown to be successful in patients with Sjögren's syndrome.[135] These implant-supported prostheses decrease soft tissue–borne prosthetic sore spots and discomfort.

Dental Implant Implications

There are no contraindications for dental implants in patients with a history of Sjögren's syndrome. However, it is advantageous for the prosthesis to be non–tissue-borne (FP-1, FP-2, FP-3) to minimize complications from xerostomia.

Systemic Lupus Erythematosus

Systemic lupus erythematosus is a chronic, potentially fatal autoimmune disease in which the immune system attacks cells and tissue in almost any part of the body. This disease usually affects women, and approximately 5 million people are afflicted with this disorder. The majority of lupus patients suffer from dermatologic manifestations such as malar rash (butterfly rash) and skin, mouth, and nasal lesions. Additional effects are hematologic, cardiac, pulmonary, and renal complications. There is no cure for lupus, and most patients are treated with corticosteroids and immunosuppressive drugs.

Dental Implant Implications

There is no direct contraindication to dental implant treatment in systemic lupus erythematosus patients. However, caution should be taken for possible associated organ damage and the use of high doses of corticosteroids and immunosuppressive drugs, which may contraindicate dental implants in those individuals.

Scleroderma

Scleroderma is a rare, chronic disease characterized by excessive deposits of collagen that causes musculoskeletal, pulmonary, and gastrointestinal involvement. The most common symptom is the hardening of the skin in which scarring can take place. Most patients have Raynaud's phenomenon, which affects the hands and feet. There is no cure for scleroderma, and various stages of the disease are treated with NSAIDs and immunosuppressant drugs.[136]

Dental Implant Implications

Numerous reports have discussed the successful treatment of scleroderma patients with dental implants. A fixed prosthesis is recommended because of the inability to retrieve a removable prosthesis because of possible dexterity problems. However, caution must given to the fact that a high percentage of these patients are being treated with immunosuppressive drugs, which may contraindicate the implant therapy.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, inflammatory autoimmune disease that causes the patient's immune system to attack the muscles and joints of the body. This disorder is known for its painful and disabling inflammation that leads to substantial loss of mobility and dexterity. Rheumatoid arthritis is treated with a wide range of medications including disease-modifying antirheumatic drugs, antiinflammatory drugs, and analgesic medications.[137] Life expectancy of patients with RA is shortened by approximately 5 to 10 years.[138]

Dental Implant Implications

There is no direct contraindication for dental implants in patients who have RA. Because of the lack of mobility and dexterity, a fixed-implant restoration is indicated. Special attention should be given to the treatment medications, as immunosuppressive and glucocorticoid therapy may contraindicate implant treatment.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) is a retrovirus that is responsible for acquired immunodeficiency syndrome (AIDS), which causes the immune system to be depressed, leading to life-threatening opportunistic

WWW.HIGHDENT.IR

infections. The World Health Organization recently estimated that 25 million have died since HIV was discovered on December 1, 1981.[139] There is no cure for either HIV or AIDS. A postexposure prophylaxis, an antiretroviral, has been shown to reduce the risk of infection after exposure. Highly active antiretroviral therapy, which is a protease inhibitor, has been highly beneficial since its introduction in 1996.

Dental Implant Implications

Numerous reports have shown successful dental implant therapy in HIV patients.[140,141] However, there are insufficient data to determine the association between HIV infection and the success of dental implants. Special care must be taken to evaluate the current status of the patient's immune system and the potentially toxic medications the patient is taking.

MEDICATIONS OF INTEREST TO IMPLANT DENTISTRY

Bisphosphonates

Bisphosphonates are a group of drugs that are widely used for several bone disorders and have been approved by the U.S. Food and Drug Administration for treatment of osteoporosis, metastatic bone cancer, and Paget's disease.[142] At this time, there are two main types of bisphosphonates: nitrogen containing and non-nitrogen containing, with subgroups of either oral or intravenous administration.

History

Bisphosphonates were first used for industrial purposes in the nineteenth century to prevent corrosion in the textile, fertilizer, and oil industries. In 1968 the first article describing use of bisphosphonates in medicine was published, discussing the inhibition of bone resorption qualities.[143] However, in 2002 reports of serious side effects from these medications after dental surgical procedures were documented. These complications from bisphosphonates are bisphosphonate osteonecrosis, bisphosphonate avascular necrosis, bisphosphonate osteomyelitis, osteochemonecrosis, and Bis-Phossy jaw.

The complications reported with respect to bisphosphonate use are very similar to conditions that were reported as early as the nineteenth century. In 1845 numerous cases of jaw necrosis were documented from workers in an industrial plant that manufactured matches. Symptoms included pain and tissue inflammation leading to progressive extension with greater areas of bone involvement and sequestration.[144] These lesions resulted in very high rates of morbidity and mortality until changes in environmental hygiene eradicated the problem. In the twentieth century, similar cases of jaw necrosis were seen in workers applying radium to watch instrument dials. These cases also were eradicated by changes in industrial hygiene.[145]

Initially, when the first cases of bisphosphonate necrosis were seen, they were treated and thought to be osteoradionecrosis. However, treatment such as surgical intervention and hyperbaric oxygen failed to produce conclusive resolution to the condition.[146,147] Marx and Ruggiero reported on bisphosphonate-induced osteonecrosis of the jaws, particularly from the more potent nitrogen-containing intravenous bisphosphonates (pamidronate and zoledronic acid). However, a small percentage of the cases involved the oral bisphosphonates: risedronate (Actonel) and alendronate (Fosamax).[148,149]

Chemistry

Bisphosphonates are synthetic compounds that have a chemical structure similar to inorganic pyrophosphate, which is an endogenous regulator of bone metabolism. Because bisphophonates comprise two phosphate groups linked together by phosphoether bonds (P-C-P structure), they are more resistant to breakdown by pyrophosphatases and hydrolysis.[150,151] The general structure of bisphosphonates is rather simple to modify; thus different generations vary dramatically according to their biological, therapeutic, and toxicologic characteristics (Box 20-6).[152]

Mechanisms of Action

Bisphosphonates work by suppressing and reducing bone resorption by osteoclasts. Directly, this is accomplished by preventing the recruitment and function of osteoclasts. Indirectly, they stimulate osteoblasts to produce inhibitors of osteoclast formation.[153] Because of this bone resorption suppression, diseases such as Paget's disease of bone, fibrous dysplasia, and metastatic bone cancer are treated very effectively and relieve pain symptoms.

The blood level half-life of bisphosphonates is very short, ranging from 30 minutes to 2 hours.[154] However, after these medications are absorbed into bone tissue, they can persist for up to 10 years in the skeletal tissues, depending on skeletal turnover time.[130,131] After jaw bone surgery, a radiolucent lesion or bone exposure may develop rather than a typical healing mechanism.

Box 20-6 Types of Bisphosphonates

Nitrogen Containing

Oral: alendronate (Fosamax); risendronate (Actonel)
Intravenous: pamidronate (Aredia); zoledronate (Zometa)

Non–Nitrogen Containing

Etidronate (Didronel)
Clodronate (Bonefas)
Tiludronate (Skelid)

WWW.HIGHDENT.IR

Osteonecrosis of the Jaws

Although there exist extensive data on the beneficial effects of bisphosphonates in the treatment of advanced bone diseases, numerous reports have documented the capability of these medications in causing local lesions of the bone osteonecrosis of the jaws.[148,149] Most cases initially reported were after a jaw bone surgery with the more potent nitrogen-containing bisphosphonates pamidronate and zoledronic acid. However, osteonecrosis lesions have been reported in the oral bisphosphonates risedronate and alendronate.

Osteonecrosis may remain asymptomatic for weeks and possibly months. Lesions usually develop around sharp bony areas and previous surgical sites, including extractions, retrograde apicoectomies, periodontal surgery, and dental implant surgery. Symptoms include pain, soft tissue swelling, infection, loosening of teeth, and drainage. Radiographically, osteolytic changes are seen and tissue biopsy has shown the presence of actinomyces, which is possibly caused by secondary infection.[154]

Management of Osteonecrosis

Initially, the first cases of biphosphonate osteonecrosis were treated with similar techniques as for osteoradionecrosis. These lesions failed to respond to antibiotics, surgical intervention, and hyperbaric oxygen. The most current recommendation of osteonecrosis is a nonsurgical approach to the management of these lesions because of impaired wound healing. Only minimal bony debridement of these lesions should be performed, such as reduction of sharp edges. Chlorhexidine mouthrinses (0.12%) and antibiotics should be used supplementally.[155] If lesions persist, referral to an oral and maxillofacial surgeon or dental specialist with experience in the treatment of this condition is recommended.

Laboratory Tests

It has been proposed that assays to monitor markers of bone turnover may help in the diagnosis and risk of developing bisphosphonate-associated osteonecrosis.[155a] C-telopeptides (CTx) are fragments of collagen that are released during bone remodeling and turnover. Because bisphosphonates reduce CTx levels, it is believed that evaluating serum CTx levels can be a reliable indicator of risk level. The CTx test (also called *C-terminal telopeptide* and *collagen type 1 C telopeptide*) is a serum blood test obtained by laboratories or hospitals (ICD9 diagnostic code 733.40)

Marx has suggested a preoperative protocol for administering bisphosphonates to patients who are undergoing oral surgical procedures.[155b] His protocol considers the type and duration of bisphosphonate use as well as radiographic and clinical risk factors. Depending upon the laboratory values obtained, a "drug holiday" may be indicated, which includes temporary interruption of bisphosphonate treatment. However, improvement of bisphosphonate levels may not be observed, because measurable levels have been to shown to persist in bone for up to 12 years after cessation of therapy[155c] (Box 20-7).

Dental Implant Implications

A comprehensive medical history is essential before any elective treatment is initiated. Potential risk factors should be documented; previous radiotherapy, chemotherapy, female gender, coagulopathies, exostosis, vascular disorders, alcohol abuse, and smoking. The most important history of bisphosphonates is the use of intravenous nitrogen-containing bisphosphonates such as pamidronate (Aredia) and zoledronic acid (Zometa). The American Academy of Periodontology stated invasive dental procedures should be avoided in patients taking IV bisphosphonate therapy unless absolutely necessary.[156] In September 2004, Novartis added bisphosphonate osteonecrosis warning to IV drug

Box 20-7 Protocol, Suggestions, and Assessment for Patients Taking Oral Bisphosphonates

Protocol and Suggestions*

Oral Bisphosophonate Use >3 Years

1. Physician approval to discontinue bisphosphonates 3 months before sugery and 3 months after sugery ("drug holiday").
2. Determine serum CTx levels during initial consultation and immediately before surgery; CTx levels must be >150 pg/mL before proceeding with surgery.
3. Detailed informed consent for bisphosphonate-associated osteonecrosis.

Oral Bisphosophonate Use <3 Years without Clinical or Radiographic Risk Factors†

1. Serum CTx level must be >150 pg/mL.
2. Proceed with surgery with detailed informed consent for bisphosphonate-associated osteonecrosis.
3. If serum CTx level <150 pg/mL, institute a physician-approved "drug holiday"; continue monitoring every 3 months until CTx levels >150 pg/mL.

Oral Bisphosophonate Use <3 Years with Clinical or Radiographic Risk Factors†

1. Physician-approved "drug holiday" for 3 months.
2. Serum CTx level must be >150 pg/mL to proceed with detailed informed consent for bisphosphonate-associated osteonecrosis.
3. If serum CTx level <150 pg/mL, continue monitoring every 3 months until CTx level >150 pg/mL.

Laboratory Risk Assessment

CTx Value (pg/mL)	Risk for Osteonecrosis
• 300-600 (normal)	None
• 150-299	None to minimal
• 101-149	Moderate
• < 100	High

*Marx RE: *Oral and intravenous bisphosphonate-induced osteonecrosis of the jaws: history, etiology, prevention, and treatment,* Chicago, 2007, Quintessence.
†Glucocorticoid use, widened lamina, or sclerotic bone.

WWW.HIGHDENT.IR

guidelines stating to obtain dental exam of the patient prior to drug administration and to "avoid" invasive dental procedures during dry use.

In the dental setting, the most common bisphosphonates that implant dentists are exposed to are oral nitrogen-containing bisphosphonates such as risedronate, ibandronate, and alendronate. The latest studies show that oral bisphosphonate has a very low probability of causing osteonecrosis.[157] For example, the risk of ulcerative colitis is possible with antibiotics, but the dentist informs the patient of the risk and prescribes the antibiotic when required. Likewise, the risk of oral bisphosphonates and bisphosphonate osteonecrosis is about the same (or less and therefore should be considered a low risk and yet prudent to inform the patient). However, because of the long half-life and the studies only being conducted for 3 years, future long-term complications may be less evident. With this in mind, the implant dentist should be cautioned on the possibility of developing osteonecrosis side effects. The risks versus benefits of dental treatment must be discussed with the patient in detail. A well-documented consent form is recommended with possible medical consultation if the patient has been on this medication for more than 3 years.

The use of glucocorticosteroids may be contraindicated in patients taking bisphosphonates, because these drugs have been associated with an increased occurrence of osteonecrosis.

Immunosuppressive Medications

Immunosuppressive drugs are medications that are used in immunosuppressive therapy to inhibit or prevent activity of the immune system. They are usually used to prevent rejection of transplanted organs and tissues and for the treatment of autoimmune diseases. These drugs have many side effects with the majority of them acting nonselectively; thus the body is unable to resist infections. There are four classes of immunosuppressive drugs: glucocorticoids (prednisone), cytostatics (chemotherapeutic agents), antibodies (polyclonal antibodies), and drugs acting on immunophilins (cyclosporine).

Cytostatics are common medications in the treatment of malignant disease. These drugs cannot discriminate between malignant and normal tissues and become cytoxic to normal tissue. Most chemotherapeutic agents are known to have cytoxic effects on bone, especially on grafted bone where the blood supply is compromised.[158] Because chemotherapeutic agents have a high toxicity for cells that have a high turnover rate, the oral mucosa is often affected. These mucosal ulcerations have been known to become secondarily infected. Very few studies have been completed on the relationship of chemotherapy and dental implants; however, the data show that there exist minimal deleterious effects on implant integration.[159,160]

Glucocorticoids have potent antiinflammatory and immunosuppressive properties. Because these drugs are widely used in the treatment of inflammatory and autoimmune diseases, special attention must be given to patients who are on long-term, high doses of glucocorticoids. These drugs impair many healthy anabolic processes in the body and suppress the immune system, which can lead to severe complications in dental implant patients.

Dental Implant Implications

In the past, chemotherapeutic agents were thought to be absolute contraindications for implant candidates with malignant disease.[161] However, with increased success of this therapy, patients now can be treated successfully, thus increasing their quality of life. Care must be taken to evaluate the timing of the chemotherapy.

Studies have shown high failure rates with dental implants and concurrent cytotoxic chemotherapy.[162] Therefore elective implant treatment is contraindicated in any patients who are actively receiving any type of chemotherapeutic medication. However, after chemotherapy treatment has been completed, implant treatment may be completed after careful consideration of the patient's immune system status and physician approval.

For patients receiving long-term, high-dose glucocorticoid therapy, medical consultation is necessary to ascertain the current status of the immune system. This medication can be a contraindication to dental implant therapy.

Anticoagulant Medications

Warfarin Sodium

Warfarin sodium (Coumadin) is used as an anticoagulant in a wide range of conditions such as ischemic heart disease, deep venous thrombosis, pulmonary emboli, and artificial heart valves. (Table 20-2 targets INR values for specific diseases.)

Warfarin sodium has a half-life of 40 hours, which has been known to vary among individuals from 20 to 60 hours. The mode of action of warfarin sodium is the interference of the synthesis of vitamin K, which is a cofactor in many reactions with the coagulation cascade.

Dental Implant Implications

Until recently, most medical practitioners have believed that the medication should be discontinued before dental surgery to prevent possible bleeding problems. However, there exist many documented cases of embolic complications in patients who discontinue the use of warfarin sodium[163,164] and thrombosis from rebound hypercaogulability.[165] In addition, studies have shown that dental surgery may be performed safely on patients receiving anticoagulant therapy as long as their INR values are within the therapeutic range.[166]

WWW.HIGHDENT.IR

Practitioners should consult with the patient's physician to determine the most recent INR before the surgery. If the INR values are within the therapeutic range (2 to 3.5), there is no need to discontinue use of the anticoagulant. If the INR value is above the therapeutic range (especially higher than 4.0), the physician should take appropriate steps to lower the INR to a safer level or possible discontinue the warfarin and supplement with heparin therapy or vitamin D. However, in all anticoagulant patients, special attention should be given to good surgical technique and use of appropriate local measures to control bleeding.

Aspirin

Aspirin or salicylic acid has been used as an antiinflammatory, analgesic, and antipyretic medication. However, in the 1980s, it was discovered that aspirin also had an antiplatelet effect at very low doses (0.5 to 1 mg/kg) versus higher doses needed for an antipyretic effect (5 to 10 mg/kg) and anti-inflammatory response (30 mg/kg).[167] Because of this research, low-dose aspirin has become a secondary preventive drug for patients who have cardiovascular and peripheral vascular disease.[168]

Aspirin works by inhibiting the formation of prostaglandin thromboxane A2 within the platelet, thus affecting thrombus formation by irreversibly decreasing platelet aggregation. There are numerous studies in the literature that advocate the discontinuation of aspirin therapy for 7 to 10 days before elective surgery,[169,170] whereas others have suggested that aspirin therapy should be continued regardless of the surgical procedure.[171,172] In a prospective dental extraction study with low-dose aspirin, it was shown that low-dose aspirin should not be discontinued before oral surgery and local hemostasis measures are sufficient.[173]

Dental Implant Implications

Because there exists no double-blind study supporting the recommendation of low-dose (<100 mg) aspirin discontinuation, especially with oral surgical procedures, there exists no reason to discontinue use for routine dental implant procedures. Interruption of aspirin therapy may expose the patient to the risk of developing thromboembolism, myocardial infarction, or cerebrovascular accident.[167]

However, for patients taking higher doses of aspirin (>100 mg), or in combination with other anticoagulants (clopidogrel, dipyridamole/aspirin [Aggrenox]), bleeding times should be obtained with possible physician consultation.

The platelet inhibitor clopidogrel (Plavix) is now number 36 in the top 50 drug list.[13] It is approved for the reduction of atherosclerotic events in patients of recent stroke, recent MI, or an established peripheral arterial disease. A recent study supports the use of clopidogrel and aspirin for at least 9 months in all cases involving coronary syndromes.[174] (The American Dental Association Council of Scientific Affairs does not support routine discontinuation of oral anticoagulant therapy and antiplatelet therapy for patients before dental treatment.[175]) However, if type 3 or 4 category treatment is scheduled, a consult with the physician before surgery is warranted to review the INR values.

Herbal Supplements
