Over-the-counter herbal and dietary supplements are being consumed at a record pace for general health improvement and treatment of chronic conditions. Herbs have been known to have unwanted side effects and cause drug interactions, and they have been associated with surgical complications (Boxes 20-8 and 20-9). Many of these supplements contain active ingredients that have strong biological effects. The doses may be unregulated and variable. The *Journal of the American Medical Association* estimates that 15 million adults are at risk for adverse interactions between herbs and prescription medications.[175a] More than 2900 adverse events related to supplements have been reported to the Food and Drug Administration, including 104 deaths.[175b]

LIFESTYLE-RELATED FACTORS

Tobacco

In the United States, approximately 21% of the population smokes cigarettes. Although this has declined by 50% (42% of the population in 1965), 45 million

Box 20-10 Detrimental Effects of Tobacco

1. Decrease blood flow (vasoconstriction)
2. Tissue hypoxia
3. Collagen deposition
4. Prostacyclin formation
5. Increases platelet aggregation
6. Polymorphonuclear neutrophil dysfunction
7. Increases fibrinogen
8. Blood viscosity
9. Systemic increase in epinephrine, norepinephrine

adults still smoke. Approximately 23% of men and 19% of women smoke cigarettes.[176] The use of tobacco has been implicated in many adverse systemic outcomes, including tooth loss and dental implant failure.[177,178]

A nationwide oral health survey established a definite association between smoking and poorer levels of periodontal health, even after adjustments had been made for age, sex, race, and oral hygiene habits.[179] Similar findings were documented in a study that established a relationship between periodontal attachment loss and smoking.[180] In addition, tobacco may be considered as a complicating factor in periodontal disease because it increases bone loss.[181,182]

In fact, the whole stomatognathic system suffers from the effect of tobacco byproducts (Box 20-10). Tobacco smoke decreases polymorphonuclear leukocyte activity, resulting in lower motility, a lower rate of chemotactic migration, and reduced phagocytic activity. These conditions contribute to a decreased resistance to inflammation, infection, and impaired wound healing potential.[183,184] Smoking is also associated with decreased calcium absorption.[185] Additional findings demonstrate a reduced mineral content in the bone of aging smokers and, to a greater degree, in postmenopausal female smokers.[185,186] The association of tobacco with intraoral carcinoma is well documented.

Reports in the literature demonstrate lower success rates for endosteal implants in smokers.[187-189] Failures seem to occur more in the maxilla than in the mandible and appear to occur in clusters.[187-190] However, similar maxillary implant survival rates have been observed in smokers, provided sufficient healing time, progressive bone loading, and prophylaxis procedures are implemented.[191,192]

With the possible detrimental effects of smoking on implants, it is recommended that patients be informed in detail about the risks of smoking and the possible consequences. Protocols have been recommended on smoking cessation before implant surgery. Smoking cessation after implant surgery has also been shown to improve implant survival.[193] Ideally, the patient is instructed to cease smoking for 2 weeks before surgery to allow for reversal of increased blood viscosity and platelet adhesion. Smoking cessation is continued for 8 weeks after implant surgery, which coincides with the osteoblastic phase of bone healing.[187] This has been shown to increase wound healing capabilities and reverse subgingival microflora.[194]

When incision line opening after surgery occurs, smoking will delay the secondary healing, contaminate a bone graft, and contribute to early bone loss during initial healing. Therefore the planning for implant surgeries with block bone grafts, especially C–h bone grafts, should emphasize the need for a smoking cessation protocol.

Dental Implant Implications

The implant team should advise potential implant patients of the detrimental effects that smoking has on their oral and systemic health. Complications must be discussed and highlighted in the informed consent. Patients should be encouraged to start a smoking cessation program before implant treatment. Smoking is not an absolute contraindication; however, the risks and possible morbidity on the respective procedures must be evaluated.

Psychological Diseases

Dental implant success may be compromised by psychological diseases such as anxiety and depression. One common type of psychological disease, depression, has been characterized as one of the leading causes of premature death and disability in the world. It is estimated that by the year 2020, depression will be second to ischemic heart disease as the leading cause of death.[195]

Depression is most often seen in patients who have a familial history of the disease, in association with chronic systemic disease, and in the elderly. Dental manifestations of this disease include the side effects from antidepressant medications, increase in caries and periodontal disease, increased smoking, xerostomia, chronic facial pain, and temporomandibular joint dysfunction.[196]

Dental Implant Management

Patients with active depression may have management problems, especially with the stress involved in undergoing implant procedures. Although this disease is episodic, special care must be taken in the treatment and monitoring of these patients. A thorough history should be taken with possible medical consultation in select cases.

Alcohol Use

Ethyl alcohol is one of the most widely used mood-altering drugs in the world. More than 95% of smokers also drink alcohol.[197] Alcoholism has been associated

WWW.HIGHDENT.IR

with diseases such as liver and metabolic dysfunction, bone marrow suppression resulting in bleeding complications, predisposition to infection, and delayed soft tissue healing.[198] The direct effect on bone includes decreased formation, increased resorption, decreased osteoblast function,[199] decreased wound healing, and increased parathyroid hormone secretion, which leads to a lower bone density.[200] However, it has been shown that withdrawal of alcohol can reverse the negative effects on osteoblast function in a matter of days.[201]

IRRADIATION

The treatment for cancer in the head and neck region is usually a combination of surgery, radiotherapy, and sometimes chemotherapy. Unfortunately, all of these treatment modalities have the potential to cause adverse effects on the soft and hard tissues of the oral cavity.[201] Surgical treatment of head and neck cancer usually results in anatomical impairment, leading to osseous defects. Head and neck radiotherapy results in progressive fibrosis of blood vessels and soft tissues, xerostomia, and decrease in the bone-healing quality of the jaws (Box 20-11).[202] Chemotherapeutic agents are associated with numerous wound healing and immunosuppressive states.

With radiotherapy, acute effects include mucositis, altered salivary function, and risk of mucosal infection. Long-term results include the tissue becoming hypovascular, hypoxic, and hypocellular. This is caused by changes in the vascularity and cellularity of hard and soft tissue, damage to the salivary glands, and increased collagen synthesis that results in fibrosis.[203] Because of these detrimental effects on the bone, wound repair and healing are significantly reduced after surgical procedures. When exposed to high levels of radiation, bone undergoes irreversible physiologic changes that include narrowing of the vascular channels (endarteritis), diminished blood flow, and loss of osteocytes. In time, the bone becomes nonvital, which leads to limited remodeling and healing potential.

From Granstrom G, Jacobsson M, Tjellstrom A: Titanium implants in irradiated tissues: benefits from hyperbaric oxygen, *Int J Oral Maxillofac Implants* 7:15-25, 1992.

Radiotherapy to Previously Placed Implants

There exist very few studies on the effects of radiotherapy on preexisting dental implants. Short-term data show very minimal complications and failures.[204] However, in longer-term studies, failure rates seem to be higher.[205] At this time, more studies need to be conducted for conclusive results.

Implant Placement after Radiotherapy

In implant dentistry, there are many controversial issues in the dental implant rehabilitation of the irradiated patient. These issues include the amount of time after radiotherapy for the initiation of implant therapy and the use of hyperbaric oxygen therapy. With respect to the healing of dental implants, the ability of the bone to osseointegrate with implants has been shown to be dependent on the area of radiation, radiation dosage, and time elapsed since radiation exposure.[206] Implants into irradiated bone are associated with an increased risk of osteoradionecrosis, especially with irradiation above 50 Gy.[201,207] With respect to time, there are two antagonistic effects on the healing of irradiated tissues. A short-term positive effect has been shown to result in the improvement of the reduced bone-healing capacity.[208] A long-term negative effect has been shown to result in increasing vascular damage.[208]

The time between radiotherapy to implant placement does seem to have effects on the prognosis of implants. Most studies have shown that the longer the period for implant placement after radiotherapy, the higher the success rate and the lower the risk of osteoradionecrosis.[209] However, this subject is still controversial because various investigators have recommended different periods to initiate implant treatment ranging from 3 to 6 months,[210] 12 months,[211] and 24 months.[212]

Caution must be emphasized on past radiation therapy as earlier forms of radiation therapy (pre-1980s) were of lower energy, in contrast to current higher-energy levels that are less destructive. Because of this lower energy and associated higher destructive radiotherapy, progressive endarteritis has been shown to take place, which increases over time.[208]

The amount of radiation that is needed to cause the adverse effects has also been a topic of concern. Studies have shown that 50 Gy is the turning point with >50 Gy (71% survival) versus <50 Gy (84% survival). Therefore the presently available literature states that implant placement surgery may be completed on patients who have been irradiated at doses lower than 50 Gy.[213,214] Unfortunately, very few patients receiving doses above 50 Gy have been rehabilitated with implants. On the other hand, a study has shown that patients treated with implants who have received doses >120 Gy, have an implant survival rate that is very low with an increased risk of osteoradionecrosis (ORN).[215] Additionally, the dose given in Gy (formerly rad) can be

WWW.HIGHDENT.IR

misleading because the total number of fractions is not given. A more accurate evaluation of absorbed radiation dose has been termed the "cumulative radiation effect," which is calculated by[216]:

$$\frac{\text{Total time of TX}}{\text{(No. of TXs)}} \times \text{(Dose per TX)} \times \text{(No. of TXs)}$$

Studies have shown that implants placed in patients with a cumulative radiation effect of 18 to 20 (approximately 48 to 65 Gy standard fractionation) have a rather high success rate. Other reports have shown doses above a cumulative radiation effect of 40 (approximately 120 Gy standard fractionation) exhibit a high degree of failure.[205,217]

Osteoradionecrosis

The most significant risk in placing implants into irradiated bone is ORN, which is an irreversible, devitalization of irradiated bone that is characterized by necrotic, soft bone that fails to heal properly. The pathophysiologic mechanism is an imbalance in oxygen demand and oxygen availability, which is caused by endarteritis of the blood vessels. Clinical symptoms include pain, exposed necrotic bone, pathologic fractures, and suppuration.[218] The incidence of ORN is twice as high in dentate patients in comparison to edentulous patients, and the use of alcohol and tobacco leads to a higher onset rate.[219] Studies have shown the overall incidence of ORN after radiotherapy to be from 3% to 22%.[220] It is this risk that favors discretion in treating patients with radiation to the implant site before surgery. It is suggested the treatment is rendered by experienced clinicians, with a range of backgrounds and facilities including hyperbaric oxygen.

Hyperbaric Oxygen Therapy

One treatment to minimize the possibility of ORN is the use of hyperbaric oxygen. Prophylactic hyperbaric oxygen has been advocated to increase oxygen tension in irradiated bone, which will promote capillary angiogenesis and bone formation.[211] Recent data show oxygen under hyperbaric conditions acts synergistically with growth factors, which stimulates bone growth and turnover and also may act as a growth factor itself.[221] Hyperbaric oxygen has also been shown to act as a stimulator of osseointegration by increasing new bone formation, increasing bone turnover, and increasing the vascular supply to irradiated bone.[209] Studies have shown a 24% reduction of ORN in patients treated with hyperbaric oxygen versus antibiotic therapy.[222] The use of hyperbaric oxygen has been controversial. It was first introduced in the 1970s for the management of irradiated-damaged tissues. This was followed by a protocol using hyperbaric oxygen for irradiated patients undergoing dental implant surgery.[222] This protocol consisted of exposing the patient to short, intermittent, 100% oxygen inhalation at a pressure greater than 1 atmosphere. Usually, a patient receives approximately 20 treatments, for 90 minutes before placement followed by 10 minutes after placement.

Table 20-18 Protocol for the Treatment of Patients Receiving Radiation Therapy

RADIATION DOSE	TREATMENT
<20 Gy cumulative (approximately <50 Gy fractionation)	Informed consent, aseptic technique
>20 Gy cumulative (approximately >50 Gy fractionation)	Medical consultation, hyperbaric oxygen
Radiation therapy >20 years ago	Medical consultation, possible referral to cancer institution or hospital

Dental Implant Implications

Because of the higher incidence of dental implant failure in irradiated bone, special attention must be given to the irradiated patient. A thorough medical history including area of radiation exposure, type, and total cumulative dose must be determined and evaluated before implant therapy. With the use of hyperbaric oxygen, the rate of ORN and implant failure has been shown to be reduced. A generic protocol for the treatment of the prospective dental implant patient is shown in Table 20-18.[223]

Irradiation Patient Prosthetics

Because of the oral effects of radiotherapy, an implant-supported prosthesis (FP-1, FP-2, FP-3) is recommended over a soft tissue prosthesis (RP-4, RP-5). This will reduce the possible soft tissue irritation that is associated with postradiotherapy patients wearing removable prostheses.

Chapter 21

Pharmacology in Implant Dentistry

Randolph R. Resnik, Carl E. Misch

Because of the increase in demand and use of dental implants in dentistry today, a thorough understanding of the indications and protocol for the use of pharmacologic agents in implant dentistry is essential. The morbidity of implant-related complications may on occasion be significant; therefore indicated drug selection and sufficient dosage levels of medications are preoperatively and postoperatively indicated. The scope of implant treatment often encompasses an older population with more complex cases. As a result, a greater understanding of compromised wound healing and inadequate immune systems with respect to pharmacology is essential.

In implant dentistry, there is no consensus on the pharmacologic protocol based on both the patient's health status and procedure type. Many practitioners use medications empirically or generically with respect to all procedures with little basis on scientific facts and studies. This chapter will provide the implant dentist with an overview of the pharmacokinetics and pharmacodynamics of various classifications of medications along with an understanding of the proper prescribing protocol used in implant dentistry today with respect to different patient and procedure characteristics.

ANTIMICROBIALS

An important complication to prevent after implant surgery is infection. Infection can lead to a multitude of problems, including pain, swelling, loss of bone, and possible failure of the implant. Because of the risk of morbidity from infections, antimicrobial therapy is an essential component of the surgical protocol. Although adverse effects are associated with antibiotic therapy, these are usually mild and infrequent. The most common antimicrobials used in implant dentistry consist of antibiotics (local and systemic) and antimicrobial rinses (0.12% chlorhexidine gluconate).

Antibiotics

The use and understanding of the various antibiotic regimens available in implant dentistry are beneficial for the initial success and long-term maintenance of implant therapy. Antibiotic therapy in implant dentistry may be classified as either prophylactic (prevent infection) or therapeutic (treat infection).

Prophylactic Antibiotics

In general surgery, including its subspecialties, principles of antibiotic prophylaxis are well established. Guidelines are specific related to the procedure, the type of antibiotic, and the dosage regimen.[1,2] The use of prophylactic antibiotics in dentistry has also been documented in the prevention of complications for patients at risk of developing infectious endocarditis and immunocompromised patients. However, in oral implantology, there exists no consensus on the use and indications for prophylactic antibiotics. Disadvantages with the use of antibiotics include development of resistant bacteria, adverse reactions and possible resultant lax surgical technique.[3-5] As a result, the need for prophylactic antibiotics in healthy patients, type of antibiotic, dosage, and duration of coverage is controversial. On the other hand, postoperative surgical wound infections can have a significant impact on the well-being of the patient and the survival of the implant. Documented cases of potential consequences of infection range from increased pain and edema to even patient death. According to Esposito and Hirsch, one of the main causes of dental implant failure may be due to bacterial contamination at implant insertion.[6]

A local inoculum must be present for a surgical wound infection to occur, to overcome the host's defenses and allow growth of the bacteria. This process has many variables including various host, local tissue, and systemic and microbial virulence factors. Antibiotic prophylaxis is only one component of this complex cascade; however, the efficacy and impact

WWW.HIGHDENT.IR

of antimicrobial prophylaxis has been proven to be significant.[3]

Several studies have concluded there is benefit of preoperative antibiotics for dental implantology.[7-9] In the most comprehensive and controlled study to date, 33 hospitals formed the Dental Implant Clinical Research Group and concluded that the use of preoperative antibiotics significantly improved dental implant survival, both in early and later stages. In the evaluation of 2973 implants, a significant difference was found with the use of preoperative antibiotics (4.6% failure) compared with no antibiotics (10% failure).[7,8]

The main goal of the use of prophylactic antibiotics is to prevent infection during the initial healing period from the surgical wound site, thus decreasing the risk of infectious complications of the soft and hard tissues. Although there is no conclusive evidence on the mechanism of preoperative antibiotics, most likely a greater aseptic local environment is achieved. A landmark study by Burke defined the scientific basis for the perioperative use of antibiotics to prevent surgical wound infection.[10] From this work, several accepted principles have been established in the perioperative use of prophylactic antibiotics.[11]

Principle 1: The Procedure Should Have a Significant Risk for and Incidence of Postoperative Infection

To evaluate the risk for postoperative wound infection, a classification of operative wounds and risk of infection was developed by the American College of Surgeons (Committee on Control of Surgical Wound Infections). All surgical procedures were classified according to four levels of contamination and infection rates (Box 21-1). Within these classifications, it is generally accepted that all class 2, class 3, and class 4 procedures warrant the use of prophylactic antibiotics.[12]

By definition, elective dental implant surgery falls within the class 2 (clean-contaminated) category. Class 2 medical and dental surgical procedures have been shown to have an infection rate of 10% to 15%. However, with proper surgical technique and prophylactic antibiotics, the incidence of infection may be reduced to less than 1%.[13,14] In a healthy patient, risk of infection after dental implant surgery is influenced by numerous factors such as type and location of surgery, skill of the surgeon, methods of intraoperative management, patient factors, and aseptic technique.[13,15] Moreover, additional patient-related (systemic and local) risk factors that are not addressed in these classifications have also been correlated with increased susceptibility to infection. These factors must be addressed in reference to evaluation for the use and duration of antibiotic prophylaxis (Box 21-2).

One of the most significant surgical factors that may contribute to infection is poor aseptic technique. Various routes of transmission of virulent bacteria include (1) direct contact with the patient's blood or other body fluids; (2) indirect contact with contaminated objects; (3) contact of infected nasal, sinus, or oral mucosa; and (4) inhalation of airborne microorganisms. To prevent these conditions, a controlled, well-monitored aseptic setting should be achieved for the surgical procedure. The aseptic surgical site includes proper disinfection and draping procedures of the patient, hand scrubbing, sterile

Box 21-1 Surgical Wound Classifications with Associated Infection Rates

Class 1: Clean (<2%)
- Elective, nontraumatic surgery, no acute inflammation, respiratory, gastrointestinal, and biliary tracts not entered

Class 2: Clean-Contaminated (10% to 15%)
- Elective opening of the respiratory, gastrointestinal, and biliary tracts entered
- Elective dental implant and bone procedures

Class 3: Contaminated (20% to 30%)
- Inflammation, gross spillage from gastrointestinal and biliary tracts along with fresh traumatic injuries

Class 4: Dirty/Infected (50%)
- Established clinical infection, perforation of respiratory, gastrointestinal, and biliary tracts

Box 21-2 Factors Associated with Increased Risk of Infection for Dental Implant Procedures

Systemic Factors

Diabetes
Long-term corticosteroid use
Smoking
Immunocompromised systemic disorders
Malnutrition, obesity
Elderly population
ASA 3 or ASA 4

Local Factors

Use/type of grafting material (autogenous, allograft, alloplast)
Periodontal disease
Tissue inflammation
Odontogenic infections
Ill-fitting provisional prosthesis
Incision line opening
Inadequate hygiene

Surgical Factors

Poor aseptic technique
Skill/experience of the surgeon
Increased duration of surgery
Wound contamination during surgery
Foreign body (implant)

ASA, American Society of Anesthesiologists, physical status classification.

WWW.HIGHDENT.IR

Table 21-1 Probability of Wound Infection by Type of Wound, Risk Index, and ASA Status

OPERATION CLASSIFICATION	RISK INDEX 0	1	2
Clean	1.0%	2.3%	5.4%
Clean-contaminated	2.1%	4.0%	9.5%

Data from Cruse PJ, Foord R: A five-year prospective study of 23,649 surgical wounds, *Arch Surg* 107:206-210, 1973.
ASA, American Society of Anesthesiologists, physical status classification; *0*; ASA 1 or ASA 2, and no local or surgical factors; *1*, ASA ≥2, at least one of the local or surgical factors is present; *2*, ASA ≥2, both local and surgical factors are present.

Box 21-3 Microorganisms Most Commonly Associated with Peri-Implant Complications

- *Staphylococcus* spp.

- Enteric gram-negative bacteria
- *Candida albicans*

gowns worn by all surgical members, and maintenance of complete sterility of the instrumentation.

Another important surgical factor related to postoperative infection is the duration of the surgical procedure. This factor has been shown to be the second most critical risk factor (after wound contamination) affecting postoperative infection rates.[18] In general, surgical operations lasting less than 1 hour have an infection rate of 1.3%, whereas those lasting 3 hours increase the rate to more than 4%.[19-21] It is postulated that the rate of infection doubles with every hour of the procedure.[16]

The skill and the experience of the surgeon with the placement of implants have been shown to be significant in postoperative infections and implant failures. A recent study has shown that less experienced surgeons (<50 implants placed) have a 7.3% increase in failure rates in comparison to experienced surgeons.[8]

In the medical literature, it is well documented that the insertion of any prosthetic implant or device increases the chance of infection at the surgical site. A dental implant can act as a foreign body, and the host's defenses may therefore be compromised. The surface of the implant has been shown to facilitate bacterial adherence and the presence of an implant can compromise the host's defenses. This may result in normal flora with low virulence potential to cause infections at the implant-host interface, which has been shown to be very difficult to treat.[22-24]

The probability of risk for infection for a given procedure is related to local, systemic, and surgical factors. The patient's American Society of Anesthesiologists (ASA) score may be used as the systemic factor and then correlated with various local and surgical factors. A risk index may then be modified from the literature to correlate these factors to dental implant surgeries (Table 21-1). The probability of wound infection may then be correlated with the type of wound contamination (class 1 to 4) and the risk index. Therefore a class 2 wound and a risk index 2 has a greater risk of complications, and a class 1 wound and risk index 0 has the least risk of postoperative infection.[19,25]

Principle 2: The Appropriate Antibiotic for the Surgical Procedure Must Be Selected

The prophylactic antibiotic should be effective against the bacteria that are most likely to cause an infection. In the majority of cases, infections after surgery are from organisms that originate from the site of surgery.[11] Most postoperative infections are caused by endogenous bacteria including aerobic gram-positive cocci (streptococci), anaerobic gram-positive cocci (peptococci), and anaerobic gram-negative rods (bacteroides)[13] (Box 21-3).

Although oral infections are mixed infections in which anaerobes outnumber aerobes 2:1, it has been shown that anaerobes need the aerobes to provide an environment to proliferate.[26] Subsequent studies have shown that the early phase of intraoral infections involve streptococci that prepare the environment for subsequent anaerobic invasion.[27,28] With that in mind, the ideal antibiotic must be effective against these pathogens.

The second factor in selecting the correct antibiotic is to use the antibiotic with the least amount of adverse effects. These effects may vary from mild nausea to the extreme allergic reaction.

The final selection factor is that the antibiotic should ideally be bactericidal. The goal of antibiotic prophylaxis is to kill and destroy the bacteria. Bacteriostatic antibiotics work by inhibiting growth and reproduction of bacteria, thus allowing the host defenses to eliminate the resultant bacteria. However, if the host's defenses are compromised in any way, the bacteria and infection may flourish. Bactericidal antibiotics are advantageous over bacteriostatic antibiotics in that (1) there is less reliance on host resistance, (2) the bacteria may be destroyed by the antibiotic alone, (3) results are faster than with bacteriostatic medications, and (4) there is greater flexibility with dosage intervals.[13]

Principle 3: An Appropriate Tissue Concentration of the Antibiotic Must Be Present at the Time of Surgery

For an antibiotic to be effective, a sufficient tissue concentration must be present at the time of bacterial

WWW.HIGHDENT.IR

invasion. To accomplish this goal, the antibiotic should be given in a dose that will reach plasma levels that are three to four times the minimum inhibitory concentration of the expected bacteria.[29] The minimum inhibitory concentration is the lowest antibiotic concentration to destroy the specific bacteria. Usually, to achieve this cellular level, the antibiotic must be given at twice the therapeutic dose and at least 1 hour before surgery.[15] It has been shown that normal therapeutic blood levels are ineffective to counteract bacterial invasion. If antibiotic administration occurs after bacterial contamination, no preventive influence has been seen as compared with taking no preoperative antibiotic.

Principle 4: Use of the Shortest Effective Antibiotic

In a healthy patient, continuing antibiotics after surgery often does not decrease the incidence of surgical wound infections.[2,30,31] In a healthy patient, a single dose of antibiotics is usually sufficient. However, for patients or procedures with increased risk factors (see Box 21-2), a longer dose of antibiotics is warranted.[11] With the high degree of morbidity associated with dental implant infections, one must weigh the benefits versus risk involved for the extended use of antibiotics.

Complications of Antibiotic Prophylaxis

It is estimated that approximately 6% to 7% of patients taking antibiotics will have some type of adverse event.[32] Incidence of significant complications with the use of prophylactic antibiotics are minimal; however, a small percentage can be life-threatening. The risks associated with antibiotics include gastrointestinal (GI) tract complications, colonization of resistant or fungal strains, cross-reactions with other medications, and allergic reactions.

Allergic reactions have a wide range of complications, ranging from mild urticaria to an anaphylaxis and death. Studies have shown that 1% to 3% of the population receiving penicillin will exhibit urticaria type of reactions, with 0.04% to 0.011% having true anaphylactic episodes. Of this small percentage of anaphylactic reactions, 10% will be fatal.[33]

An unusual but increasing complication in the general population after antibiotic use is pseudomembranous colitis. This condition is caused by the intestinal flora being altered and colonized by *Clostridium difficile*. Penicillin and clindamycin use has been significantly associated with pseudomembranous colitis; however, all antibiotics have been shown as potential causative agents. The risk levels of colitis related to antibiotics are outlined in Table 21-2. The most common treatment for antibiotic-induced colitis is vancomycin or metronidazole.

The most recent concern of antibiotic use is the development of resistant bacteria. It has been observed that the overgrowth of resistant bacteria begins only after the host's susceptible bacteria are killed, which usually takes at least 3 days of antibiotic use. Therefore short-term (1 day) use of antibiotics has been shown to have little influence on the growth of resistant bacteria.[13]

Antibiotics Used in Implant Dentistry

Beta-Lactam Antibiotics

The most common beta-lactam antibiotics used in dentistry are the penicillins and cephalosporins. These antibiotics have similar chemical structures, and the mechanism of action is by inhibiting bacterial cell wall synthesis (bacteriocidal) via the interruption of the cross linking between peptidoglycan molecules.

Penicillin V

Penicillin V is one of the more common antibiotics used in dentistry today. It is well absorbed and will achieve peak serum levels within 30 minutes of administration with detectable blood levels for 4 hours. Penicillin V is effective against most *Streptococcus* species and oral anaerobes. The main disadvantages of penicillin are four times per day dosing and susceptibility to resistant bacteria.

Amoxicillin

Amoxicillin is a derivative of ampicillin, with the advantage of superior absorption and a bioavailability of 70% to 80% with a very low toxicity. It has excellent diffusion in infected tissues and adequate tissue concentrations are easily achieved. Amoxicillin is considered broad spectrum and is effective against gram-negative cocci and gram-negative bacilli. This antibiotic also has greater activity than penicillin V against streptococci and oral anaerobes.

Amoxicillin/Clavulanic Acid (Augmentin)

To counteract the activity of beta-lactamase destruction of penicillins by resistant bacteria such as *Streptococcus aureus*, a combination of two antibiotics was synthesized. Clavulanic acid, a beta-lactam antibiotic, was added to amoxicillin to form Augmentin. This combination antibiotic has an affinity for penicillinase-producing bacteria. It functions as a "suicide molecule" that inactivates the resistant bacteria. As a result of an increase in the prevalence of these specific bacteria (especially in the sinus), Augmentin is becoming more popular in oral implantology. This antibiotic is used mainly in cases in which penicillinase bacteria is suspected (or known by culture) and is very practical as a perioperative antibiotic for sinus augmentation (Figure 21-1).

Table 21-2 Risks for Antibiotic-Induced Pseudomembranous Colitis

HIGH	MEDIUM	LOW
Ampicillin	Penicillin	Tetracyclines
Amoxicillin	Erythromycin	Metronidazole
Cephalosporin	Quinolones	Vancomycin
Clindamycin		

WWW.HIGHDENT.IR

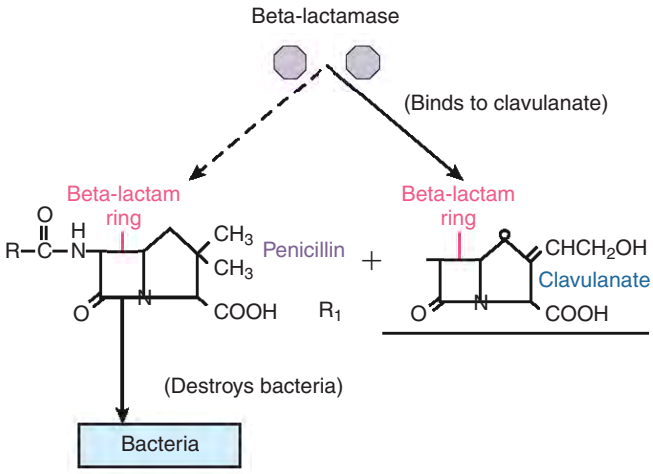

Figure 21-1 Beta-lactamase inactivation by the addition of clavulanic acid to amoxicillin (Augmentin). Because of the high binding affinity of clavulanic acid, beta-lactamase will be inactivated, allowing penicillin to destroy the bacteria.

Cephalexin/Cefadroxil

The first-generation cephalexin/cefadroxil antibiotics have an antibacterial spectrum similar to amoxicillin. However, they have the advantage of not being susceptible to beta-lactamase destruction by *S. aureus*. They are often used in dentistry as an alternative for the penicillin-allergic patient, although cross-reactivity between these two drugs may occur. Rates of cross-reactivity to first-generation cephalosporins with penicillin-allergic patients have been cited to be approximately 8% to 18%. The most recent studies have shown only patients who have had type I (immunoglobulin E: immediate hypersensitivity reactions) should not be administered a cephalosporin. If the patient has a previous history of a reaction that was not immunoglobulin E–mediated (types II, III, IV, or idiopathic reactions) a first-generation cephalosporin may be administered. Newer second- and third-generation cephalosporins exhibit a broader spectrum, less cross-reactivity, and a greater resistance to beta-lactamase destruction.[34]

Macrolides

The most common macrolide used in dentistry is erythromycin. It is active against most streptococci, staphylococci, and some anaerobes, and it is an alternative for patients who are allergic to penicillin. Erythromycin has the advantage of excellent absorption and, unlike many drugs, is affected by the presence of food. It is administered primarily by the oral route and has a relatively low toxicity. However, this antibiotic has a high incidence of nausea and is bacteriostatic rather than bacteriocidal, and it is therefore not an ideal first-line choice for infections in the oral cavity.

These characteristics are also unattractive when either high doses are required, severe infection exists, or the patient is immunocompromised and requires bacteriocidal activity. Even more disturbing is its implication in numerous drug interactions, including its proclivity for elevating serum levels of digoxin, theophylline, and carbamazepine. Erythromycin has also been found to retard conversion of terfenadine (Seldane), a nonsedating antihistamine, to its active metabolite. As a result, elevated serum concentrations of the predrug may result and lead to cardiotoxicity, presenting a particular form of ventricular tachycardia called *torsades de pointes*.

During the past several years, three novel macrolides have been introduced that offer advantages over erythromycin (i.e., clarithromycin [Biaxin], azithromycin [Zithromax]). Unlike other macrolides, they do not appear to inhibit hepatic cytochrome P450 isozymes, which account for most drug interactions of erythromycin. Biaxin produces less nausea and has better gram activity; Zithromax appears to be more effective against *Haemophilus influenzae*.

Clindamycin

The use of clindamycin has increased for the treatment of dental infections primarily because of its activity against anaerobic bacteria. It also is active against aerobic bacteria, such as streptococci and staphylococci, and it has superior effects against *Bacteroides fragilis*. Clindamycin (Cleocin phosphate) is also supplied in an aqueous 300-mg/2-mL solution that is sometimes used in the incorporation of graft material for sinus augmentation procedures. However, it is bacteriostatic in normal concentrations and has a rather high toxicity in larger concentrations. As a result, the main disadvantage of clindamycin is the occurrence of diarrhea in 20% to 30% of patients treated. This antibiotic also has a higher incidence of antibiotic-associated pseudomembranous colitis (PMC) caused by *C. difficile* when administrated for extended periods. PMC has been reported to occur with most long-term antibiotics.

The toxicity of antibiotics related to PMC is elevated with ampicillin, amoxicillin, cephalosporin, and clindamycin. Penicillin, erythromycin, and quinolones are moderate risk, and the lowest occurrence is with tetracycline, metronidazole, and vancomycin. The latter group is often used to even treat PMC conditions.

The patient should be informed that if either diarrhea or abdominal cramping occurs during or shortly after antibiotic therapy, the drug should be discontinued and the doctor should be notified.

Antidiarrheal medications should be avoided in these cases, because they hinder the fecal elimination of the pathogen. If it is necessary to continue management of the dental infection, imidazole or vancomycin is most logical (if not the original cause of the complications). Metronidazole is not only effective against anaerobes contributing to the dental infection, but is effective against *C. difficile*, the causative agent. If the condition persists after 3 days, the patient should be assessed by an internist for fluid and electrolyte imbalance.

WWW.HIGHDENT.IR

Tetracyclines

Tetracyclines have been available since the 1950s and have a wide spectrum of activity against streptococci, staphylococci, oral anaerobes, and gram-negative aerobic rods. Because this antibiotic has been so extensively used in the past, there exists a high degree of bacterial resistance. Tetracycline is an attractive adjunct for the treatment of gingival and periodontal disease with a high bioavailability in the gingival sulcus. For these reasons, tetracyclines are primary agents for treating implant disease and infections around implant posts. Their efficacy for managing infrabony infections is questionable, considering their inactivity when chelated with calcium complexes. The disadvantages of this antibiotic include a high incidence of promoting *Candida* spp. infections and may be associated with photosensitivity reactions.

Fluoroquinolones

A recent classification of antibiotics has had a definite impact on the treatment of infections in dentistry and medicine. Flouroquinolones are bactericidal antibiotics and have a broad antibacterial spectrum, which may be used either orally or parenterally. Ciprofloxacin was one of the first-generation quinolones and is the prototype antibiotic for this antibiotic classification. Newer third- and fourth-generation quinolones have been developed with great activity against resistant bacteria and anaerobic bacteria. In implant dentistry, fluoroquinolones are used mainly in the prophylactic and therapeutic treatment of sinus augmentation procedures.

Metronidazole

Metronidazole is a bacteriocidal antibiotic that is most often used for anaerobic infections. Because metronidazole has no activity against aerobic bacteria, it is seldom used for mixed infections unless it is combined with another antibiotic. However, it may be combined with penicillin when managing severe infections. Patients should be cautioned against drinking alcoholic beverages while taking this medication, because disulfiram-like reactions have been reported. These consist of severe nausea and abdominal cramping caused by the formation of a toxic compound resembling formaldehyde. Metronidazole should not be prescribed for patients taking the oral anticoagulant warfarin (Coumadin). The more common antibiotics and dosages used in oral implantology for prophylaxis, grafting and implant insertion, postoperative infection, and long-term complications are listed in Table 21-3.

Prophylactic Antibiotics in Oral Implantology

Postoperative wound infections can have a significant effect on the success of dental implants and bone grafting procedures. The occurrence of surgical host defenses allows an environment conducive to bacterial growth. This process is complex, with interactions of host, local tissues, and systemic and microbial virulence factors. Various measures attempt to minimize infection by modifying the host and local tissue factors. The use of antimicrobials has been shown to be significant in reducing postoperative infections.

The antibiotic chosen for prophylaxis should encompass the bacteria most known to be responsible for the type of infection found with the surgical procedure. Therefore the following antibiotics are suggested against pathogens known to cause postoperative surgical wound infections in bone grafting or implant surgery:

1. Amoxicillin: the usual drug of choice

If allergic,

2. Cephalexin (nonanaphylactic allergy to penicillin)
3. Clindamycin (anaphylactic allergy to penicillin)

For sinus involvement procedures (e.g., sinus grafts):

1. Augmentin
2. Levaquin (if history of recent use of antibiotics [within 4 weeks])

THERAPEUTIC USE OF ANTIBIOTICS: POSTOPERATIVE INFECTIONS

Acute postoperative infections have been shown to occur on the third to fourth day after surgery. The most common microorganisms associated with peri-implant, postoperative complications have been previously stated as listed in Box 21-3.

Local signs of infection are pain, inflammation, bleeding, and exudate at the site of surgery. Systemic signs include fever, headache, nausea, muscle aches, vomiting, and weakness. When surgical wound infections arise, a specific diagnosis is advantageous to treat the complication. When evaluating the various antibiotics possible that are effective against the bacteria in question, a broad-spectrum beta-lactam antibiotic is most often the first-line medication. The duration of treatment should include antibiotic administration for 3 days beyond the occurrence of significant clinical improvement, usually at the fourth day and therefore for a minimum of 7 days.[35]

Therapeutic Antibiotics in Implant Dentistry

The recommended treatment for intraoral infections associated with grafting or implant therapy include the following:

1. Surgical drainage

and

2. Systemic antibiotics

Table 21-3 Commonly Used Antibiotics in Oral Implantology

GENERIC NAME	BRAND NAME	BACTERICIDAL/ BACTERIOSTATIC	THERAPEUTIC USUAL ADULT DOSE	MAXIMUM ADULT DOSE	PROPHYLACTIC DOSES
Amoxicillin	Amoxil Polymox Trimox	Bactericidal	250-500 mg TID	4 g/day`	SBE: 2 g 1 hr before Surgical: 1 g 1 hr before
Amoxicillin/ clavulanic acid	Augmentin	Bactericidal	250-500 mg TID or 825 mg BID	4 g/day	Surgical: 825 mg
Cephalexin	Biocef Cefanex Keftab Keflex	Bactericidal	250 mg QID or 500 mg BID	4 g/day	SBE: 2 g 1 hr before Surgical: 1 g 1 hr before
Cefadroxil	Duricef Ultracef	Bactericidal	500 mg BID	4 g/day	SBE: 2 g 1 hr before Surgical: 1 g 1 hr before
Azithromycin	Zithromax	Bacteriostatic	500 mg immediately, 1000 mg/day	—	SBE: 500 mg 1 hr before
Clarithromycin	Biaxin	Bacteriostatic	250 mg	—	SBE: 500 mg 1 hr before
Erythromycin	E-mycin E-tab	Bacteriostatic	250 mg QID	4 g/day	—
Tetracycline	Achromycin Sumycin	Bacteriostatic	250 mg QID	4 g/day	—
Clindamycin hydrochloride	Cleocin HCl	Bacteriostatic	150-300 mg TID or QID	1.8 mg/day	SBE: 600 mg 1 hr before Surgical: 600 mg 1 hr before
Metronidazole	Flagyl	Bactericidal	250 mg TID or QID	4 g/day	
Levofloxacin	Levaquin	Bactericidal	500 mg/day	500 mg/day	Surgical: 500 mg
Moxifloxacin	Avelox	Bactericidal	400 mg/day	400 mg/day	—
Trimethoprim/ sulfametho-xazole	Bactrim Septra	Bacteriostatic	160 mg (DS) BID 80 mg BID	—	—

SBE, Subacute bacterial endocarditis; *DS,* double strength.

Amoxicillin (500 mg): Two immediately, then one tablet three times daily for 1 week

or if penicillin allergy exists

Clindamycin (300 mg): Two immediately, then one tablet three times daily for 1 week

NOTE: If no improvement is seen after 4 days, a culture and sensitivity test should be administered to select the antibiotic most effective against the responsible organisms.

Until culture and sensitivity test results are obtained, change antibiotic to:

Levaquin (50 mg): one tablet daily for 1 week

and

3. 0.12% chlorhexidine gluconate rinse (1/2 oz twice daily for 2 weeks)

Chlorhexidine

Another modality for antimicrobial prophylaxis for implant surgery is the use of an oral rinse, 0.12% chlorhexidine digluconate (Peridex; Procter & Gamble, Cincinnati, Ohio). Chlorhexidine gluconate is a potent antibacterial that causes lysis by binding to bacterial cell membranes. It has high substantivity that allows it, at high concentrations, to exhibit bacteriocidal qualities by causing bacterial cytoplasm precipitation and cell

WWW.HIGHDENT.IR

death.[36,37] In the oral cavity, chlorhexidine has been shown to have a slow release from tissue surfaces over a 12-hour period.[38,39]

In vitro studies have shown an inhibitory effect of chlorhexidine on cultured epithelium and cell growth; however, clinical studies have not shown this effect.[40,41,44] To the contrary, the use of chlorhexidine has been shown to be an effective adjuvant in reducing plaque accumulation, enhance mucosal health,[42-44] improve soft tissue healing,[45,46] treat periodontal disease, prevent alveolar osteitis,[47,48] improve tissue healing after extractions,[49] reverse peri-implantitis,[50] and been shown to have no adverse affect on implant surfaces.[51]

When evaluating the effect of preoperative chlorhexidine before dental implant surgery, a significant reduction in the number of infectious complications (2 to 1), and a sixfold difference in implant failures in comparison to no use of chlorhexidine has been shown.[52]

Use of Chlorhexidine in Oral Implantology

As a consequence of many reported benefits of chlorhexidine, the use of this antiseptic is suggested in many ways in oral implantology as follows:

1. Patient presurgical rinse: used in the aseptic protocol before surgery for reduction of bacterial load
2. Surface antiseptic: intra- and extraoral scrub of patient, scrubbing of hands before gowns and gloves
3. Postsurgical rinse: rinse twice a day until incision line closure
4. Peri-implant maintenance on daily basis
5. Treatment of postoperative infections

MANAGEMENT OF POSTOPERATIVE INFLAMMATION

The management of postsurgical swelling is crucial to the pain management, control of edema, and incidence of postoperative infection. In most dental implant surgeries, tissue is traumatized, which results in some degree of an inflammatory reaction. By controlling the extent of inflammation associated with surgical procedures, edema, trismus, pain, and infection may be reduced.

The mediators of the inflammatory process include cyclooxygenase and prostaglandins, which play a significant role in the development of postoperative inflammation and pain (Figure 21-2). When tissue manipulation or damage occurs, phospholipids are converted into arachidonic acid by way of phospholipase A_2. Arachidonic acid, which is an amino acid, is released into the tissue, which produces prostaglandins by enzymatic breakdown by cyclooxygenases. The end result is the formation of leukotrienes, prostacyclins, prostaglandins, and thromboxane A_2, which are the mediators for inflammation and pain. For postoperative treatment, medications such as ibuprofen (nonsteroidal antiinflammatory drugs [NSAIDs]) and glucocorticosteroids (steroids) are used, which play an integral part in counteracting the negative effects of this cascade.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs have an analgesic effect as well as an antiinflammatory effect. This drug class reduces inflammation by inhibiting the synthesis of prostaglandins from arachidonic acid. Therefore the use of the popular analgesic drug ibuprofen has a secondary beneficial antiinflammatory effect. NSAIDs do not have a ceiling effect for inflammation; however, higher doses to achieve antiinflammatory qualities are accompanied by serious side effects. In implant dentistry, the use of ibuprofen is suggested as a preemptive analgesic agent, because it has antiinflammatory properties in type 1 to 4 procedures.

Glucocorticosteroids

The adrenal cortex, which uses cholesterol as a substrate, synthesizes and secretes two types of steroid hormones—the androgens and corticosteroids. The corticosteroids are classified additionally by there major actions: (1) glucocorticoids, which have effects on carbohydrate metabolism and have potent antiinflammatory actions, and (2) mineralocorticoids, which have sodium-retaining qualities. The use of synthetic glucocorticosteroids has become very popular in the postoperative management of inflammation after oral surgical procedures. These synthetic glucocorticoids have greater antiinflammatory potency in comparison to natural steroids with very little sodium and water retention. Most of these steroids have similar chemical structures; however, they differ in their milligram potency.[53] Their antiinflammatory effects are achieved by altering the connective tissue response to injury, thus causing a decrease in hyperemia, which results in less exudation and cellular migration along with infiltration at the site of injury.[54,55]

There is a wide range of glucocorticoid preparations available for local, oral, and parenteral administration.

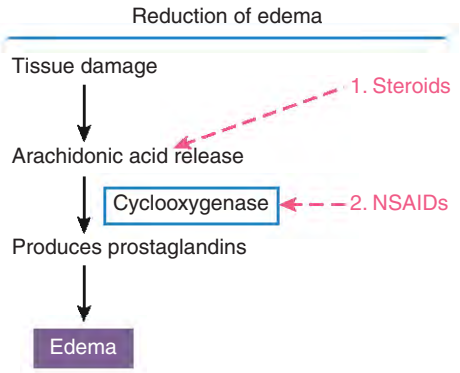

Figure 21-2 Mechanism of action for nonsteroidal antiinflammatory drugs (NSAIDs) and steroids in the reduction of inflammation.

WWW.HIGHDENT.IR
انجمن دندانسازان و دندانپزشکان

Table 21-4 Synthetic Glucocorticoids

GLUCOCORTICOIDS	ANTIINFLAMMATORY POTENCY	EQUIVALENT DOSE (mg)	DURATION (hr)
Short-acting			
Hydrocortisone	1.0	20	<12
Cortisone	0.8	25	<12
Intermediate-acting			
Prednisone	4.0	5	24 to 36
Prednisolone	4.0	5	24 to 36
Long-acting			
Dexamethasone	25	0.75	>48

In relation to the naturally occurring cortisol (hydrocortisone), synthetic glucocorticoids are longer acting and more potent. The main differences are based on the classification as short-acting (<12 hours), intermediate-acting (12 to 36 hours), and long-acting (>36 hours). A summary of the most common glucocorticosteroids is shown in Table 21-4.[53]

Mechanism of Action

Glucocorticoids bind to glucocorticoid receptors within cells and form a glucocorticoid-GR complex. This complex alters the synthesis of mRNA from the DNA molecule, thus affecting the production of different proteins. By suppressing the production of proteins that are involved in inflammation, glucocorticoids also activate lipocortins, which have been shown to inhibit the action of phospholipase A2. Phospholipase A2 is a key enzyme involved in the release of arachidonic acid from cell membranes.

Arachidonic acid is an omega-6 fatty acid that is incorporated into cell membranes. When a cell is damaged, arachidonic acid is released from cell membranes and is converted into inflammatory and pain prostaglandins by cyclooxygenase (COX)-2 enzymes. The release of arachidonic acid requires the activation of enzyme PLA2. However, lipocortins, which cause the inhibition of PLA2, prevent the release of arachidonic acid, thereby reducing the amounts of inflammatory prostaglandins.

Adrenal Suppression

Glucocorticoids are essential for the body to adapt to stressful situations. Adrenal insufficiency may predispose a person to an inability to respond to stress. Adrenal suppression has been shown to occur after 7 to 10 days of steroid administration. In stressful situations, cardiovascular collapse may occur and, if not treated appropriately, may be life-threatening. Because most dental implant procedures maintain a high level of stress, the implant dentist must be able to assess the level of adrenal suppression on patients taking glucocorticoid replacement therapy.

Prolonged, long-term steroid therapy causing adrenal suppression is a well-known phenomenon. The amount of suppression is a function of both the duration of treatment and the dose administered. Studies have shown that short-term use of corticosteroids does not significantly affect the hypothalamus-pituitary adrenal (HPA) axis, and normal levels of cortisol, which are initially suppressed, recover to normal levels after 7 days.[57] The conclusion is that the HPA axis, although altered by the initial dexamethasone therapy, is restored completely. Additionally, the amount of surgical stress involved with oral surgical procedures appears to be of insufficient magnitude to overcome the HPA suppression of the negative feedback mechanism caused by the steroid administration. Therapeutic levels of steroid are present at a cellular level to prevent any manifestations of adrenal insufficiency.[58]

Timing

The use of synthetic steroids should be based on the production of the natural steroid cortisol (hydrocortisone) in the body. Normally, cortisol is produced from plasma cholesterol at a rate of 15 to 30 mg per day.[59] Under stressful situations (e.g., infection, illness, trauma), as much as 300 mg of cortisol can be secreted. Plasma concentrations of cortisol are several-fold higher in the morning as compared with the afternoon. Studies have shown that a dose of dexamethasone given in the morning (8:00 AM) does not significantly alter the level of endogenous circulating cortisol. However, the same dose in the late afternoon (4:00 PM) can cause complete suppression of the HPA cycle.[60] This secretion rate is dictated by the pituitary-adrenal axis with a feedback-inhibition cycle.[61] Therefore administration of glucocorticoids should ideally be given in the morning so that simulation of normal diurnal rhythm is achieved, thus minimizing the possibility of HPA suppression.[62]

Glucocorticoids in Medicine and Dentistry

Since the advent of glucocorticoids in 1942, these medications have been used clinically in two ways: (1) therapeutic treatments in various inflammatory diseases

WWW.HIGHDENT.IR

and autoimmune diseases and (2) prophylactic treatment of inflammation and associated pain. Today, they are still used for an array of autoimmune diseases. Glucocorticoids have been well documented in the dental literature as being advantageous in the prevention of postoperative complications after traumatic oral surgery,[63] intraoral sagittal osteotomy,[64] vestibuloplasty with palatal mucosal grafts, and reduction of edema and pain after oral surgical procedures.[54-56,65] Additionally, they have been shown to be associated with less need of pain medication after oral surgical procedures.[66,67] These drugs have been shown to have the ability to be long-lasting in duration and cause minimal effects on wound healing, infection, and adrenal suppression, with minimal central nervous system alteration.[61]

Glucocorticoids in Implant Dentistry

The use of glucocorticoids is an integral part in the treatment of postsurgical edema after dental implant procedures. The selection of the ideal synthetic glucocorticoid for dental implant surgery should maintain high antiinflammatory potency with minimal mineralocorticoid effects. The glucocorticoid that best suits the requirements is the long-acting glucocorticoid dexamethasone (Decadron). It is imperative that this drug be administered before surgery so that adequate blood levels are obtained. Also, it should be given in the morning in conjunction with the natural release of cortisol. This timing will interfere the least with the adrenocortical system. Because inflammation usually peaks between 48 and 72 hours, the postoperative regimen of dexamethasone should not exceed 3 days after surgery. The dose should not exceed the equivalence of 300 mg of cortisol with a decreasing dose the second and third day to reduce possible side effects. This high-dose, short-term glucocorticoid therapy has been shown not to significantly effect the HPA axis.[58,68,69]

A significant additional benefit of the administration of dexamethasone is the potent antiemetic effects for the prophylactic treatment of postoperative nausea and vomiting. This is now an accepted medication for hospital-based outpatient surgery usually given in doses of 8 to 10 mg intravenously.[70,71,106]

Contraindications to the use of corticosteroids include active infections (viral, bacterial, fungal), tuberculosis, ocular herpes simplex, primary glaucoma, acute psychosis, and diabetes mellitus. Special attention must be given to diabetic patients, as glucocorticoids have an anti-insulin action that results in increased serum glucose and glycosuria.[72]

Cryotherapy

An additional therapeutic regimen to help reduce the amount and duration of postoperative inflammation is the application of cold dressings. It is reported that cold dressings in the form of ice bags or premanufactured ice packs applied extraorally to the surgical site will minimize edema.[73] The application of cold dressings is believed to cause vasoconstriction of the capillary vessels, thus reducing the flow of blood and lymph in this region, resulting in less inflammation.[74] Also, with the lower temperature at the surgical site, cell metabolism is reduced. As a result, the cells in the trauma region consume less oxygen, which allows them to survive a longer time period of ischemia.

Cryotherapy as an Antiinflammatory Agent

The use of cryotherapy is highly advised in any implant procedure in which excessive inflammation is expected. Cold dressings (ice packs) should be applied extraorally over the surgical site for 20 minutes on/20 minutes off for the first 24 to 36 hours. Caution must be taken to limit the application of ice for no longer than 2 days, because prolonged use may cause rebound swelling and cell destruction.

POSTSURGICAL PAIN MANAGEMENT

Pain has been documented to be inadequately treated in 50% of all surgical procedures.[75] These painful experiences predispose the patient to amplification of noxious stimuli (hyperalgesia) and cause typically painless sensations to be experienced as pain (allodynia).[76,77] Therefore patients who have had painful experiences may have increased pain and the need for additional analgesic use in future surgeries. The goal for pain control in oral implantology is to have adequate analgesic levels before the cessation of local anesthesia and a well-administrated postoperative analgesic regimen for patient comfort.

Preemptive Analgesia

Preemptive analgesia is defined as the introduction of an analgesic regimen before the onset of noxious stimuli. In relation to dental implant surgery, it is advantageous to have adequate analgesic blood levels present before the initiation of surgery. The goal is to prevent sensitization of the nervous system to subsequent stimuli that could possibly amplify pain. Dental implant surgery is ideal for this type of treatment because it is usually elective and the timing of noxious stimuli is known.

Manipulation of hard and soft tissues during implant and bone grafting procedures predispose the patient to postoperative pain. The extent of tissue reflection, amount of bone preparation, inherent patient factors, and duration of the surgical procedure have an effect on the intensity and duration of postoperative pain. Hyperalgesia is characterized by enhanced sensations of pain, a pain threshold reduction, and an increase in the suprathreshold noxious stimuli. With administration of analgesics before tissue damage, the sensitivity of these receptors is dramatically reduced and may be eliminated.[80]

Mechanism of Pain

The mechanism of painful stimuli is modulated by the peripheral and central nervous systems. Noxious stimuli (tissue damage) cause peripheral nociceptors to transmit signals along nerve fibers lying in the dorsal root ganglion. Their axons synapse in the dorsal horn of the spinal cord and then travel along the spinothalamic tract of the spinal cord to the thalamus and the cortex. Within the cortex and thalamus, the signals originating from tissue damage form the subjective interpretation of pain.

With repeated noxious stimuli, peripheral nociceptors become more responsive. The sensitivity to these receptors are further enhanced by tissue factors and inflammatory mediators released in the course of tissue damage. Numerous inflammatory mediators are present which include prostaglandins, kinins, leukotrienes, substance P, and histamine. These mediators initiate and magnify the nociceptive impulses that are transmitted to the central nervous system for the perception of pain.

The most important mediators, prostaglandins, are extremely important in sensitizing peripheral neurons to the local stimuli. Prostaglandins are also synthesized in the spinal cord and brain and enhance pain sensitivity by recruiting secondary neurons to respond to the primary stimulus.[81]

One of most commonly used analgesics, NSAIDs, work at the site of tissue damage and the spinal cord and brain to prevent prostaglandin formation by inhibiting cyclooxygenase (COX). COX is an enzyme that breaks down arachidonic acid to prostaglandin synthesis. In the tissue, there exist two well-identified cyclooxygenases, COX-1 and COX-2. COX-1 enzymes support hemostasis (platelet degranulation and adhesion), stomach mucosal integrity, and regulation of kidney function. COX-2 enzymes are an inducible form whose synthesis is activated in damaged tissue, which leads to the formation of proinflammatory prostaglandins that play a major role in inflammation, pain, and fever. A relatively new COX has been described (COX-3) that is found in the brain and is thought to be the site of action of acetaminophen.[82]

In contrast to NSAIDs, opioids have a different mechanism of action to reduce pain. Opioids act on the central nervous system by binding to specific receptors (μ opioid), thus preventing transmission of nociceptive pathways, while also activating inhibitory pathways that descend to the spinal cord. By binding to these μ-opioid receptors, substance P is prevented from being released, thus preventing painful stimuli.[83]

MANAGEMENT OF POSTOPERATIVE PAIN

In implant dentistry, different classifications and mechanisms of pain suppression may be used. A pain control protocol has been established, which simplifies and standardizes the various aspects of pain relief (Figure 21-3; Box 21-4; Table 21-5).

1. Nonopioid analgesics (nonnarcotics)
2. Opioid analgesics (narcotics)
3. Adjuvants

Nonopioid Medications

The nonopioid analgesics used in implant dentistry include acetaminophen, NSAIDs, COX-2 inhibitors, and tramadol.

Acetaminophen

The mode of action of acetaminophen is not known; however, it is believed to involve the prostaglandin pathways within the central nervous system with little influence on peripheral prostaglandin synthesis. COX-3 enzyme has been described that is fully expressed in the brain, spinal cord, and heart. The primary function

Propoxyphene	Darvon	0.5-1	2-2.5	4-6	65-130 mg	4-6	

is to regulate pain responses and fever and has been postulated to be the site of action of acetaminophen.[84]

Acetaminophen is indicated for mild to moderate pain and a safe alternative to NSAIDs. It has excellent analgesic and antipyretic properties and is void of side effects that are associated with NSAIDs. Like NSAIDs, acetaminophen also has a ceiling dose (4 g/day) for analgesic effects. However, unlike NSAIDs, acetaminophen is limited in that it has minimal anti-inflammatory qualities. The main side effect is liver damage, which is associated with long-term use of this drug.

Nonsteriodal Antiinflammatory Drugs

The NSAIDs are one of the most commonly used analgesics in implant dentistry today. Clinical trials have shown that NSAIDs are effective in all levels of pain (mild, moderate, severe).[85,86] The mechanism of action of NSAIDs is thought to arise from the inhibition of the synthesis of prostaglandins from arachidonic acid. With the inhibition of COX, conversion of arachidonic acid to the immediate precursors of prostaglandins is prevented. Thus with the lack of prostaglandins in the tissue, the hyperanalgesia and edema associated with the acute inflammation is minimized.[87]

The main reasons that NSAIDs are so widely used is the fact that they work very well as analgesics and have variable effects on inflammation (drug and dose dependent). Inflammation and pain are two separate entities with analgesic doses having a ceiling effect[88] and antiinflammatory doses not having a ceiling effect. In regards to the analgesic effect, there exists no reason to exceed the analgesic ceiling for the treatment of acute pain, as higher doses give no additional pain relief while increasing the likelihood of side effects.

The side effects of NSAIDs are numerous, including GI disturbances (dyspepsia, erosions, ulcerations) and liver, renal, and cardiac effects.[89] This group of medications is responsible for the largest number of serious drug-related complications, surpassing all other drugs by a wide margin.[90] In 2005, GI-related deaths from NSAIDs were the fourteenth leading cause of death in the United States, ranked after homicides (thirteenth) and before atherosclerosis (fifteenth).[91] The various types of NSAIDs and their associated risks are shown in Table 21-6.[103]

Table 21-6 Relative Risks of NSAIDs for Gastrointestinal Complications

NSAID	RELATIVE RISK
None	1
Ibuprofen	2.1
Ketoprofen	3.2
Naproxen	4.3
Indomethacin	5.5
Aspirin	8 to 11
Ketorolac	24.7

NSAID, Nonsteroidal antiinflammatory drug.

NSAIDs have very little effect on platelet aggregation because bleeding times are not prolonged. With prolonged use of NSAIDs, interference with most classes of antihypertensives has been noted. Therefore if patients take NSAIDs for more than 5 days postoperatively, blood pressure should be monitored.

Ibuprofen

Ibuprofen was first introduced in 1969 as a new NSAID and has since been the most popular prescribed NSAID.[93] Ibuprofen is used to treat mild to moderate pain and has been proven to significantly reduce postoperative

WWW.HIGHDENT.IR

dental pain in clinical studies.[94,95] The analgesic ceiling dose is 400 mg/dose and 1200 mg/day[96]; at these doses it has been shown to be as safe as acetaminophen, while achieving better analgesia with less nausea and cramping.[98]

Aspirin

Acetylsalicylic acid (ASA) was the first prototypical NSAID. It has analgesic, antiinflammatory, and antipyretic properties. However, at analgesic doses its relative risk for GI complications is high. Acetylsalicylic acid is not a drug of choice in the management of dental implant surgical patients because of its very significant antiplatelet effects.

Tramadol

Tramadol represents a unique classification of analgesic because it is a centrally acting analgesic with two complementary characteristics: opioid and antidepressant. It works by inhibition of norepinephrine and serotonin reuptake within pain pathways of the central nervous system and also by its relative weak affinity for the μ-opioid receptor.[98] Tramadol is a nonscheduled drug and is associated with fewer opioid-like side effects, such as dependence, sedation, respiratory depression, and constipation.[99,100] Tramadol's analgesic efficacy is similar to codeine (60 mg) and is indicated for moderate to moderately severe pain management. This drug is an appropriate analgesic alternative for the treatment of postoperative pain in patients who have NSAID-related GI and opioid intolerance. Tramadol has been shown to be effective in the reduction of pain when used in combination with acetaminophen. Ultracet (tramadol/acetaminophen) has demonstrated excellent efficacy in pain studies and is supplied as a combination analgesic containing 37.5 mg tramadol and 325 mg acetaminophen.[101,102]

COX-2 Inhibitors

The latest classification of analgesic drugs to fight pain and inflammation is the COX-2 inhibitors (i.e., celecoxib, rofecoxib, valdecoxib). The main advantage of this classification of medications is the lack of GI side effects. Recently, several of these drugs have been recalled by the U.S. Food and Drug Administration because of serious cardiovascular complications. Additionally, this classification of medication has not been shown to achieve better pain control or antiinflammatory properties than ibuprofen.

Narcotics (Opioids)

Narcotics (opioids) are the primary medications for analgesia of moderate to severe pain from dental origin. They are centrally acting analgesics that act as agonists at μ and κ opioid receptors. Morphine, which is a naturally occurring opioid, is generally accepted as the prototypical narcotic. All other narcotics are compared in potency to morphine.

Unlike nonopioids, opioids do not have a ceiling effect for analgesia. As the dose increases, the analgesic effect increases. However, in addition to relieving pain by μ-receptor binding, euphoria, nausea, vomiting, and constipation may occur. With high doses, sedation and respiratory depression are possible. With chronic use, physical and psychological dependence are common.

The following section discusses the most commonly used narcotics in oral implantology. Structurally, these narcotics are similar to morphine and provide the same degree of pain relief and unlimited efficacy at equipotent doses.

Codeine

Codeine is a naturally occurring alkaloid that is classified as a mild analgesic. Codeine has excellent antitussive properties; however, it is associated with high degrees of nausea and constipation. Orally administered codeine is only 60% bioavailable, which results in only 10% being demethylated to morphine. This 10% is the only part responsible for analgesic properties, thus allowing 90% to have no analgesic efficacy. Because of the side effects and low potency compared with other opioids, codeine is usually not the first choice of narcotics used in oral implantology.

Hydrocodone

Hydrocodone bitartrate is a semisynthetic narcotic analgesic and antitussive with multiple actions qualitatively similar to codeine. It is usually used as a combination analgesic, being combined with either acetaminophen or ibuprofen. For several years, this narcotic has been the most frequently dispensed prescription medication in the United States. Hydrocodone is habit forming, and the most frequent adverse reactions are dizziness, sedation, nausea, and vomiting.

Oxycodone

Oxycodone is a semisynthetic opioid with analgesic action similar to morphine. It is recommended for moderate to severe pain with its principal actions being analgesia and sedation. It has excellent oral bioavailability because it retains half of its analgesic activity when administered orally. Oxycodone has the same adverse effects as most other opioids, with an increased potential for abuse and drug dependence. Oxycodone is marketed as a combination narcotic, combined with either acetaminophen (Percocet) or aspirin (Percodan). A slow-release oxycodone (Oxycontin) has recently been released, which has a high abuse potential.

Meperidine

Meperidine is mostly used in hospital settings via intramuscular administration. A majority of meperidine

7.5 mg hydrocodone/200 mg ibuprofen	Vicoprofen	1-2 tablets every 6 hr	III
5 mg oxycodone/325 mg acetaminophen	Percocet 5/325	1-2 tablets every 4-6 hr	II
7.5 mg oxycodone/500 mg acetaminophen	Percocet 7.5/500	1-2 tablets every 4-6 hr/ maximum 8/day	II
10 mg oxycodone/650 mg acetaminophen	Percocet 10/650	1 tablet 4-6 hr	II
5 mg oxycodone/400 mg ibuprofen	Combunox	1 tablet every 6 hr/maximum 4/day	II

is converted to normeperidine, which is a metabolite that has no analgesic property; however, is a very strong central nervous system (CNS) stimulant. Because meperidine in oral form has a poor oral bioavailability (25%), a greater risk evolves with the accumulation of normeperidine. As a result, meperidine is a poor choice for an orally administered opioid.

COMBINATION ANALGESIC THERAPY FOR POSTOPERATIVE PAIN

A pain management strategy using multiple analgesics with different mechanisms of action is termed *combination analgesic therapy*. The goal of combining different types of analgesics is to increase the analgesic effect while decreasing possible side effects. When multiple drugs are used in combination, synergistic and additive effects allow for the use of lower doses of each individual drug.

With combination therapy, acetaminophen or NSAIDs are used with an opioid. Because of the ceiling effects of acetaminophen and NSAIDs, further increases in dosage will not provide any additional analgesia; however, they will increase side effects (Table 21-7).

Analgesic Agents in Oral Implantology

The selection of an analgesic or analgesic regimen for management of postsurgical pain is ideally based on the expected pain intensity. This may be based on the patient's medical history, past pain threshold, type of procedure, extent of tissue reflection, and duration of procedure. Because of the various agents and numerous options for the treatment of postsurgical pain after dental implant surgery, a pain control protocol was formulated to aid in the proper administration of these agents. According to the World Health Organization guidelines, the procedure and patient must be evaluated and classified as mild, moderate, or severe.

Mild Pain

Mild pain is self-limited and usually will be resolved with normal recommended doses of NSAIDs.

Moderate Pain

Moderate pain is more intense pain than mild and usually will not be resolved totally by NSAIDs. It will interfere with function and disrupt the activities of daily living.

Severe Pain

Severe pain is defined as pain that interferes with some or all of the activities of daily living. The patient may be confined to bed, and strong opioid treatment will need to be continued for days. Adjuvant drug therapies may be needed for supplementation.

Control of Postoperative Surgical Pain

The goal of postsurgical pain management is to optimize patient comfort through pharmacologic and behavioral strategies. The World Health Organization formulated an analgesic "ladder" for the treatment of pain management. The following protocol describes three steps in the treatment of acute pain (Box 21-5)[103]:

1. The first step is to maximize the use of NSAIDs (acetaminophen, ibuprofen) for mild to moderate pain. Adjuvant medications such as glucocorticoids and cryotherapy are often suggested.
2. When moderate pain is expected or persists, an opioid (hydrocodone, codeine) should be added

WWW.HIGHDENT.IR

Box 21-5 World Health Organization Analgesic Ladder

Three-Step Conceptual Model

1. Nonopioid + adjuvant
2. Nonopioid + adjuvant + opioid (moderate)
3. Nonopioid + adjuvant + opioid (severe)

to the NSAID. The fixed dose of opioids with the NSAIDs provides additive analgesia. Glucocorticoids and cryotherapy are encouraged.

3. Moderate to severe pain that is expected or persists should be treated by increasing the dosage of the opioid. Glucocorticoids and cryotherapy are of particular benefit when not contraindicated.

With the guidelines from the World Health Organization, a pain control protocol was formulated for treatment of procedures based on the expected postoperative pain (Table 21-8).

Table 21-8 Recommended Pain Control Protocol

DRUG	DOSE
PCP1: Mild Pain Expected	
Ibuprofen	400 mg 1 hr before
PCP 2: Mild to Moderate Pain Expected	
Ibuprofen + Hydrocodone (Vicodin)	400 mg 1 hr before surgery + continue 4 times daily for 2 days 5 mg/500 mg as needed
PCP 3: Moderate Pain Expected	
Ibuprofen + Hydrocodone (Vicodin ES)	400 mg 1 hr before surgery + continue 4 times daily for 2 days, then as needed 7.5 mg/750 mg 4 times daily for 2 days, then as needed
PCP 4: Severe Pain Expected	
Ibuprofen + Hydrocodone (Vicodin HP)	400 mg 1 hr before surgery + continue 4 times daily for 4 days, then as needed 10 mg/660 mg 4 times daily for 2 days, then as needed

Local Anesthetics

Local anesthetics are an integral component of all dental implant surgical procedures. They are necessary to perform surgery without pain and are effective for decreasing onset and duration of pain. The dental surgeon must have significant knowledge of the pharmacokinetics of the different local anesthetics used in implant dentistry. The most commonly used dental anesthetics are amides, which are known for their low toxicity and relative lack of allergenicity.

Local anesthetics prevent postoperative pain by blocking the generation and conduction of action potentials in sensory neurons. This will prevent surgically induced nociceptive impulses from reaching the central nervous system and causing centrally mediated postoperative hyperalgesia. Table 21-9 provides local anesthetic dosage information.

Lidocaine

The compound with which most other local anesthetics are compared is 2% lidocaine-1/100,000 epinephrine.

Table 21-9 Local Anesthetic Dosage Information

ANESTHETIC SOLUTION	MAXIMUM DOSE	pKa	ONSET (min)	DURATION (min)		ELIMINATION HALF-LIFE (min)
				MAXILLA	MANDIBLE	
2% Lidocaine (1:100 K epinephrine)	7 mg/kg	7.9	2-4	170	190	90
2% Mepivacaine (1:20 K neocobefrin)	6.6 mg/kg	7.6	2-4	130	185	115
4% Articaine (1:100 K epinephrine)	7 mg/kg	7.8	2-4	140	270	20
0.5% Bupivacaine (1:200 K epinephrine)	1.3 mg/kg	8.1	5-8	340	440	210
3% Mepivacaine No epinephrine	6.6 mg/kg	7.6	2-4	90	165	115

Data from Haas DA: An update on local anesthetics in dentistry, *J Can Dent Assoc* 68:546-551, 2002.

WWW.HIGHDENT.IR

This solution is most commonly used in infiltration or block anesthesia and is considered a medium-duration anesthetic. Lidocaine is supplied in two other forms: a higher-concentration vasoconstrictor (1/50,000 epinephrine) and with no vasoconstrictor (plain).

Mepivacaine

Mepivacaine is an anesthetic that is very similar to lidocaine in onset of action, duration, and toxicity. The usual dosage used in dentistry is a 2% solution with the addition of 1/20,000 levonordefrin (Neo-Cobefrin) as the vasoconstrictor. This local anesthetic is also made in a 3% (plain) solution, which is used for short procedures or when a vasoconstrictor is contraindicated.

Articaine

Articaine is a newer amide-type of anesthetic that was approved in 2000 by the U.S. Food and Drug Association for use in the United States. Articaine differs structurally from other amide anesthetics, allowing it to have a better lipid solubility, which improves permeability of the lipid barriers in nerve membranes. Second, articaine has a very short half-life (20 minutes) in comparison to the other amide anesthetics. This shorter half-life results because it is hydrolyzed over 90% by plasma esterases and not by the liver as with the other amides. As a result, articaine is of less concern in liver-impaired individuals and a safer drug for reinjections in longer-duration procedures.

Long-Acting Anesthetics

Postoperative dental pain has been shown to reach its maximum intensity during the first 12 hours postoperatively.[104] When comparing analgesia (reduction in the sensation of pain) with anesthesia (complete elimination of feeling and sensation of pain), complete elimination of pain can be beneficial throughout the immediate postoperative period. Local anesthetics play a key role in the postoperative pain experience for the patients. If the implant surgeon can keep the patient comfortable during the initial period, pain and discomfort in the short term will also be minimized. The greater duration of anesthesia and decreased postoperative pain is effective in reducing the amount of analgesics required after surgery.[105]

The most common long-acting amide anesthetic is bupivacaine (Marcaine). This local anesthetic can play a vital role in pain management. Because of its unique pharmacokinetics, bupivacaine has been studied extensively and has been proven to be safe and far superior to other long-acting local anesthetics. Bupivacaine is an amide local anesthetic that is structurally similar to lidocaine and mepivacaine. It is more potent and less toxic than other types of amide anesthetics. Because of its high pKa (8.1), bupivacaine lasts two to three times longer than lidocaine or mepivacaine. The epinephrine concentration of bupivacaine is much lower (1/200,000 epinephrine) than standard anesthetics, thus limiting its ability to affect hemostasis.

Local Anesthetic Overdosage

A serious complication, local anesthetic overdosage, is of great concern in implant dentistry. Because many implant-related surgeries are of longer duration, a greater amount of anesthetic is often administered. Special attention must be taken during implant surgery as to the number of cartridges and type of anesthetic used during a procedure. Table 21-10 lists anesthetics and the manufacturers' maximum recommended dose by weight of patient to carpules. However, the maximum number of cartridges is time-dependent. The elimination half-life is not indicative of anesthetic duration; however, it may be used as a guide for repeated anesthetic administration during a lengthy procedure. After one half-life, as much as 50% of the permissible dose can be administered with reasonable safety if liver function is normal.

Special care must be given to the use of combination local anesthetics. In implant dentistry, it is common to use two amide anesthetics together—lidocaine and bupivacaine. Although acceptable, total doses should not exceed combined maximum recommended doses. Calculations should factor in the total dose of the combination and whether sufficient time has elapsed for elimination of the initial dose.[106] If local anesthetic toxicity reactions occur,[107] CNS excitation, convulsions,

Lack of muscle tone
Mild drop in blood pressure, heart, and respiratory rate

Adapted from Bennett CR: *Monheinis local anesthesia and pain control in dental practice,* ed 7, St Louis, 1984, Mosby.

respiratory depression, and cardiac arrest may occur (Box 21-6).

Most amide anesthetics (except for articaine) are metabolized by the liver by a microsomal enzyme system. Therefore special attention should be given to patients with decreased liver function, especially in elderly patients (e.g., chronic alcoholism, hepatitis). The half-life of lidocaine has been shown to be greater than 2.5 times the normal values in patients with hepatic disease.[108] Special attention must be given to the amount of anesthetic used and concern for reinjection must be strictly evaluated in these patients. In addition to liver dysfunction, the kidneys are the primary organs responsible for excretion of the local anesthetics and its metabolites. Patients with significant renal impairment will also have difficulty in removing the anesthetics from the blood, resulting in an increased chance of toxicity.

Patients with cardiovascular disease should be well evaluated before the use of epinephrine-containing anesthetics, and care should be taken as to the amount of epinephrine administered. Recommendations on the maximum safe dose for a healthy patient are 0.2 mg epinephrine versus 0.04 mg epinephrine for the cardiac-impaired patient. It should be noted that when epinephrine is not included in the anesthetic, the systemic uptake of the drug is more rapid and the maximum number of carpules given is significantly less in comparison to anesthetics with vasoconstrictors.

Long-Acting Anesthetics in Implant Dentistry

To keep the patient as comfortable as possible, the use of long-acting anesthetics is highly recommended both in the beginning and at the end of the procedure. By administering a long-acting anesthetic at the end, the patient will remain "pain free" longer and will have a decrease in the initiation of noxious stimuli. However, care must be given to the number and amount of local anesthetic to avoid overdosage.

SEDATIVE AGENTS

The use of conscious sedation is a valuable adjunct to dental implant procedures. The American Dental Association defines *conscious sedation* as a minimally depressed level of consciousness that retains the patient's ability to independently and continuously maintain an airway and respond appropriately to physical stimulation or verbal command and that is produced by a pharmacologic or nonpharmacologic method or combination thereof.[109] Several sedative agents are currently available for oral and intravenous sedation. Table 21-11 provides the most commonly used oral and intravenous sedative agents.

Benzodiazepines

The benzodiazepines are the most effective drugs available for dental-related anxiety. These drugs have depressant effects on the subcortical levels of the CNS. Benzodiazepines produce anxiolysis and anterograde amnesia, which are extremely useful for patients undergoing conscious sedation for dental procedures. The exact mechanism is not known, but benzodiazepines are thought to have an effect on the limbic system and the thalamus, which are involved with emotions and behavior.[110]

Diazepam (Valium)

Diazepam is usually not an effective agent for highly apprehensive patients unless administered intravenously. However, it is extremely effective if given orally the night before the procedure with a dose of 5 to 10 mg. Advantages of diazepam for dental procedures is that it reduces salivary flow and relaxes skeletal muscles. The main disadvantage of diazepam is the 24-hour half-life for adults and an 85-hour half-life for elderly patients. The active metabolites (desmethyldiazepam and oxazepam) are responsible for the prolonged sedation and recovery along with impaired psychomotor impairment.[110,111]

Midazolam (Versed)

Midazolam is a fast-acting benzodiazepine that is twice as potent as diazepam. It is available as a syrup and also as a formulated injectable solution. Midazolam possesses anticonvulsant properties and also is an excellent muscle relaxant, sedative, and amnesic. The inhibitory effects in the CNS are intensified; therefore midazolam should not be combined with other CNS depressant drugs.

Triazolam (Halcion)

Triazolam is an orally administered benzodiazepine and short-term hypnotic drug. When given orally, this drug is fast acting and has been shown to be safe and effective for dental procedures. Studies have shown that triazolam given in doses of 0.25 to 0.5 mg does not produce adverse effects in respiration, heart rate, or arterial pressure. This drug is also ideal for patients with hypertension, as the blood pressure has been shown to decrease by five points.[110, 111]

Additional Sedative Anxiolytics

Fentanyl

Fentanyl is a synthetic opioid agonist narcotic that produces analgesia, drowsiness, sedation, and euphoria, but no amnesia. All opioid agonists produce dose-dependent depression of ventilation. Respiratory depression is a result of a decreased response of the ventilatory centers to carbon dioxide. For this reason, care should be taken when administering opioid agonists, especially in combination with other sedatives. Nausea and vomiting are another undesirable effect of opioid agonists. Opioid-induced nausea and vomiting are caused by direct stimulation of dopamine receptors in the chemoreceptor trigger zone in the fourth floor of the fourth ventricle.[110]

Propofol (Diprivan)

Propofol is an intravenous sedative-hypnotic agent commercially introduced in the United States in 1989 by Zeneca Pharmaceuticals. It was the first of a new class of intravenous anesthetic agents: the alkylphenols. Propofol is an ideal sedative anesthetic for dentistry because it is fast-acting and possesses a short half-life. The elimination half-life of propofol has been estimated to be between 2 and 24 hours. However, its duration of clinical effect is much shorter because propofol is rapidly distributed into peripheral tissues. Because of its pronounced respiratory depressant effect and its narrow therapeutic range, propofol should be administered only by individuals trained in airway management.[110,111]

Reversal Agents

Flumazenil (Anexate, Lanexat, Mazicon, Romazicon) is a benzodiazepine antagonist used as a reversal agent for the treatment of benzodiazepine overdose. It reverses the effects of benzodiazepines by competitive inhibition at the benzodiazepine binding site on the $GABA_A$ receptor. It was introduced in 1987 by Hoffman-LaRoche under the name Anexate.

The onset of action is rapid and usually effects are seen within 1 to 2 minutes. The peak effect is seen at 6 to 10 minutes. The recommended dose for adults is 200 µg every 1 to 2 minutes until the effect is seen, to a maximum of 3 mg per hour. It is available as a clear, colorless solution for intravenous injection, containing 500 µg in 5 mL. It is hepatically metabolized to inactive compounds, which are excreted in the urine.[110,111]

NOTE: Many benzodiazepines have longer half-lives than flumazenil. Therefore repeated doses of flumazenil may be required to prevent recurrent symptoms of overdosage after the initial dose of flumazenil wears off. It is hepatically metabolized to inactive compounds that are excreted in the urine.

Naloxone (Narcan) is a drug used as a reversal for narcotic toxicity. Naloxone is injected intravenously for fastest action. The drug acts after about 2 minutes, and its effects may last about 45 minutes.

Many opioids have a longer half-life than naloxone. Therefore patients receiving naloxone should be monitored for resedation and may require repeated doses of naloxone if resedation or respiratory depress occurs.[110,111]

COMPREHENSIVE PHARMACOLOGIC PROTOCOL

Because of the many variables (e.g., local, systemic, surgical) that need to be considered with the use of pharmacologic agents in implant dentistry, a protocol has been developed to standardize the prophylactic use of these agents. A four-category classification is proposed based on the patient's ASA status and procedure type (Table 21-12).

Chapter 22

Applied Anatomy for Dental Implants

Mohamed Sharawy, Carl E. Misch

The surgical anatomy of the maxilla and mandible provide the foundation required to safely insert dental implants. The anatomy is also a requisite to the understanding of complications that may inadvertently occur during surgery, such as injury to blood vessels or nerves, as well as postoperative complication such as infection. This information also provides the operator with the confidence needed to deal with these complications. This chapter addresses those issues important in the field of oral implantology.

SURGICAL ANATOMY OF THE MAXILLA AS AN ORGAN

The maxilla is pyramidal in shape with the root of the zygoma as its apex (Figures 22-1 and 22-2). The latter can be palpated in the buccal vestibule of the oral cavity. It divides the facial surface of the maxilla into anterolateral and posterolateral surfaces of the pyramid. The third surface of the pyramid is the orbital plate of the maxilla. The base of the pyramid is the lateral wall of the nose or the medial wall of the maxillary sinus. The alveolar process of the maxilla related to the anterolateral surface carries the incisors, the canines, and the premolars, whereas that of the posterolateral surface carries the molars and ends as the maxillary tuberosity. The intraoral part of the maxilla is limited by the mucobuccal fold and the orbicularis oris muscle anteriorly and by the buccinator muscle posteriorly. The posterolateral surface of the maxilla above the mucobuccal fold forms the anterior wall of the infratemporal fossa and is difficult to palpate. However, the anterolateral surface of the maxilla beyond the mucobuccal fold can be palpated easily under the skin, as can the anterior nasal spine, the anterior nasal aperture, and the frontal process of the maxilla. Intraorally, it is possible to palpate the canine eminence, the canine fossa (distal to the canine eminence and a common site for facial access to the maxillary sinus), the maxillary tuberosity, and the hamular notch. The maxilla extends as a horizontal plate medially to form the anterior two thirds of hard palate. The horizontal plate of the palatine bone forms the posterior one third of hard palate. The palatine bone has a vertical plate that articulates with the base of the maxilla; it also has a pyramidal process that interposes between the maxillary tuberosity and the pterygoid processes of the sphenoid bone. Mucosal incision at the maxillary tuberosity that extends into the hamular notch may expose the pyramidal process of the palatine bone. Distal to this point, one may expose the medial pterygoid muscle, which takes origin from the tuberosity and the lateral pterygoid plate of the sphenoid. The medial wall of the maxilla begins at the sharp edge of the anterior nasal aperture and extends posteriorly, with a concavity that bounds the nasal fossa and continues distal to the canine. Once there, it forms the medial wall of the maxillary sinus and continues all the way back to the maxillary tuberosity. The medial wall of the maxilla provides attachment to

the inferior nasal concha and to the vertical plate of the palatine bone. The opening of the maxillary sinus is found in the medial wall of the maxilla, close to the floor of the orbit. The opening is reduced in diameter by the uncinate process of the ethmoid bone. The latter provides the superior and middle conchae of the lateral nasal wall. The orbital plate of the maxilla forms the floor of the orbit and also the roof of the maxillary sinus. The infraorbital canal carries the infraorbital nerve and vessels, and it forms a ridge that can be seen in the sinus cavity.

Muscles Attached to the Maxilla

As the maxillary alveolar bone resorbs, the crest of the residual ridge migrates toward the muscles that take their origin from the basal bone of the maxilla. Descriptions of muscles of surgical importance to oral implantologists follow (Figures 22-3 to 22-5).

Orbicularis Oris Muscle

The orbicularis oris muscle originates from the modiolus at each corner of the mouth. The muscle fibers fan out into the upper and lower lips, where they form upper and lower peripheral portions under the skin and marginal portions under the vermilion zone of the lips. Some of the orbicularis oris fibers attach to the ala of the nose and to the nasal septum. In the midline of the upper lip, the peripheral portions from both sides interdigitate to create the philtrum. The marginal portions interdigitate and create the labial tubercle. Although unattached to the bone of the maxilla, the muscle limits the depth of the upper and lower facial vestibule. The orbicularis oris receives innervation from the buccal and mandibular branches of the facial nerve.

Incisivus Labii Superioris Muscle

The incisivus labii superioris muscle originates from the floor of the incisive fossa of the maxilla above the eminence of the lateral incisor and deep to the orbicularis oris. To expose the bone of the premaxilla between the canines, a mucoperiosteal flap reflection may detach the incisivus labii superioris. It may also detach the septalis and oblique fibers of nasalis muscle. The first is attached to the skin of the nasal septum and the latter to the ala of the nose. These small muscles will reattach after placement of the flap. However, if the muscles were damaged, then drooping of the septum and flaring of the ala of the nose may result.

Buccinator Muscle

The buccinator muscle originates from the base of the alveolar process opposite to the first, second, and third molar of both jaws. This muscle also takes origin from the pterygoid hamulus of the medial pterygoid plate of the sphenoid bone and therefore bridges the gap between the maxillary tuberosity anteriorly and the hamulus posteriorly. Extension of a subperiosteal frame design into the pterygoid plates may interfere with the fibers of these muscles without adding too much

to the retention of the implant. When incising and reflecting the mucosa overlying the areas of the maxillary tuberosity and hamular notch before taking impressions for maxillary subperiosteal implants, avoid injuring the tendon of the tensor veli transact muscle, which passes around the pterygoid hamulus. The tendon moves on an underlying bursa whenever the soft palate moves; therefore it may become irritated by the subperiosteal frame and result in inflammation and pain. Fibers of the buccinator and medial pterygoid muscles are also found in the area of reflection. The majority of the fibers of the medial pterygoid muscle originate from the medial surface of the lateral pterygoid plate of the sphenoid bone, whereas the rest of the fibers form the tuberal head, which takes origin from the maxillary tuberosity. Near the pterygoid hamulus, a fibrous tissue raphe or, in some cases, a broad fascialike structure is found between the transaction and the superior pharyngeal constrictor muscles. In some cases, no raphe or fascia is found. Injury to the latter muscle should be avoided during reflection of the mucosa, particularly on the palatal aspect of the area of the hamulus.

Levator Labii Superioris Muscle

The levator labii superioris muscle takes origin from the infraorbital margin above the infraorbital foramen and therefore is rarely of concern to the implant surgeon. The zygomatic branch of the facial nerve innervates this muscle.

Levator Anguli Oris (Caninus) Muscle

The levator anguli oris muscle originates in the maxilla below the infraorbital foramen. The infraorbital nerve and vessels arise between this muscle and the levator labii superioris. In the severe atrophic division D maxilla, the infraorbital foramen is relatively close to the crest of the ridge. Reflection of the tissues for autogenous grafts and implant placement into sinus grafts may approximate this region and cause parasthesia. In subperiosteal implant cases that require extensive framework extension for retention, the operator should be aware of the location of the infraorbital neurovascular bundle in relation to the caninus and levator labii superioris muscles. The zygomatic branch of the facial nerve innervates the caninus muscle.

Sensory Innervation of the Maxilla

The maxillary nerve (V2) innervates the maxilla (Figure 22-6). The nerve leaves the middle cranial fossa by passing through the foramen rotundum and appears in the pterygopalatine fossa. It exits the fossa and passes briefly into the infratemporal fossa; from there it enters the floor of the orbit or the roof of the maxillary sinus by passing through the infraorbital fissure. It

WWW.HIGHDENT.IR

then exits the orbit via the infraorbital foramen. The pterygopalatine portion of the maxillary nerve provides the descending palatine and sphenopalatine branches. The sphenopalatine nerve enters the nasal cavity from the pterygopalatine fossa by passing through the sphenopalatine foramen. It supplies the nasal cavity and becomes the incisive nerve that supplies the palatine mucosa opposite to the upper six anterior teeth. The descending palatine nerve terminates as the great palatine nerve, which supplies the mucosa of the hard palate, and the lesser palatine nerves, which supply the mucosa of soft palate. These sensory nerves also carry parasympathetic fibers from the sphenopalatine ganglion that innervate the mucous glands of the palate. The infratemporal portion of V2 branches into the posterior alveolar nerve and zygomatic nerve. The latter divides into the zygomaticofacial and zygomaticotemporal cutaneous nerves. The posterior superior alveolar nerve supplies the buccal gingiva, buccal alveolar bone, second and third molars, and two roots of first molar. The infraorbital portion of V2 gives rise to anterior superior alveolar and occasionally middle superior alveolar nerves. These nerves run in bony grooves in the facial wall of the maxillary sinus under the Schneiderian membrane. The nerves supply the sinus wall and the premolars; the canine, lateral, and central incisor on the same side; and also the central incisor at the contralateral side. The infraorbital nerve exits the maxilla at the infraorbital foramen and supplies cutaneous branches to the lower eyelid, side of the nose, and upper lip. Implantologists often need to block V2 or several of its branches. Luckily these can be achieved by an intraoral route. V2 can be reached via the great palatine foramen and descending palatine canal, or via the pterygomaxillary fissure by following the slope of the posterolateral surface of the maxilla into the pterygopalatine fossa.

Posterior Superior Alveolar (Dental) Nerve

The nerve arises within the pterygopalatine fossa, courses downward and forward, passing through the pterygomaxillary fissure, and enters the posterior aspect of the maxilla. It runs between the bone and the lining of the maxillary sinus. This nerve supplies the sinus, the molars, the buccal gingiva, and the adjoining portion of the cheek; it may be injured during a sinus augmentation with a lateral approach. Clinically this does not appear to be of major consequence.

Infraorbital Nerve

This nerve is a continuation of the main trunk of the maxillary division. It leaves the pterygopalatine fossa by passing through the inferior orbital fissure to enter the floor of the orbit. It runs in the infraorbital groove and then in the infraorbital canal. The nerve exits the orbit through the infraorbital foramen to give cutaneous branches to the lower eyelid, the ala of the nose and the skin, and the mucous membrane of the lip and cheek. The infraorbital foramen is located between the levator labii superioris muscle, which takes origin above the foramen, and the levator anguli oris (caninus) muscle, which takes origin below the foramen. This foramen and neurovascular contents are within 5 to 10 mm of an extremely resorbed maxilla. When applying onlay grafts, which expose the entire maxilla, the implant dentist must be very aware of this situation. Fixation screws or implants may cause paresthesia when inserted through the graft and into this structure. Subperiosteal implants designed for an atrophied maxilla should not extend into the site of the infraorbital nerve and vessels. In some cases of maxillary sinus disorder, the site of the infraorbital foramen becomes tender, probably as a result of inflammation of the infraorbital nerve. This is an important diagnostic test for possible postoperative involvement after sinus augmentation procedures.

Middle Superior Alveolar (Dental) Nerve

This branch of the infraorbital nerve is given off as the infraorbital nerve passes through the infraorbital groove. The middle superior alveolar nerve runs downward and forward in the lateral wall of the sinus to supply the maxillary premolars. This region is routinely violated for the lateral approach to sinus grafts, with apparently no consequence.

Anterior Superior Alveolar (Dental) Nerve

This branch of the infraorbital nerve arises within the infraorbital canal. It initially runs laterally within the sinus wall and then curves medially to pass beneath the infraorbital foramen. It turns downward to supply the maxillary anterior teeth. A nasal branch passes into the nasal cavity to supply the mucosal lining of a portion of the nasal cavity. Before elevation of nasal mucosa and placement of grafts, this nerve must be anesthetized. The infraorbital nerve block or V2 block anesthesia is suggested. Implant dentists must also anesthetize this branch before placement of implants in the incisor region. The anterior, middle, and posterior superior alveolar nerves intermingle to form the superior dental plexus. The posterior, middle, and anterior superior alveolar nerves run in the facial wall of the maxillary sinus between its lining membrane and the bone. During antrostomy procedures to augment the floor of the sinus, the operator should be aware of these structures, which are present even in the absence of teeth.

Palatine Nerve

The greater (anterior) and lesser (posterior) palatine nerves supply the hard and soft palate, respectively. They exit the pterygopalatine fossa through the superior opening of the descending palatine canal, travel downward, and enter the oral cavity by way of the greater and lesser palatine foramina. The greater palatine nerve runs forward in a groove on the inferior surface of the hard palate to supply the palatal mucosa as far forward

WWW.HIGHDENT.IR

as the incisor teeth. Here the nerve communicates with the nasopalatine nerve. The nerve supplies the gingiva, mucous membrane, and glands of the hard palate. The greater palatine artery and vein accompany the nerve during its course in the hard palate. As the maxillary alveolar process atrophies, it shifts to the palate and brings the crest of the ridge closer to the groove where the greater palatine neurovascular bundle is found. The restoring dentist should be aware that an incision too palatal to the crest of the ridge in the atrophied maxilla might injure these vital structures. This foramen is entered for a V2 block anesthesia. One may find it by taking a blunt instrument and pressing firmly along the alveolar palatal bone angle. The instrument will depress over the foramen when in the correct position.

Nasopalatine (Sphenopalatine) Nerve

The nasopalatine nerve leaves the pterygopalatine fossa through the sphenopalatine foramen located in the medial wall of the fossa. It enters the nasal cavity and supplies portions of the lateral and superior aspects of the nasal cavity. The longest branch reaches the nasal septum, where it turns downward and forward, traveling on the surface of the septum. While on the septum it forms a groove on the vomer bone. The nerve supplies the nasal mucosa, descends to the floor of the nose near the septum, passes through the nasopalatine canal, and then exits onto the hard palate through the incisive foramen. The latter opening is deep to the incisive papilla. The nerve communicates with the greater palatine nerve. The incisive nerve should be anesthetized before elevation of the mucosa of the floor of the nose for subnasal grafts or implants that engage the nasal floor in the incisor region.

Arterial Supply to the Maxilla

The majority of arterial blood supply (Figure 22-7) comes from the maxillary artery, which is one of the terminal branches of the external carotid artery. The artery starts deep to the neck of the mandibular condyle (mandibular portion) and then proceeds either superficial or deep to the lateral pterygoid muscle (pterygoid portion). It then branches close to the pterygomaxillary fissure, where one branch enters the fossa (pterygopalatine portion). The other branch, called the *infraorbital artery*, enters the floor of the orbit via the infraorbital fissure; it proceeds in the infraorbital canal and exits on the face by passing through the infraorbital foramen. Branches of the maxillary artery are as follows:

1. Mandibular portion: deep auricular, tympanic, middle meningeal, and inferior alveolar arteries
2. Pterygoid portion: deep temporal, lateral pterygoid, medial pterygoid, and masseteric arteries
3. Pterygopalatine portion: posterior superior alveolar, descending palatine, and sphenopalatine arteries

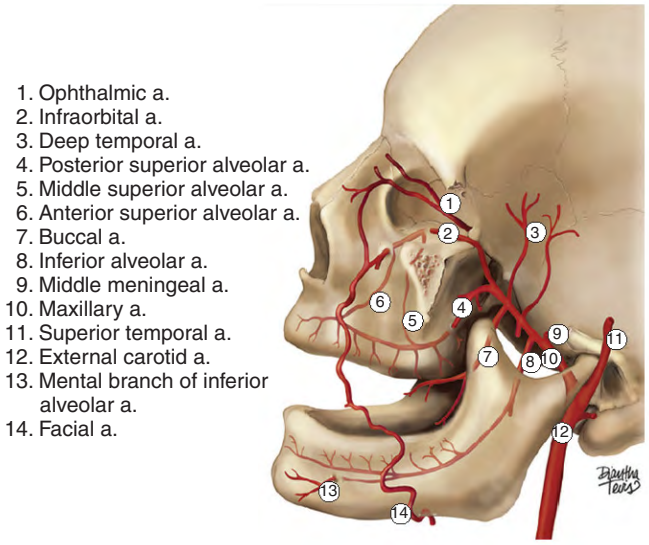

Figure 22-7 Arterial supply of the maxilla and mandible.

4. Infraorbital portion: anterior and middle superior alveolar, palpebral, nasal, and labial arteries

Supplemental arterial blood supply reaches the maxilla via two branches from the cervical portion of the facial artery (ascending palatine and tonsillar arteries), two dorsolingual arteries from the lingual artery, and the ascending pharyngeal branch of external carotid artery. All the collateral circulation reaches the maxilla from the area of the soft palate. During orthognathic surgery to correct maxillary prognathism, the surgeon often cuts the posterior, middle, and anterior superior alveolar arteries, as well as the descending palatine arteries, without compromising the blood supply to the maxilla because of the presence of supplemental blood supply from the branches mentioned previously. It is important to note that the maxillary artery supplies blood to the bone of the mandible via its inferior alveolar artery and its branches to the muscles of mastication. Detaching the masseter and medial pterygoid muscles without reattaching it could result in necrosis of the ramus of the mandible. In addition, all the arterial branches mentioned previously arise from the external carotid; therefore bilateral arteriosclerosis of the carotids, which is common in old age and in uncontrolled diabetic patients, may compromise the blood supply to the maxilla and could result in delay of healing after insertion of implants or bone grafting to the area. More detailed consideration of applied anatomy of the arterial supply to both the maxilla and mandible is presented at the end of this chapter.

Venous Drainage of the Maxilla

The veins follow the arteries and carry the same names. The maxilla drains into the maxillary vein. The latter communicates freely with the pterygoid plexus of veins and then joins the superficial temporal vein to form the

WWW.HIGHDENT.IR

posterior facial vein within the parotid gland. Infection from the maxilla may follow the maxillary vein to the pterygoid plexus veins and then to the cavernous sinuses via emissary veins, causing infected cavernous sinus thrombosis. Adequate arterial supply and healthy venous drainage are essential for bone regeneration and remodeling of bone grafts.

Lymphatic Drainage

The maxilla, including the maxillary sinuses, drains its lymphatics into the submandibular lymph nodes. In addition, the posterior portion of the maxilla and soft palate drain into the deep facial lymph nodes, part of the deep cervical nodes. Palpation of lymph nodes is an essential part of the physical examination of the head and neck.

SURGICAL ANATOMY OF THE MANDIBLE

The clinician should be familiar with the anatomical features of dentulous and edentulous mandibles, not only from radiographs but also from physical examination (see Figures 22-1 to 22-4). The symphysis, inferior border, premasseteric notch, gonial angle, lateral pole of condyle, and coronoid process are all palpable under the skin. Intraoral palpable features of the mandible from the facial surface include the external oblique ridge and retromolar triangle, with the coronoid process at its tip, the external oblique ridge bordering it laterally, and the internal oblique ridge bordering it medially. The latter is called the *temporal crest* because this is the site for insertion of the medial tendon of the temporalis muscle. The mental foramen can be located at the midpupillary line at the apices of the premolars. From the lingual aspect, palpate the internal oblique ridge and torus mandibularis at the premolar region. Reflection of mucoperiosteal flap beyond the mucobuccal fold facially exposes the mentalis muscles lateral to the midline, the mental foramen with the mental neurovascular bundle, the depressor labii inferioris and triangularis close to the inferior border in the premolar region, the transaction at the base of the alveolar process opposite to the molars, and the temporalis tendons at the anterior border of the ramus. An atrophied edentulous mandible loosens the alveolar process, and the crest of the ridge may be found at the same level as the external and internal oblique ridge. It is possible to palpate the superior genial tubercles with its genioglossus muscle attachment. Reflection of the mucoperiosteal flap after midcrest incision may expose the mental neurovascular bundle, which is abnormally located at or occasionally lingual to the crest of the ridge. The transact muscle may loose its attachment to the external oblique ridge, whereas the mylohyoid may rise above the level of the ridge. The lingual nerve, which has a close relationship to the alveolar bone of the third molar in the dentulous mandible, may run close to the crest of the edentulous ridge; in some cases it may be found under the retromolar pad.

Muscle Attachment to the Mandible

The loss of teeth begins a cascade of events that leads to alveolar bone loss in width and height. As the mandibular alveolar bone resorbs, the residual ridge migrates toward many of the muscles that originate or insert on the mandible (see Figures 22-3 to 22-5). The origin, insertion, innervation, and function of the muscles of surgical importance to the implant dentist are discussed.[1-7]

Lingual or Medial Attachments

Mylohyoid Muscle

The mylohyoid muscle is the main muscle of the floor of the mouth. It takes origin from the entire length of the mylohyoid lines on the medial aspect of the mandible bilaterally. The most posterior fibers of the mylohyoid insert into the body of the hyoid bone, whereas the other fibers meet in the midline to form a median raphe that extends from the mandible to the hyoid bone. The structures above the mylohyoid muscle are sublingual or intraoral in location, and the structures below the mylohyoid muscle are extraoral or subcutaneous. With a severely resorbed residual ridge, the origin of the mylohyoid muscle approximates the crest of the ridge, especially in the posterior mandible. In these cases surgical manipulation at the crest of the ridge may injure the mylohyoid muscle. A mandibular periosteal reflection for subperiosteal implant often reflects this muscle to the second molar region. The substructure of the implant then has a permucosal site in the first molar area and a lingual primary strut above and below the mylohyoid muscle. Surgical manipulation of the tissue of the floor of the mouth may lead to edematous swelling of the sublingual space (above the mylohyoid muscle), swelling of the submandibular space (below the mylohyoid muscle), or both. Ecchymosis resulting from blood accumulation may occur subcutaneously and/or submucosally. In some cases, infection may start and spread lingually and lead to an abscess or cellulitis either sublingually (intraoral) or submandibularly (extraoral), depending on the site of origin of the infection in relation to the origin of the mylohyoid muscle. Extensive bilateral cellulitis of the sublingual spaces may push the tongue backward or compress the pharynx, which may result in airway obstruction and necessitate a tracheotomy or cricothyroidotomy to maintain the airway. Functionally, the mylohyoid muscle raises the hyoid bone and floor of the mouth, or it can depress the mandible if the hyoid bone is fixed. The mylohyoid nerve that innervates the muscle is a motor branch of the inferior alveolar nerve. The latter is a branch of the mandibular nerve (V3).

WWW.HIGHDENT.IR

Genioglossus Muscle

The genioglossus muscle forms the bulk of the tongue. It takes origin from the superior genial tubercle. The anterior fibers insert into the dorsal surface of the tongue from the root to its tip, and the posterior fibers insert into the body of the hyoid bone. The genioglossus muscle is the main protruder of the tongue. The genial tubercles, particularly the superior pair, may be located near the crest of the alveolar ridge in Divisions C to D atrophic mandible. During the elevation of the lingual mucosa and before making an impression for a subperiosteal implant, one should be aware of the origin of this structure to avoid causing injury during the procedure. A portion of this muscle may be reflected from the genial tubercle. However, the muscle should not be completely detached from the tubercle, because this may result in retrusion of the tongue and possible airway obstruction. A branch of the hypoglossal nerve (cranial nerve XII) supplies the genioglossus.

Medial Pterygoid Muscle

The majority of the fibers of the medial pterygoid muscle take origin from the medial surface of the lateral pterygoid plate of the sphenoid bone. A small slip of muscle originates from the tuberosity of the maxilla. The muscle inserts on the medial surface of the angle of the mandible. The medial pterygoid muscle bounds the pterygomandibular space medially. This space is entered when an inferior dental nerve block is administered. Furthermore, during surgical procedures medial to the medial tendon of the temporalis muscle, such as in preparation for the insertion of unilateral subperiosteal implant, the pterygomandibular space is usually involved. Infection of this space is dangerous because of its proximity to the parapharyngeal space and the potential for spread of the infection to the mediastinum. Surgical exposure of tissue posterior to the maxillary tuberosity may also involve the medial pterygoid muscle because a portion of the muscle takes origin from the maxillary tuberosity. However, the numbers of fibers originating from the tuberosity are few in comparison with the fibers from the medial surface of the lateral pterygoid plate. A branch of the mandibular division (V3) of the trigeminal nerve innervates the muscle.

Lateral Pterygoid Muscle

Although the lateral pterygoid muscles rarely are involved in surgery for implants, their possible action in mandibular flexure or adduction during opening, as well as the effect of this phenomenon on subperiosteal implants or prosthetic full-arch splitting of mandibular implants in the molar region, warrants their consideration. The lateral pterygoid muscle consists of superior and inferior heads. The superior head takes origin from the infratemporal surface and crest of the greater wing of the sphenoid bone (roof of the infratemporal fossa), whereas the inferior head takes origin from the lateral surface of the lateral plate of the pterygoid process of the sphenoid bone. The fibers of the superior head run downward to insert on the anterior band of the temporomandibular joint (TMJ) disk (about 15% of its fibers) and the pterygoid fovea on the neck of the mandible. The fibers of the inferior head run upward to insert on the pterygoid fovea and also on the medial pole of the condyle, median capsule, and median collateral ligament of the TMJ disk. Because of the angulation of the lateral pterygoid muscles, many authors believe that the mandibular flexure causing alteration in the mandibular arch width, and sometimes pain in patients with a full-arch subperiosteal implant or prosthetic splint, may be caused by contraction of the lateral pterygoid muscles. The muscles normally function in protraction of the mandible and are innervated by a branch of the mandibular nerve (V3).

Temporalis Muscle

The temporalis is a fan-shaped muscle of mastication. It takes origin from the temporal fossa and inserts into the coronoid process of the mandible and the anterior border of the ramus as far inferiorly as the last molar at the site of the retromolar fossa. The muscle has two tendons that insert into the mandible. The superficial tendon is located laterally, and the deep tendon is inserted medially. The temporalis tendons and their associated fascia project anteromedially and inferiorly and serve as a common point for attachment for the temporalis, masseter, and medial pterygoid muscles, as well as for the transaction and superior pharyngeal constrictor muscles. The long buccal nerve and vessels are also located in this area. This temporalis tendon-fascial complex extends into what is traditionally called the *retromolar triangle*. Surgical exposure of the mandibular ramus medially would involve this tendon-fascial complex, with its contents of muscle fibers, nerves, and vessels, and may lead to transaction and postoperative pain. Incisions placed on the anterior ascending ramus for subperiosteal implants or harvesting bone from the external oblique and ramus should be inferior to the insertion of the two tendons of the temporalis muscle. The temporalis muscle is a powerful elevator and retractor of the mandible and, like all the major muscles of mastication, is innervated by a branch of V3.

Buccal or Facial Muscle Attachments

Mentalis Muscle

The external surface of the mandible in the midline presents a ridge indicative of the location of the symphysis menti (see Figure 22-5). The ridge leads inferiorly to a triangular elevation known as the *mental protuberance*. The base of the triangle is raised on either side into the mental tubercles. The mentalis muscles take origin from the periosteum of the mental tubercles and the sides of the mental eminence and insert into the skin of the chin and superiorly interdigitate with the orbicularis oris of the lower lip. Above the mentalis origin, the incisivus muscles take origin from small fossae called the *incisivus fossae*. Complete reflection of the mentalis muscles for the purpose of extension of a subperiosteal

WWW.HIGHDENT.IR

implant or symphyseal intraoral graft may result in "witch's chin," probably caused by the failure of muscle reattachment. If the muscle is completely detached to expose the symphysis, then an elastic bandage is applied externally to the chin for 4 days to help in the reattachment of the muscle. Another approach is to incise the muscle and leave a proximal portion attached to bone and reflect the distal portion. The distal and proximal portions should be approximated with resorbable sutures before suturing the mucosa. The mentalis muscle receives its nerve supply from the marginal (mandibular) branch of the facial nerve.

Buccinator Muscle

The fibers of the transaction muscle (cheek muscle) take origin from the lateral surfaces of the alveolar processes of the maxilla and the mandible in the area of the molars, the maxillary tuberosity, the pterygoid hamulus, the pterygomandibular raphe, and the retromolar fossa of the mandible. The insertion of the muscle is complex. The upper and lower fibers of the transaction blend with the fibers of the orbicularis oris at the upper and lower lips. The central fibers decussate at the modiolus before they insert into the orbicularis oris. The modiolus is the site of crossing and intermingling of fibers from the transaction muscle with fibers from the elevator and depressor muscles of the angle of the mouth. The modiolus forms a palpable node inside the angle of the mouth opposite the upper first premolar tooth. The parotid duct opposite the maxillary second molar pierces the transaction muscle. The buccopharyngeal fascia, which is a part of the visceral fascia of the neck, covers the muscle. Lateral to the fascia is the buccal pad of fat.

Some patients wearing lower subperiosteal implants complain of episodic swelling and pain at the site of origin of the transaction muscle, particularly after periods of heavy mastication or bruxism. Incision of these swellings does not usually yield exudate or purulence. The condition responds well to heat application, transactionary drugs, and rest. Although the cause for this condition is not known, one may speculate that myositis of a detached transaction muscle may cause it. The process of muscle reattachment to the implant surface or to a new site should be investigated. The buccal branch of the facial nerve innervates the muscle.

Masseter Muscle

This strong muscle of mastication covers the lateral surface of the ramus and angle of the mandible. The masseter has a dual origin from superficial and deep heads. The superficial head takes origin from the anterior two thirds of the lower border of the zygomatic arch. The deep head originates from the posterior one third of the zygomatic arch and the entire deep surface of the arch. The muscle inserts into the outer surface of the ramus of the mandible from the sigmoid notch to the angle. However, the muscle can be deflected easily during surgery to expose the bone for the ramus extension needed for lateral support of a subperiosteal implant. The space between the masseteric fascia and the muscle is a potential surgical space, known as the *masseteric space*, into which an infection may spread, causing myositis and trismus. The masseter is one of the main elevators of the jaw. The masseteric nerve provides the innervation of the muscle and is a branch of the mandibular division (V3) of the trigeminal nerve.

Innervation of the Lower Jaw and Associated Structures

Inferior Alveolar (Dental) Nerve

This nerve arises as a branch of the mandibular nerve (V3) in the infratemporal fossa (see Figure 22-6). It appears at the inferior border of the inferior head of the lateral pterygoid muscle, courses downward, and enters the mandibular foramen on the medial aspect of the ramus. Before the nerve enters the mandibular foramen, it gives numerous sensory branches that innervate the mandibular bone. These small nerves are in association with small vessels in neurovascular channels. The inferior dental nerve can run as one unit through the mandibular canal until it reaches the premolar region, where it divides into the mental and the incisive nerves. The mental nerve exits the canal through the mental foramen. In an excessively resorbed ridge, the mental foramen, with its contents of mental nerve and vessels, can be found on the crest of the ridge. When making an incision or reflection of the mucosa in this area, avoid injury to these vital structures. Knowledge of the position of the inferior dental canal in vertical and buccolingual dimensions is of paramount importance during site preparation for implants. The potential use of reconstruction techniques on computed tomographic scans and magnetic resonance imaging may increase clinicians' ability to locate the inferior dental canal precisely within the jawbone. Much less expensive techniques using panoramic cross-sectional tomographic imaging are also available. In some cases the inferior dental nerve may divide into two or three rami that occupy separate canals as the nerve travels in the mandible to supply the bone. These variations can be determined by conventional radiographic techniques, and the operator should modify the surgical approach and type of implant to avoid injury to the portion of the nerve that exits the foramen. Injury to the portion of the inferior alveolar nerve that remains in the atrophied bone and does not innervate soft tissues is of far less consequence. The nerves in the bone, when in contact with an implant, may account for the rare but occasional observation of tenderness, even though the implant is rigid and appears healthy. In addition, the fibrous tissue around these nerves may cause an increase in the amount of fibrous tissue around an implant that is inserted in contact with these structures.

Lingual Nerve

The lingual nerve is a branch of the mandibular nerve that is given off in the infratemporal fossa. It appears

WWW.HIGHDENT.IR

at the inferior border of the inferior head of the lateral pterygoid muscle anterior to the inferior alveolar nerve. It passes downward and forward between the ramus of the mandible and the medial pterygoid muscle. The nerve enters the oral cavity above the posterior edge of the mylohyoid muscle close to its origin at the third molar region. Because the nerve lies just medial to the retromolar pad, incisions in this region should remain lateral to the pad, and the mucosal reflection should be done with the periosteal elevator in constant contact with bone to prevent injury to the nerve. The nerve proceeds on the surface of the hyoglossus muscle and then crosses the duct of the submandibular gland medially to enter the floor of the mouth and the tongue. While in the infratemporal fossa, the nerve is joined by the chorda tympani nerve, which is a branch of cranial nerve VII. The chorda tympani nerve carries taste fibers from the anterior two thirds of the tongue and parasympathetic preganglionic fibers to the submandibular autonomic ganglion. The ganglion is connected to the lingual nerve on the surface of the hyoglossus muscle. The postganglionic neurons from the submandibular ganglion supply the submandibular and sublingual salivary glands. The branches of the lingual nerve in the oral cavity carry sensory information from the lingual mucosa, the mucosa of the floor of the mouth, and the anterior two thirds of the tongue. Improper reflection of a lingual mucoperiosteal flap may injure the lingual nerve and produce ipsilateral paresthesia or anesthesia of the innervated mucosa, loss of taste, and reduction of salivary secretion. The extent of involvement depends on the degree of injury to the nerve.

Nerve to the Mylohyoid

The mylohyoid motor branch of the inferior dental nerve is given off just before the nerve enters the mandibular foramen. This branch descends in a groove on the medial surface of the mandibular ramus and then appears in the submandibular triangle at the posterior border of the mylohyoid muscle. The nerve supplies the mylohyoid muscle and then proceeds on its surface with the submental artery (branch of the facial artery) until it reaches the anterior belly of the digastric muscle, which it also supplies. Because the nerve is so closely related to the ramus of the mandible, surgical intervention in this area may lead to injury of this important motor nerve.

Long Buccal Nerve

This nerve is a sensory branch of the mandibular division of the trigeminal nerve and is distributed to the skin and mucous membrane of the cheek and the buccal transact opposite the mandibular molar region. The nerve courses between the two heads of the lateral pterygoid muscle, then precedes medial to, or sometimes within, the medial temporalis tendon to gain access to the surface of the buccinator muscle. The nerve supplies the skin of the cheek and runs down to the level of the external oblique ridge, penetrates the buccinator, and spread its branches under the cheek mucosa, alveolar mucosa, and attached gingivae opposite to molar teeth. The implantologist who is planning to access the ramus for the purpose of excising a block graft should be aware of the buccal nerve and avoid injuring it. In addition, surgical manipulation in this area (e.g., during insertion of a subperiosteal implant) may injure this nerve.

BLOOD SUPPLY TO THE MAXILLA AND MANDIBLE

The head and neck region has an abundant blood supply, with many anastomoses (see Figure 22-7). The upper and lower jaws are no exception. The blood supply to both the mandible and maxilla is derived from a common source, the external carotid artery. The external carotid artery is a branch of the common carotid artery, which is a direct branch off the arch of the aorta on the left side and a branch of the brachiocephalic artery on the right side of the body.

The main artery supplying the mandible is the inferior alveolar (dental) artery, which serves as the nutrient artery to the bone and other tissues within the lower jaw. The bone tissue of the maxillae is supplied by branches of two major vessels, the posterior superior alveolar (dental) artery, and the infraorbital artery. The major branch of the infraorbital artery that supplies the maxilla is the anterior superior alveolar (dental) artery. The posterior superior alveolar and infraorbital arteries are branches of the maxillary artery, which is one of the two terminal branches of the external carotid artery.

General Concepts

The circulation of blood within long bones is centrifugal; that is, the blood circulates from the marrow (medullary) region outward through the cortical bone to end in vessels located in the periosteum and soft tissues associated with the bone.[8,9] The blood supply to the medullary region is by way of nutrient arteries, which are relatively large vessels that pass through the bone by way of nutrient canals to enter the marrow spaces. Within the marrow spaces, the nutrient artery forms a network of vessels called the *endosteal* or *medullary plexus*. Vessels from this plexus enter the cortical bone through Volkmann's canals and eventually reach the surface of the bone. While blood is passing through the cortical bone, numerous vessels are given off at right angles to these intraosseous vessels within Volkmann's canals. These branches are the vessels that are found within the haversian canals of the osteons.[8,9] Osteonal bone is the major type of bone found in the cortical bone of the jaws. Once the intraosseous vessels reach the outer surface of the bone, they anastomose with

WWW.HIGHDENT.IR

vessels within the fibrous layer of the periosteum or with arteries supplying the soft tissues. The network of vessels associated with the periosteum is called the *periosteal plexus*. The periosteal plexus in turn communicates with vessels that are supplying arterial blood to muscles and other soft tissues in the area.

The mandible and maxilla are membrane bones and as such do not develop in the same manner as long bones. Most researchers agree that the circulation of blood within the body of the mandible[10] and in the maxilla[11,12] is centrifugal under normal conditions. As in the long bones, endosteal and periosteal plexuses exist that are connected with one another.[12,13] In addition to these vascular networks, a periodontal plexus is found associated with the teeth.[12,13] When teeth are present, intraosseous vessels send branches into the alveolar processes (intraalveolar arteries), to the teeth (apical arteries), and to branches of the periodontal plexus. The intraalveolar arteries and periodontal plexus in turn connect with vessels of the periosteal plexus, as well as with vessels within the soft tissues surrounding the bone. Once a tooth is removed, its periodontal plexus is lost. When abnormal circulatory conditions exist within the mandible or maxilla, such as occlusion of the nutrient artery, the blood supply to the bone is reversed so that the direction of flow is from the outside to the inside of the bone.[10,11,14] This is called *centripetal circulation*.

Maxilla

The vessels that supply the maxilla are branches of the third part of the maxillary artery. The posterior superior alveolar artery leaves the maxillary artery and travels on the infratemporal portion of the maxilla, where it divides into several branches. Some of the branches enter alveolar canals within the posterior aspect of the maxilla to become intraosseous arteries, which supply the molar and premolar teeth and the lining of the maxillary sinus. Other branches of the posterior superior alveolar artery travel on the surface of the maxilla to supply the transact of the posterior maxillary teeth. Injury to this artery within the bone during lateral-approach sinus elevation procedures may cause hemorrhage, which requires coagulation or the use of bone wax to control the bone bleeding.

The infraorbital artery leaves the maxillary artery and enters the orbital cavity by way of the inferior orbital fissure. The artery runs in the infraorbital groove and later in the infraorbital canal. Both of these structures are located in the floor of the orbit. The infraorbital canal opens on the face as the infraorbital foramen. Within the canal the artery gives off the anterior superior alveolar artery, which descends through anterior alveolar canals to supply the maxillary anterior teeth and the mucous membrane of the maxillary sinus. The anterior and posterior superior alveolar arteries join together to form an arterial loop. The middle superior alveolar artery is rarely a separate branch.[15] The infraorbital artery also supplies branches to the maxillary sinus.[16]

Gingival, buccal, labial, palatal, nasal, and maxillary sinus blood vessels anastomose with the arterial networks associated with the maxilla. These vessels not only join with the periosteal plexus, but also penetrate the bone to connect with vessels of the endosteal and periodontal plexuses. In addition, abundant midline crossover is possible in the soft tissues of the palate and face.[13]

The mucoperiosteum of the anterior maxilla is supplied by branches of the infraorbital artery and the branches of the superior labial artery, which is a major branch of the facial artery.[13] The buccal mucoperiosteum of the maxilla is supplied by vessels of the posterior superior alveolar, anterior superior alveolar, and buccal arteries. Branches from the greater (anterior) palatine and the nasopalatine arteries supply the mucoperiosteum of the hard palate. The lesser (posterior) palatine artery supplies the soft palate. Communications of the lesser palatine arteries with the ascending pharyngeal branch of the external carotid artery and the ascending palatine branch of the facial artery are critical in many of the surgical orthognathic procedures that are performed on the maxilla.[12] In these surgical procedures, the major nutrient arteries to the maxilla are sometimes severed, but the blood supply is maintained by means of the anastomoses present in the soft palate. The vessels of the soft palate unite with vessels of the hard palate, which in turn communicate with the periosteal, periodontal, and endosteal plexuses of the upper jaw. Thus the vitality of the tissues of the maxilla is maintained through an arterial supply derived entirely from vessels that normally supply the soft palate.

Mandible

The major artery supplying the blood of the mandible is the inferior alveolar artery. The artery enters the medial aspect of the ramus of the mandible and courses downward and forward within the mandibular canal to enter the body of the mandible. The artery branches in the premolar region to give rise to two terminal branches: the mental and incisive arteries. The incisive artery continues medially within the body to anastomose with the artery of the opposite side. This artery is often severed during the harvest of a monocortical symphyseal block of bone for grafting resorbed ridges. Crushing bone around the vessel or using bone wax easily controls the bleeding. The mental artery exits the body of the mandible through the mental foramen and supplies the region of the chin and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a lingual branch, which supplies blood to the oral mucosa.[16]

Studies in animals have demonstrated that the coronoid process, the condylar process, and the angle of the mandible are supplied by arteries that provide blood

WWW.HIGHDENT.IR

to the muscles that attach to these sites.[16] Studies of human cadaver material show that the condylar process is supplied by the vascular network of the TMJ joint capsule and the lateral pterygoid muscle. In addition, researchers found that vessels from the temporalis muscle supplied the coronoid process exclusively, and the inferior alveolar artery supplied the angle of the mandible, as well as the muscles attached to the area. The same researchers found that the vessels that supply the pterygomasseteric sling (i.e., the medial pterygoid and masseter muscles) also supply the anterior portion of the ramus.[17] Empirical findings from mandibular osteotomy procedures in humans support many of these findings.[18] Thus the repositioning of the inferior alveolar artery laterally, a procedure that may be needed in some cases before implant insertion, should not eliminate the blood supply to the bone in this region (see the discussion that follows).

Changes in Blood Supply to the Mandible with Age

Although the normal circulation within the body of the mandible is centrifugal in young individuals, the direction of blood flow may reverse with aging. It has been shown that the inferior alveolar artery is susceptible to arteriosclerotic changes and tends to become tortuous and narrow with age.[19,20] Blockage of the inferior alveolar artery occurs years before any clinical evidence of blockage in the carotid vessels is found. Angiographic studies of living human subjects of all ages demonstrated blockage of the inferior alveolar artery in 79% of all individuals studied, and in 33% of the patients arterial flow was absent.[20] The incidence of absence of flow in the inferior alveolar artery increased with age. The reduction or absence in flow within the inferior alveolar artery may be associated with tooth extraction.[20] Studies in completely edentulous humans indicate that the inferior alveolar artery degenerates to such an extent as to be negligible in the supply of blood to the mandible.[19] In these cases the blood supply to the bone and internal structures was dependent on the connections with the external blood supply located within the periosteum and soft tissues associated with the mandible.[19,20] Major arteries that probably supply blood to the mandible after the interruption of the inferior alveolar artery blood flow include the mental artery,[14] the mandibular branch of the sublingual artery,[14] the facial artery,[10] and muscular branches of the maxillary artery. These anastomoses are critical in surgical procedures in which mucoperiosteal flaps are created in the mandible. The changes in pattern of blood flow to the atrophic mandible are of special importance to implant dentistry. Mucoperiosteal flap reflection for subperiosteal implant usually exposes 75% of the body of the mandible and approximately 50% of the inferior one third of the rami. Dehiscence of the mucosa at the incision lines has been reported. The reduction in atrophied bone blood supply may be a contributing factor. Onlay grafts from the iliac crest to severely atrophied mandibles are also associated with occasional incision line opening postoperatively. Limitation of surgical reflection of muscles that attach to the bone improves blood supply but may complicate primary closure without tension. However, muscle attachments at the basal bone of the mandible, which are not in the way of the graft placement, should not be reflected. In addition, endosteal implants placed in an atrophied anterior mandible may have less blood supply to the interface and may require longer time for load-bearing bone to develop. Misch has suggested 5 months of healing in very dense bone when found in an atrophied anterior mandible.[21] These speculations, of course, require experimental verification. Similar blood flow reversal with age has not been reported in the maxilla, but final comment concerning blood flow in the aged edentulous maxilla awaits further investigation.

Implantologists may encounter neurovascular bundles such as the infraorbital, incisal, greater palatine, anterior, middle, and posterior superior alveolar nerves in the maxilla (e.g., during antral augmentation procedures or mucoperiosteal flap reflection) and the mental nerve, inferior dental nerve, and the lingual nerve in the mandible (e.g., during placement of root or blade implants or reflection of microperiosteal flaps). Stretching, compression, partial resection, or total transaction can mechanically injure the nerve.

Factors that affect nerve response to mechanical injury include the following:

1. Size and number of funiculi (nerve bundles) within the nerve trunk
2. Funicular pattern: The branching within the nerve trunk will lead to an increase in density or number of nerve fibers per cross section of the nerve. Therefore injury to the nerve at one spot may cause damage to more fibers than to the adjacent area of the nerve that has less funicular branching.
3. The amount of epineural tissue: The connective tissue that surrounds the nerve is called the *epineurium*. The thinner the epineurium is, the greater the possibility is that partial injury to the nerve could damage the nerve fibers.
4. Position of the nerve fibers in the nerve trunk: The peripheral fibers leave the nerve first, whereas the central fibers innervate the most distal tissue. If a patient develops paresthesia of the lower lip after surgical placement of implants in the molar region, then it will mean that the nerve damage went through the center of the nerve to affect the mental nerve fibers.
5. Physiologic susceptibility: For an unknown reason, the motor fibers respond differently when subjected to mechanical deformation as compared with sensory fibers.

Nerve fibers of the peripheral nervous system (PNS) show greater capacity for regeneration than nerves of

WWW.HIGHDENT.IR

the central nervous system (CNS). The axons of both myelinated and unmyelinated fibers in the PNS are surrounded by Schwann cells, which are covered by basal lamina. They later provide a continuous tube, even after the nerve fiber is cut into distal and proximal segments. The proximal segment is still connected to a living nerve cell body, whereas the distal segment gradually degenerates and eventually disappears. This is known as *wallerian degeneration*. The Schwann cells of the distal segment proliferate and form a cell strand known as a *Schwann cell column* or *band of Biingner* within the basal lamina tube.[22] The Schwann cells also become phagocytic, and along with macrophages they clean the distal segment from degenerating axons. Sprouting of new axons takes place approximately 4 weeks after injury, and it takes 5 weeks for a sizeable number of axons to occupy the distal segment. The excess sprouts degenerate, and one fiber finds its way into the distal segments. If regenerating axons evade the Schwann cell column and enter the connective tissue, then they cease to grow after elongation of a few millimeters. The Schwann cells and the basal lamina are indispensable for axonal regeneration because they retain growth factors. The Schwann cells also provide new myelin for the regenerating fibers, although the conduction property is less efficient and the functional recovery may never be complete. The sprouting stage may cause pain to the patient, and the area may be sensitive to touch. The rate of recovery will depend on the type of injury (e.g., a crushed nerve regenerates faster than a severed nerve).

Chapter 23

Spread of Dental Infection in the Head and Neck

Mohamed Sharawy, Carl E. Misch

SIGNIFICANT COMPLICATIONS AND IMPLANT DENTISTRY

Few significant complications are associated with implant dentistry. However, identification of potentially life-threatening problems is in the best interest of all concerned. Death in dental practice has been related to air emboli and spread of infection. These complications have a similar foundation: the vascular-lymphatic network and fascial planes. Routes associated with these potential situations are reviewed in this chapter.

The three stages in the development of infection in the head and neck region are the development, extension, and complication stages. The development stage permits the infection to spread through the bone and form an abscess under the periosteum (subperiosteal abscess). This may occur with teeth or implants. When related to an endosteal implant, it is usually associated with a device that is splinted to rigid implants or teeth in the same prosthesis. A subperiosteal implant also may be associated with this complication without the infection coming from within the bone. Most often, before subperiosteal abscess develops, purulent exudate may be found around the permucosal regions of the implant. On rare occasions, a fibrous tissue at the interface between implant and bone may become infected, and the infection may spread through the bone from a retrograde direction. For the most part, implant infection begins from the permucosal region and spreads in an apical direction. Also, an implant placed in an infected immediate extraction site may become involved in retrograde infection.

The extension stage of the development of infection occurs when the subperiosteal abscess penetrates the periosteum and extends to the fascial spaces, producing a cellulitis or fascial abscess. Mandibular subperiosteal implants most often produce this entity in the posterior region, along the posterior body of the mandible. In maxillary subperiosteal or sinus graft surgeries, this stage of infection may develop along the lateral aspect of the maxilla just below the zygomatic arch. The source of the infection is primarily from the maxillary sinus and often has an anaerobic component. On rare occasions, this extension stage has been observed in the submental region from endosteal implants placed through the inferior border of the mandible.

The complication stage results when the infection spreads and causes cavernous sinus thrombosis, brain abscess, neck and mediastinal involvement, pleurisy, or pericarditis. These complications have been reported following sinus surgeries, primarily when the antrum was infected at the time of surgery.

The principal routes for the spread of dental infection are through the following four mechanisms:

1. Bacteremia permits the infectious process to spread by way of blood.
2. Infection may spread to the walls of the veins, which may also thrombose and create a condition referred to as *thrombophlebitis*. Lack of valves in the head venous system allows retrograde flow of blood and may involve the cavernous sinus, pterygoid, and pharyngeal plexuses with infected thrombi.
3. The lymph vessels are very prevalent in the head and neck. They commonly drain the infected site and carry the infection to regional lymph nodes. The nodes become tender, enlarged, soft, and mobile on palpation. This is called *lymphadenitis*.
4. Once the infection is outside the bone, the loose areolar connective tissue produces a path of least resistance into the various surgical spaces of the head and neck and mediastinum. The muscle attachment and fascial compartments limit or direct the path of infection. Infections that may occur after surgeries involving reflection of muscle attachments may permit the infection to spread more easily into these surgical spaces. Therefore it is prudent to prophylactically cover patients with antibiotics when larger

WWW.HIGHDENT.IR

regions of soft tissues are reflected beyond muscle attachments.

Subperiosteal implants often extend beyond muscle attachments or fascial planes. Infections associated with primary struts should be closely supervised and aggressively treated because the infection may spread by continuing beyond these structures. Endosteal implants are most often positioned beyond the apices of natural teeth. As a result, infections beyond their apices may perforate bone beyond the usual limiting borders associated with the roots of teeth and may result in subcutaneous rather than submucosal infection.

PATHOLOGIC ENTITIES

The definitions of specific terms that describe infections of the head and neck provide keys to methodology of treatment and improved communications. An acute cellulitis involves diffuse inflammation of the areolar connective tissue and loose subcutaneous tissues. Lymphadenitis is a condition in which the regional lymph nodes become inflamed, enlarged, and tender. The node may become suppurated, break through the capsule, and involve the surrounding tissues. Abscess formation results when tissues break down and leukocytes die, thus forming pus. Staphylococci and streptococci are the usual bacteria involved in this process; however, a more varied population is prevalent in sinus infections. Phlegmon is any cellulitis that does not go on to suppuration. In this condition, the inflammatory infiltration of the subcutaneous tissue leads to accumulation of foul-smelling, brownish exudate. Hemolytic streptococci are usually present. A chronic cellulitis follows an acute cellulitis and may be the result of inadequate treatment or a subvirulent organism with no suppuration. A chronic abscess is a well-encapsulated entity caused by a subvirulent organism. In this case, a bone sequestrum or retained root tip is the more common source of the infection. A chronic skin fistula is a sign of retained focus of infection and, in some cases, a more serious condition of bone and bone marrow inflammation called *osteomyelitis* (Figure 23-1). This has been observed in the mandible and is associated with infection of both endosteal and subperiosteal implants in patients who have poor dental awareness and lack of implant maintenance. A noma starts as a gangrenous stomatitis and spreads to adjacent bone and muscles, causing lysis and necrosis of tissue. This rare condition perforates the cheek, floor of the mouth, or both, and is usually seen in debilitated individuals.

MAXILLARY INFECTIONS

Acute suppurative periapical abscesses in the maxilla may penetrate the alveolar bone and form a subperiosteal abscess under the periosteum. If the abscess penetrates the periosteum above the attachment of the buccinator muscle, it causes a buccal abscess.

If the abscess continues to spread, it may involve the skin, forming a cutaneous abscess. The infection may progress superiorly and involve the temporal region. Downward extension may involve the submandibular space. If the abscess perforates the buccal alveolar bone and periosteum below the attachment of the buccinator muscle, the abscess wall appears intraorally in the buccal vestibule and forms a gingival or alveolar abscess.

Palatal extension of the infection is rare. Usually it is from lingual roots of the upper molars, forming a palatal abscess. On occasion, an implant may perforate the palatal bone and cause an infection that may be evident at a later date.

The maxillary sinus may become invaded by an infection of the maxillary teeth, resulting in an acute sinusitis. Radiographs reveal a clouded sinus resulting from accumulation of inflammatory exudates within the sinus cavity. Sinus graft surgeries may penetrate an already infected antrum, or one that becomes infected shortly after surgery, with subsequent extension of the infection into the whole implanted region. The risk of sinus infection immediately following surgery is approximately 3%.

The loose, fat-containing connective tissue of the lips and cheeks is continuous and is traversed by the muscles of facial expression, which arise from the bones of the face, traverse the subcutaneous tissue, and end in the skin. These muscles, with their thin perimysium, play a role in directing the spread of infection. Dental or implant abscesses that erode and perforate the facial alveolar compact bone sometimes find their way through the subcutaneous tissue and produce remarkable swelling of the upper lip and cheek and may spread to the lower and upper eyelids due to the lack of fascial barriers on the face (Figure 23-2).

Most often, maxillary dental infections involve four regions of the maxilla: the upper lip, canine fossa, buccal space, and infratemporal space. The most common

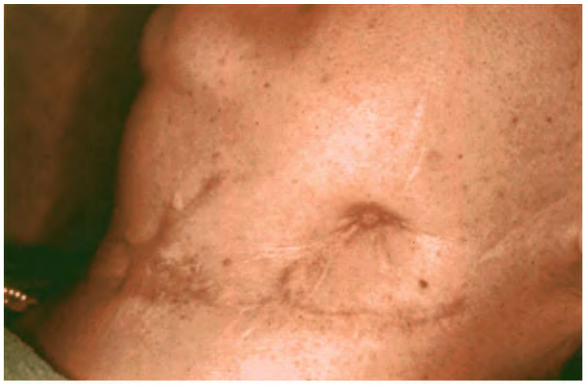

Figure 23-1 Multiple sinuses in a case of osteomyelitis of the mandible. The patient has a failing subperiosteal implant.

WWW.HIGHDENT.IR

Figure 23-2 Facial infection secondary to spread of dental infection. Once infection reaches the facial space, it can spread to the eyelids.

maxillary implant-associated infection is in the buccal space (Figure 23-3).

Lip

The lip contains weak and small muscles, but this does not limit the spread of infection. Infection of the base of the upper lip is most often caused by infection of the maxillary central region, which first produces a collateral edema and then a cellulitis of the upper lip. The abscess usually forms on the oral side of the orbicularis oris muscle in the buccal sulcus and may extend upward between the levator anguli oris and levator labii superioris. The side of the nose and lower lid of the eye may then swell. In these cases, a potential exists for the development of a cavernous sinus thrombosis by spread of infection through the angular vein to the superior ophthalmic vein to the cavernous sinus. Infected maxillary subperiosteal implants may result in infected onlay grafts and would have the potential for spreading into facial veins and the cavernous sinus.

Treatment is usually by incision and drainage. A horizontal incision is made down to the bone in the apex area of the involved tooth, implant, or piece of bone graft. The loose bone is then removed, or the tooth is treated endodontically and a rubber drain is inserted within the incision. An implant is evaluated for mobility and, if present, is usually extracted. A stable implant may remain and be evaluated after the infection is controlled.

Infection of Canine Fossa

Infection of the canine fossa is commonly caused by the spread of infection from the maxillary canine and premolars. It may also be found when sinus grafts are performed in this region. The nasolabial fold is obliterated, and edema of the eyelids results. The infection forms between the levator labii superioris and orbicularis oris anteriorly and the buccinator posteriorly. This same space can be drained intraorally by making an incision at the fluctuant swelling in the buccal sulcus and the insertion of a clamp to drain the canine space superiorly. Sinus-related infections are most often controlled with antibiotics. However, if the infection becomes localized, drainage is indicated.

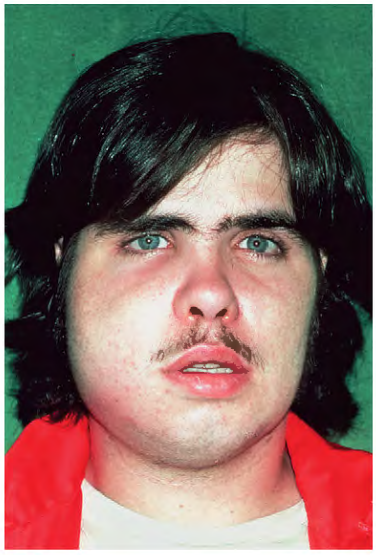

Figure 23-3 Buccal surgical space infection with spread to the submandibular space. *(From Hupp JR, Tucker MR, Ellis E:* Contemporary oral and maxillofacial surgery, *ed 5, St Louis, 2009, Mosby.)*

Infection of Buccal Space

The buccal space lies between the skin of the cheek and buccinator and contains a fat pad that extends upward and inward between the muscles of mastication, filling the retrozygomatic fossa and infratemporal space.

Abscesses of the second and third maxillary molars above the attachment of the buccinator frequently involve the buccal space. The infection may extend superiorly to the temporal space, inferiorly to the submandibular space, or posteriorly to the masticatory spaces (Figure 23-4).

Skin incision at the highest point of fluctuance, with blunt dissection to obtain adequate drainage of the space, is recommended. Anesthesia for this procedure is difficult to achieve, and a referral to an experienced practitioner is strongly suggested. A decision has to be made in individual cases as to whether the maxillary implants should be removed or conservatively treated by curettage of the infected granulation tissue with close monitoring of the progress of healing. When infections from implants extend to the infratemporal space, strong consideration should be given to their removal, rather than attempting to salvage the implants and prosthesis.

Infratemporal Space

The infratemporal space lies below a horizontal plane drawn through the zygomatic arch and is bounded laterally by the ramus of the mandible and medially

WWW.HIGHDENT.IR

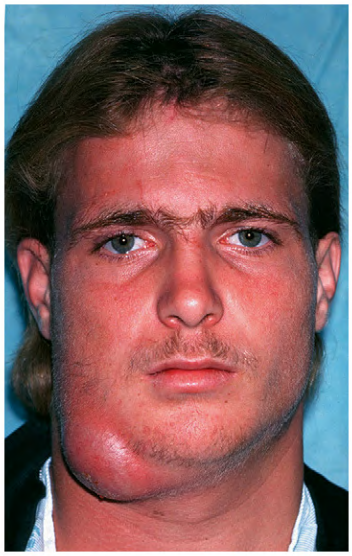

Figure 23-4 This patient had trismus and pain on swallowing. Infection spread to the submandibular, and pterygomandibular spaces. This patient needs to be admitted to the hospital for multiple incisions and drainage. *(From Hupp JR, Tucker MR, Ellis E:* Contemporary oral and maxillofacial surgery, *ed 5, St Louis, 2009, Mosby.)*

by the medial pterygoid muscle. The infratemporal space includes the pterygomandibular space between the ramus and medial pterygoid muscle, postzygomatic space, and pterygomaxillary fossa.

Infections of the maxillary teeth or endosteal implants extending above the attachment of the buccinator muscle can spread into the postzygomatic or infratemporal space. Infections of the mandibular second and third molars are more likely to infect the pterygomandibular part. Infection of this space, fortunately, is not common. It is serious because of the complications that can follow.

Infratemporal space infection may involve the pterygoid plexus of veins and subsequently the cavernous sinus. The infection may also spread through the infraorbital fissure and cause periorbital infection.

The temporal fossa, which is almost completely filled by the temporalis muscle and covered by the temporal fascia, may become involved from extension of an infection of the infratemporal space. Such involvement causes a painful swelling of the region, elevating the temporalis fascia and preventing opening of the jaw.

Incision and drainage constitute the treatment of choice. Whether an intraoral or extraoral incision is made will depend on the presence or absence of trismus, whether the intraoral approach is adequate for drainage of deep pockets of pus, and whether the maintenance of drainage from the intraoral site would constitute a health hazard from aspiration.

Incision and drainage by an intraoral approach is usually made by incising the mucosa medial and parallel to the ascending ramus along the anterior border of the medial pterygoid muscle. The surgical spaces are then approached by blunt dissection in a posteromedial direction for the pterygomandibular and parapharyngeal spaces, in an upward direction for the temporalis space, and posterolaterally into the masseteric space. Extraoral incision at the angle of the mandible is recommended for more adequate drainage of these spaces. The temporalis space may also be drained by a skin incision parallel and superior to the zygomatic arch to avoid injury to the temporal and zygomatic branches of the facial nerve.

MANDIBULAR INFECTIONS

In mandibular dental or implant infections, the mylohyoid muscle attachment on the medial surface of the mandible and the buccinator attachment on the outer surface of the mandible play an important part in limiting or directing the spread of infection.

The line of origin of the mylohyoid muscle begins close to the lower border of the mandible and ascends posteriorly and diagonally across the inner surface of the mandible to the socket of the last molar. The apical level of the roots of the incisors, canines, premolars, and first molar is always above the mylohyoid line, whereas the third molar consistently reaches below the line and the second molar does so sometimes. If a periapical abscess of the incisors, canines, and premolars perforates the lingual plate of the mandible, it will involve the floor of the mouth above the mylohyoid muscle and cause sublingual abscess or cellulitis. If the infection originates from the third molar (and sometimes the first and second molars) below the mylohyoid muscle origin, the subcutaneous connective tissue of the submandibular space is invaded with the potential for the infection to spread posteriorly and medially to the parapharyngeal space, causing a descending cervical cellulitis. A lingual perforation of the periapical abscess of the mandibular molars is an exception because of the lingual inclination of these teeth; the root tips are positioned closer to the buccal plate. Endosteal implants in the anterior and posterior regions usually extend beyond the mylohyoid muscle attachment and often are positioned more lingually than the roots of teeth. Infections may therefore penetrate the bone and appear in the submandibular space. Subperiosteal implants also extend below the muscle attachments and favor the spread of infection into the submandibular space.

Mandibular infection has the potential to spread to the submandibular space, the sublingual spaces, the parotid space, the masticatory spaces, and the parapharyngeal space. The infection may spread from the head to the neck region by following the carotid sheath, the perivisceral space, and perivertebral space—all of which communicate with the superior mediastinum. When infections extend into the sublingual space, very aggressive monitoring of the tongue size and position is needed to avoid possible obstruction of the airway. Implantologists need to be aware of these life-threatening complications, and early implant extraction may be indicated. It is often more prudent to remove

WWW.HIGHDENT.IR

the implants rather than place the patient at risk with the ailing, failing device.

Circumscribed Mandibular Abscess

Circumscribed mandibular abscess generally is caused by a mandibular premolar and is usually seen at the side of the mandible, anterior to the facial artery. It is not usually palpable under the skin and at times is closely adherent to the mandible. The abscess is usually drained by a skin incision made parallel with the lower border of the affected area of the mandible, followed by a blunt dissection with a hemostat and placement of a rubber drain. This region may also be involved with a mandibular subperiosteal implant.

Subperiosteal implants may cause swelling in the region not associated with infection. Commonly, traumatic inflammation caused by the implant casting rubbing against the buccinator muscle or bone may cause local swelling. Incision and drainage is not indicated. The condition is usually caused by hyperfunction resulting from overly aggressive eating episodes. Heat application coupled with brief avoidance of mastication on the affected side usually reduces the swelling and returns the region to normal within 1 to 3 days.

Infection of the Submandibular Space

The submandibular space is frequently involved in the spread of dental infections, osteomyelitis, and fracture of the angle of the mandible. The submandibular space is found between the mylohyoid muscle and the skin and is bound by the posterior part of the mandible laterally.

The involvement of this space is usually from infection related to deciduous or permanent molars extending through the bone below the mylohyoid muscle or descending beneath the periosteum, from a periodontal abscess or pericoronitis, or from the area around the outer aspect of the mandible. Subperiosteal or endosteal implants may be placed into or close to the sublingual space. The lingual strut of the first molar post of a subperiosteal implant should be placed above the mylohyoid attachment when possible to limit any potential infection from spreading directly into the submandibular space. Sublingual infection may also migrate on the surface of the mylohyoid muscle and descend beyond its posterior border to the submandibular space. Conversely, infection from the submandibular space may spread around the posterior part of the mylohyoid into the sublingual space to the adjacent parotid space and parapharyngeal space. When both the submandibular and sublingual spaces are involved, the floor of the mouth and tongue are elevated. In these cases, the tongue may retrude and cause difficulty in breathing.

Submandibular infection usually is drained by a skin incision 1 cm below the inferior border of the mandible, posterior to the facial artery. The areas anterior and posterior to the submandibular gland are explored by a hemostat. A rubber drain is placed.

Infection of the Masticatory Space

The masseteric space is found between the fascia and the masseter muscle (see Figure 23-4). The lateral wings of the subperiosteal implant extend along the lateral portion of the ramus. Infection of the ramus permucosal posts may extend into this region. The pterygomandibular space is found between the ramus of the mandible and the medial pterygoid muscle. The temporalis space is found between the thick temporalis fascia and the temporalis muscle.

Infection in the buccal space may spread in a posterolateral direction to involve the masseteric space or in a posteromedial direction to involve the pterygomandibular space, or it may migrate superiorly along the temporalis tendons to involve the temporalis space. Infection of the muscles will lead to myositis. The patient usually complains of trismus and pain on opening the jaw. Infection from the pterygomandibular space commonly spreads to the parapharyngeal space and may cause pain on swallowing.

Infection of the Sublingual Space

Two sublingual spaces lie above the mylohyoid on each side of the median raphe. There is no natural barrier to the spread of infection from one sublingual space to the other. The sublingual abscesses are generally derived from an infected tooth in the anterior part of the jaw. The infection emerges on the lingual side of the mandible above the mylohyoid. This will lead to swelling of the floor of the mouth, elevation of the tongue, and difficulty and pain on swallowing.

The sublingual space is drained by an incision made at the base of the alveolar process of the mandible in the lingual sulcus so that the sublingual gland, lingual nerve, and submandibular duct will not be injured. A hemostat is passed down between the sublingual gland and the geniohyoid muscle. If no pus is found, a subperiosteal abscess on the inner surface of the mandible should be investigated; if found, incision of the periosteum is made. The drain should be sutured, as it may become displaced by the tongue. The sublingual spaces can also be accessed by a skin incision in the area of the submental triangle. The mylohyoid muscles, which form the floor of the triangle, should be incised, and a hemostat can be introduced in the midline to drain the sublingual spaces (Figure 23-5).

Infection of the Submental Space

The submental space lies within the boundaries of the submental triangle, which is bound by the anterior

WWW.HIGHDENT.IR

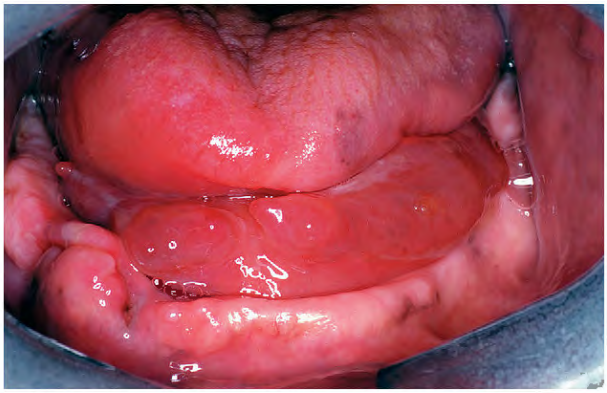

Figure 23-5 Sublingual abscess spreading into right and left surgical spaces. *(From Hupp JR, Tucker MR, Ellis E:* Contemporary oral and maxillofacial surgery, *ed 5, St Louis, 2009, Mosby.)*

bellies of digastric muscles laterally and the hyoid bone inferiorly. Pus accumulates between the skin and platysma inferiorly and the mylohyoid muscle covered by suprahyoid fascia superiorly. Posteriorly, the space extends to the submandibular space. The infection forms an abscess or cellulitis emerging below the chin.

This space is drained by transverse incision below the mandible along skin folds, and a hemostat is inserted forward and backward to open the entire area.

Ludwig's Angina

The distinct clinical entity of Ludwig's angina is characterized by a deep, tender swelling of both the submandibular and sublingual spaces, swelling of the floor of the mouth, and elevation of the tongue.

This condition is usually a nonsuppurative cellulitis that originates in the submandibular space and spreads rapidly toward the floor of the mouth. It is caused almost exclusively from mandibular molar teeth because their root apices may reach below the mylohyoid ridge. An apical infection may spread directly to the submandibular space, and from there it may extend to adjacent regions by continuity. The subperiosteal implant does not extend below this structure beyond the first molar, so the risk of infection below the muscle is reduced. The main danger from this infection is asphyxiation as a result of rapidly increasing respiratory embarrassment caused by swelling and displacement of the tongue backward and edema of the glottis. Early in the disease there is no pus, and thus no fluctuation. If pus does form, it will be found between the mylohyoid and geniohyoid or between the geniohyoid and genioglossus. This will make swallowing and speech more difficult.

Bilateral incisions of the submandibular spaces with a blunt dissection into the submental region are needed. An incision into the submental space through the mylohyoid muscle should also be made. A clamp is inserted toward the base of the tongue to explore the sublingual space. A through-and-through drain should be placed between the submandibular spaces.

Infection of the Parotid Space

The parotid space contains the parotid gland and lies between two layers of deep fascia. It is in direct communication with the parapharyngeal and submandibular spaces. The infection may start within the parotid, as in septic parotitis, or result from spread of dental infection. The condition causes pain on eating and swallowing, and there is purulent discharge from the parotid duct.

To establish drainage of the parotid space, an incision is made around and below the angle of the mandible. The space is entered with a clamp, and a drain is placed.

Infection of the Parapharyngeal Space

The parapharyngeal space extends upward between the lateral wall of the pharynx and the medial surface of the medial pterygoid muscle. Behind the medial pterygoid muscle, the parapharyngeal space widens considerably and reaches laterally to the styloid process with its muscles, and to the deep surface of the parapharyngeal space around the anterior and posterior borders of the medial pterygoid muscle. The patient usually experiences difficulty and pain during swallowing. The swelling of the tonsillar area can usually be seen intraorally. The infections may easily disseminate either upward through various foramina at the base of the skull, producing brain abscesses, meningitis, or sinus thrombosis, or downward along the carotid sheath or the visceral space toward the mediastinum.

This space is more commonly involved from acute infection around the mandibular third molar or from extension of pterygomandibular abscess, pharyngitis, tonsillitis, and parotitis.

The lateral or parapharyngeal abscess can be drained by intraoral incision of the lateral pharyngeal wall if there is no trismus or by skin incision at the anterior border of the sternocleidomastoid muscle at the level of the hyoid bone, followed by dissection along the posterior border of the posterior belly of the digastric muscle to the parapharyngeal space.

Infection of Perivisceral and Perivertebral Surgical Spaces of the Neck

Deep cervical fascias surround the pharynx, larynx, trachea, esophagus, and thyroid gland and extend through the thoracic inlet into the mediastinum. There is a potential space between the fascia and the viscera, called the *perivisceral space*. The peripharyngeal, peritracheal, and periesophageal areas are all parts of the perivisceral space. Cervical vertebrae and perivertebral muscles are similarly surrounded by a deep cervical fascia known

WWW.HIGHDENT.IR

as the *perivertebral fascia*. There is a potential space between the perivertebral fascia and the perivertebral muscles known as the *perivertebral space,* or "dangerous space." The space continues into the mediastinum. Infection in the perivisceral or perivertebral spaces commonly spreads into the thoracic mediastinum and may cause pleurisy, pericarditis, and lung abscesses. Patients who suffer from parapharyngeal space infection should be referred to a specialist for urgent incision and drainage. Those dangerous spaces can be accessed through an incision of the skin along the anterior border of sternocleidomastoid muscle below the hyoid bone, followed by retraction of the muscle and carotid sheath, blunt dissection of the spaces, and placement of a drain. A tracheostomy or cricothyroidotomy is also performed if there is respiratory obstruction caused by the spread of infection to the peritracheal space.

Infection of the Carotid Sheath

The carotid sheath is a fascial condensation around the internal jugular vein, the vagus nerve, and the common and internal carotid arteries. It lies deep to the sternocleidomastoid.

The infection could spread to the carotid sheath from the submandibular space, infratemporal space, parotid space, and parapharyngeal space. Involvement is frequently associated with thrombosis of the internal jugular vein. This condition is serious, as there is no anatomical barrier to downward spread of infection to the mediastinum. An incision is made over, and extending below, the region involved along the anterior border of the sternocleidomastoid muscle, generally above the omohyoid muscle. If the internal jugular vein is thrombosed, it is ligated below its lowest limit of involvement to prevent further descent of the infection.

SIGNIFICANT COMPLICATIONS OF INFECTIONS IN THE FACE AND NECK

Cavernous Sinus Thrombosis

Cavernous sinus thrombosis is one of the major complications of infection of the head and neck. It may occur from infection of the upper or lower jaw. The prognosis was poor before the advent of penicillin; 90% to 100% of patients died of advanced toxemia or meningitis in 5 days. The dentist should be able to recognize the early signs of cavernous sinus thrombosis and refer the patient immediately for hospital care by a specialist.

Cavernous sinus thrombosis may be caused by direct extension from the infratemporal space through the foramina or through the bone by osteomyelitis caused by staphylococcal infection or by venous thrombi originating in the venous system. One of three pathways is usually involved: the facial vein, angular vein, or superior ophthalmic vein to cavernous sinuses; the deep facial vein, pterygoid plexus of veins, and emissary veins to cavernous sinuses; or the maxillary vein (drains upper and lower jaws) to pterygoid plexus of veins to cavernous sinuses.

The clinical signs and symptoms usually include all or a combination of some of the following: edema of the eyelids; hemorrhagic skin of nose and eyelids; ophthalmoplegia caused by involvement of cranial nerves III, IV, and VI; burning and tingling sensation of the forehead caused by involvement of nerve V_1; proptosis caused by periorbital edema; or chills, fever, restlessness, and severe headache.

Brain Abscess

A brain abscess may result from bacteremia or by direct spread of infection and may occur as single or multiple abscesses, not always on the same side as the involved tooth or implant. Clinical signs consist of convulsive seizure, headache, stupor, slurred speech, and hemiparesis. Meningitis may develop, and death may occur in 2 to 6 weeks. Brain abscess has been reported after sinus surgery.

LYMPHATIC SPREAD OF INFECTION

The lymphatic circulation begins with blind-ended capillaries that drain the tissue fluid and carry it to larger vessels and eventually to two main lymphatic ducts (left thoracic and right common lymphatic ducts), which drain finally into the venous blood at the root of the neck. The lymphatic vessels are interrupted by lymph nodes. Each region of the body has a primary lymph node group that drains it. The knowledge of the regional nodes permits the diagnosis of the hitherto hidden site of infection. Although the sites of regional lymph nodes are fairly constant, there is great variability in their number and size.

Submental Lymph Nodes

The unpaired group of submental nodes lies between the hyoid bone and the anterior bellies of the digastric muscles in the submental triangle. They drain the middle part of the lower lip, the skin of the chin, and the tip of the tongue. Lymph from the lower incisors and the gingiva in this region flows at least partly into the submental nodes.

Submandibular Lymph Nodes

The submandibular lymph nodes are located in the submandibular triangle between the two bellies of the digastric muscle and the lower border of the mandible. They can be subdivided into an anterior, a middle, and

WWW.HIGHDENT.IR

a posterior group, each represented by one large or two or more smaller lymph nodes. Some of these nodes located in the submandibular niche (the space between the mylohyoid muscle and the medial surface of the mandible) are hidden by the body of the mandible and can be palpated only by pressing the finger upward on the inner surface of the lower jaw. This manipulation is facilitated with the patient's head tilted forward and toward the side being examined.

The anterior submandibular node or nodes are found along the submental vein close to the chin. The middle group is always represented by two or three small nodes situated around the anterior facial vein and facial artery, above the submandibular salivary gland. The posterior group of submandibular lymph nodes is located behind the anterior facial vein.

The submandibular lymph nodes collect the lymph of the upper and lower teeth with the exception of the incisors of the lower jaw; the lymph from the upper and lower lips with the exception of the middle part of the lower lip; the lymph from the anterior parts of the nasal cavity and palate; and finally, the lymph from the body of the tongue. Because of their relation to the teeth, the submental and submandibular lymph nodes are sometimes described as *dental lymph nodes*. The submandibular lymph nodes drain into the superficial and deep cervical lymph nodes.

Accessory lymph nodes are frequently associated with the submandibular lymph nodes and are closely related to the submandibular salivary gland. They are situated inside the capsule of the gland or even in its interlobular connective tissue (paramandibular lymph nodes).

Cervical Lymph Nodes

Cervical lymph nodes are found along the external and internal jugular veins. A subdivision into superficial and deep groups is made according to the relation of the nodes to the deep fasciae of the neck. The superficial cervical lymph nodes are, as a rule, restricted to the upper region of the neck and are found in the angle between the mandibular ramus and the sternocleidomastoid muscle. These superficial nodes receive the lymph directly from the ear lobe and the adjacent part of the skin and are secondary to the preauricular and postauricular lymph nodes.

The deep cervical lymph nodes may be subdivided into an upper and lower group; the latter sometimes are termed *supraclavicular lymph nodes.* If a continuous chain of nodes accompanies the internal jugular vein, the omohyoid muscle is taken as the arbitrary boundary between the upper and lower deep cervical lymph nodes. In addition, each of these two groups again is subdivided into an anterior (or medial) and a posterior (or lateral) group. Superior and inferior deep cervical lymph nodes, situated in front of or covered by the sternocleidomastoid muscle, are classified as anterior or medial deep cervical lymph nodes; those situated in the posterior triangle of the neck behind the sternocleidomastoid are posterior or lateral deep cervical lymph nodes.

The deep cervical lymph nodes are primary sites for the drainage of the base of the tongue, the sublingual region, and the posterior part of the palate. They are secondary and tertiary nodes into which the lymph of the auricular, submental, and submandibular and accessory nodes of the face empty, as well as the lymph from the viscera of the neck. The two lymph nodes that are normally palpable are the jugulodigastric (tonsil) lymph node and the juguloomohyoid (tongue) lymph nodes.

The superior deep cervical lymph nodes send their lymph into the inferior deep cervical or supraclavicular lymph nodes. The lymph on the right side is then collected by the right common lymphatic duct, and the left side by the thoracic duct. The two main lymphatic vessels empty on either side into the "venous angle," where the internal jugular and subclavian veins unite; thus the lymph enters the venous system by way of brachiocephalic veins.

SUMMARY

The complications from spread of dental infection are described in detail in this chapter to make the implantologist aware of the potential danger of involving the surgical spaces of the head with infection from dental origin. The early signs of infection need to be recognized and considered urgently, especially when the patient's swallowing or breathing is compromised. Also, early signs of cavernous sinus thrombosis need to be recognized and the patient referred immediately to a specialist.

Endosteal implants are usually inserted beyond the apex position of natural teeth. Subperiosteal implants traverse natural barriers of infection when extended beyond muscle attachments. Intraoral infections may extend to the base of implants, which may cause more concern than infections of natural teeth.

The implant dentist must be aware of the changes in the patient's symptoms as infection progresses and, when indicated, refer the patient immediately to a specialist for treatment. As discussed in this chapter, the infection may start as a painful swelling in the face region with little or no change in the ability of the patient to open the mouth, swallow, or breathe, and with only mild signs of toxemia. The dentist has to be extremely alert to the possibility of a progression of the infection to involve the masticatory, parapharyngeal, perivertebral, and perivisceral spaces and similar areas, with accompanying signs and symptoms, such as the inability to open the mouth and the compromise of

WWW.HIGHDENT.IR

vital signs, such as breathing. When this occurs, the patient should be hospitalized without hesitation. It is important that extraoral incisions and management of infection of the head and neck be handled by the appropriate specialists.

Chapter 24

Biomaterials for Dental Implants

Jack E. Lemons, Francine Misch-Dietsh

COMPATIBILITY OF SURGICAL BIOMATERIALS AND THE ROLE OF SYNTHETIC MATERIALS

The biocompatibility profiles of synthetic substances (biomaterials) used for the replacement or augmentation of biological tissues have always been a critical concern within the health care disciplines. Special circumstances are associated with dental implant prosthetic reconstruction of the oral-maxillofacial areas because the devices extend from the mouth, across the protective epithelial zones, and onto or into the underlying bone. The functional aspects of use also include the transfer of force from the occlusal surfaces of the teeth through the crown and bridge and neck-connector region of the implant into the implant for interfacial transfer to the supporting soft and hard tissues. This situation represents a very complex series of chemical and mechanical environmental conditions.

This most critical aspect of biocompatibility is, of course, dependent on the basic bulk and surface properties of the biomaterial. All aspects of basic manufacturing, finishing, packaging and delivering, sterilizing, and placing (including surgical placement) must be adequately controlled to ensure clean and nontraumatizing conditions. The importance of these considerations has been reemphasized through the concept and practice of osteointegration of endosteal root form implant systems.

The disciplines of biomaterials and biomechanics are complementary to the understanding of device-based function. The physical, mechanical, chemical, and electrical properties of the basic material components must always be fully evaluated for any biomaterial application, because these properties provide key inputs into the interrelated biomechanical and biological analyses of function. It is important to separate the roles of macroscopic implant shape from the microscopic transfer of stress and strain along biomaterial-tissue interfaces. The macroscopic distribution of mechanical stress and strain is predominantly controlled by the shape and form of the implant device. One important material property related to design (shape and form) optimization is the elastic strain (one component of the elastic modulus) of the material.

The localized microscopic strain distribution is controlled more by the basic properties of the biomaterial (e.g., surface chemistry, microtopography, modulus of elasticity) and by whether the biomaterial surface is attached to the adjacent tissues. Engineering analyses of implant systems include optimization considerations related both to the design and to the biomaterial used for construction. Therefore the desire to positively influence tissue responses and to minimize biodegradation often places restrictions on which materials can be safely used within the oral and tissue environments. Designs are often evolved for specific biomaterials because of the imposed environmental or restorative conditions.

BULK PROPERTIES

History of Materials and Designs

Over the past several decades, definitions of material biocompatibilities have evolved and reflect an ever-changing opinion related to philosophies of surgical implant treatment. In general, the definition of biocompatibility has been given as an appropriate response to a material (biomaterial) within a device (design) for a specific clinical application.[1] Metallic and nonmetallic implantable materials have been studied in the field of orthopedics since the turn of the twentieth century.[2-7] In the 1960s, emphasis was placed on making the biomaterials more inert and chemically stable within biological environments. The high-purity ceramics of aluminum oxide (Al_2O_3), carbon, and carbon-silicon compounds and extra-low-interstitial (ELI) grade alloys are classic examples of these trends. In the 1970s, biocompatibility was defined in terms of minimal harm to the host or to the biomaterial. The importance of a stable interaction then moved into central focus for both the research and the clinical communities. In the 1980s the focus transferred to bioactive substrates intended to positively influence tissue responses,

WWW.HIGHDENT.IR

whereas in the last two decades, emphasis on chemically and mechanically anisotropic substrates combined with growth (mitogenic) and inductive (morphogenic) substances. Today many biomaterials are being constituted, fabricated, and surface modified to directly influence short- and long-term tissue responses. Bioactive coatings on most classes of biomaterials have continued to evolve from human clinical trials to acceptable modalities of surface preparation, and research focus has shifted to combinations of active synthetic and biological implants.

Of interest, dental implants have significantly influenced these trends. In the 1960s, dental devices were recognized as being in a research and development phase, and critical longitudinal reviews of clinical applications were strongly recommended.[8] During this time, longevity studies of various devices demonstrated that the longest duration of clinical applications were for orthopedic prostheses. In the 1980s, controlled clinical trials showed that dental implants provided functional longevities that exceeded most other types of functional tissue replacement modalities.[9,10] Clearly, these clinical studies have strongly influenced both the research and development and the clinical application processes. At the present time, the exponential growth of implant use and related scientific reports support the views expressed by early visionaries several decades ago.

The evolution of any implant modality is a multipart story in which significant roles have been played by biomaterials; biomechanical analyses of designs, tissues, and function; wound healing along interfaces; surgical methods to minimize mechanical, chemical, and thermal trauma; prosthodontic and periodontal restorative and maintenance treatment modalities; and protocols for controlled multidisciplinary clinical trials. The interdependence of all phases of basic and applied research should be recognized. All interrelate and must evolve to provide a level of better understanding of the basic physical and biological phenomena associated with the implant systems before the longer clinical outcomes will be fully described.

Evaluations of endosteal and subperiosteal dental implants raise interesting questions with respect to the interrelationships between material and design selection. Opportunities exist to select a material from a number of systems, such as metals, ceramics, carbons, polymers, or composites. In addition, only the available anatomical dimensions and the requirement to attach some form of intraoral restorative device limit implant shape and form (design). Because of the wide range of biomaterial properties demonstrated by the classes of materials available, it is not advisable to fabricate any new implant design without a thorough biomechanical analysis. Another approach now often used is to determine a specific design based on clinical considerations and then to select the biomaterial of choice from computer-based analyses. The safety of these combinations can then be demonstrated through laboratory and animal investigations. Controlled clinical trials following prospective protocols, of course, provide the final evaluation for both safety and effectiveness. Long-term success is thus determined clinically in investigator follow-up studies and is clearly an area that should be emphasized for many available dental implant systems.

Research and Development

Basic studies within the physical and biological sciences have been supportive of the development of surgical implant systems. One example is the continued progress from materials that have been available for industrial applications to the new classes of composites that have evolved for biomedical applications. This same situation exists within a broad area; for example, surface science and technology, mechanics and biomechanics of three-dimensional structures, pathways and processes of wound healing along biomaterial interfaces, and the description of the first biofilms that evolve on contact with blood or tissue fluids.[11-14] The progressive move from materials to quantitatively characterized biomaterials has been extremely important to the biomedical applications of surgical implants. Dental implant investigations now play a leadership role within selected areas of this overall process, and all phases of medicine and dentistry should benefit.

PHYSICAL, MECHANICAL, AND CHEMICAL REQUIREMENTS FOR IMPLANT MATERIALS

Physical and Mechanical Properties

Forces exerted on the implant material consist of tensile, compressive, and shear components. As for most materials, compressive strengths of implant materials are usually greater than their shear and tensile counterparts. A hypothesis that dental implants are less affected by alternating stresses than implants of the cardiovascular and locomotor systems because of the significantly lower number of loading cycles must be qualified because of the special concern that dental implants are considerably smaller in physical dimension. All fatigue failures obey mechanical laws correlating the dimensions of the material to the mechanical properties of said material.[11,15] In addition, when present, parafunction (nocturnal and/or diurnal) can be greatly detrimental to longevity because of the mechanical properties, such as maximum yield strength, fatigue strength, creep deformability, ductility, and fracture. Limitations of the relevance of these properties are mainly caused by the variable shape and surface features of implant designs. A recurring problem exists between the mechanical strength and deformability of the material and the recipient bone. A different approach to match more closely the implanted material and hard tissue properties led to the

WWW.HIGHDENT.IR

انجمن علمی کارشناسان دندانسازان و دندانپزشکان

experimentation of polymeric, carbonitic, and metallic materials of low modulus of elasticity.[16,17]

Because bone can modify its structure in response to forces exerted on it, implant materials and designs must be designed to account for the increased performance of the musculature and bone in jaws restored with implants. The upper stress limit decreases with an increasing number of loading cycles sometimes reaching the fatigue limit after 10^6 to 10^7 loading cycles.[11,15,18] In other words, the higher the applied load, the higher the mechanical stress—and therefore the greater the possibility for exceeding the fatigue endurance limit of the material.

In general, the fatigue limit of metallic implant materials reaches approximately 50% of their ultimate tensile strength.[11,18] However, this relationship is only applicable to metallic systems, and polymeric systems have no lower limit in terms of endurance fatigue strength. Ceramic materials are weak under shear forces because of the combination of fracture strength and no ductility, which can lead to brittle fracture. Metals can be heated for varying periods to influence properties, modified by the addition of alloying elements or altered by mechanical processing such as drawing, swagging, or forging, followed by age or dispersion hardening, until the strength and ductility of the processed material are optimized for the intended application.

The modifying elements in metallic systems may be metals or nonmetals. A general rule is that constitution or mechanical process hardening procedures result in an increased strength but also invariably correspond to a loss of ductility. This is especially relevant for dental implants. Most all consensus standards for metals (American Society for Testing and Material [ASTM], International Standardization Organization [ISO], American Dental Association [ADA]) require a minimum of 8% ductility to minimize brittle fractures. Mixed microstructural phase hardening of austenitic materials with nitrogen (e.g., stainless steels) and the increasing purity of the alloys seem most indicated to achieve maximum strength and maintain this high level of possible plastic deformation.[1,15,19-23]

Corrosion and Biodegradation

Corrosion is a special concern for metallic materials in dental implantology, because implants protrude into the oral cavity where electrolyte and oxygen compositions differ from that of tissue fluids. In addition, the pH can vary significantly in areas below plaque and within the oral cavity. This increases the range of pH that implants are exposed to in the oral cavity compared with specific sites in tissue.[24-29]

Plenk and Zitter[15] state that galvanic corrosion (GC) could be greater for dental implants than for orthopedic implants. Galvanic processes depend on the passivity of oxide layers, which are characterized by a minimal dissolution rate and high regenerative power for metals such as titanium. The passive layer is only a few nanometers thick and usually composed of oxides or hydroxides of the metallic elements that have greatest affinity for oxygen. In reactive group metals such as titanium, niobium, zirconium, tantalum, and related alloys, the base materials determine the properties of the passive layer. The stability zones of the oxides of passivable elements cover the redox potentials and pH values typical of the oral environment. However, titanium, tantalum, and niobium oxides cover a markedly larger zone of environmental stability compared with chromium oxides.

The risk of mechanical degradation, such as scratching or fretting of implanted materials, combined with corrosion and release into bone and remote organs has been previously considered. For example, investigators such as Laing,[30] Willert et al.,[31] and Lemons,[32,33] have extensively studied the corrosion of metallic implants. Steinemann[34] and Fontana and Greene[35] have presented many of the basic relationships specific to implant corrosion. Mears[26] addressed concerns about GC and studied the local tissue response to stainless steel and cobalt-chromium-molybdenum (Co-Cr-Mo) and showed the release of metal ions in the tissues. Williams[36] suggested that three types of corrosion were most relevant to dental implants: (1) stress corrosion cracking (SCC), (2) GC, and (3) fretting corrosion (FC).

Stress Corrosion Cracking

The combination of high magnitudes of applied mechanical stress plus simultaneous exposure to a corrosive environment can result in the failure of metallic materials by cracking, where neither condition alone would cause the failure. Williams[36] presented this phenomenon of SCC in multicomponent orthopedic implants. Others hypothesized that it may be responsible for some implant failures in view of high concentrations of forces in the area of the abutment-implant body interface.[37-39] Most traditional implant body designs under three-dimensional finite element stress analysis show a concentration of stresses at the crest of the bone support and cervical third of the implant. This tends to support potential SCC at the implant interface area (i.e., a transition zone for altered chemical and mechanical environmental conditions). This has also been described in terms of corrosion fatigue (i.e., cyclical load cycle failures accelerated by locally aggressive medium). In addition, nonpassive prosthetic superstructures may incorporate permanent stress, which strongly influences this phenomenon under loaded prostheses[37,40,41] (Figure 24-1, *A* and *B*).

Galvanic corrosion occurs when two dissimilar metallic materials are in contact and are within an electrolyte resulting in current flowing between the two. The metallic materials with the dissimilar potentials can have their corrosion currents altered, thereby resulting

WWW.HIGHDENT.IR

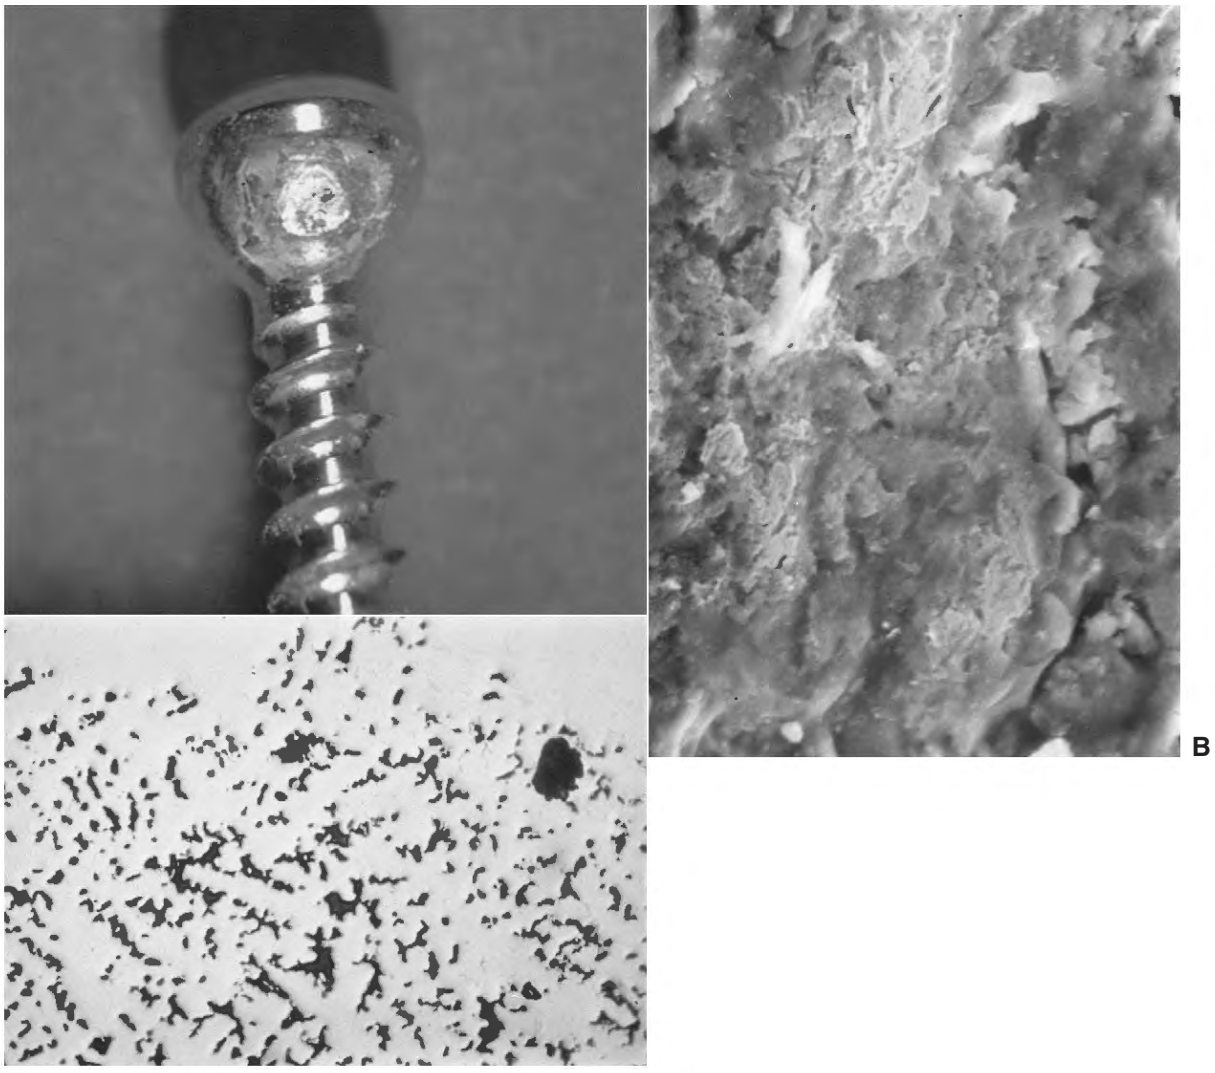

Figure 24-1 **A,** Stainless steel (316L) fracture fixation screw showing crevice corrosion after 1 year in vivo (approximately ×5). **B,** Microscopic characteristics of cobalt alloy root form surface showing environmental degradation (approximately ×100). **C,** As-polished microstructure of cobalt alloy subperiosteal showing porosity associated with galvanically assisted corrosion (approximately ×100).

in a greater corrosion rate (Figure 24-1, *C*). Fretting corrosion occurs when a micromotion and rubbing contact occurs within a corrosive environment (e.g., the perforation of the passive layers and shear-directed loading along adjacent contacting surfaces). The loss of any protective film can result in the acceleration of metallic ion loss. Fretting corrosion has been shown to occur along implant body-abutment-superstructure interfaces.

Normally the passive oxide layers on metallic substrates dissolve at such slower rates that the resultant loss of mass is of no mechanical consequence to the implant. A more critical problem is the irreversible local perforation of the passive layer that chloride ions often cause, which may result in localized pitting corrosion. Such perforations can often be observed for iron-chromium-nickel-molybdenum (Fe-Cr-Ni-Mo) steels that contain an insufficient amount of the alloying elements stabilizing the passive layer (i.e., Cr and Mo) or local regions of implants that are subjected to abnormal environments. Even ceramic oxide materials are not fully degradation resistant. Corrosion-like behavior of ceramic materials can then be compared with the chemical dissolution of the oxides into ions or complex ions of respective metallic oxide substrates. An example of this is the solubility of aluminum oxide as alumina or titanium oxide as titania. This statement is generally valid; however, most metallic oxides and nonmetallic substrates have amorphous-hydroxide inclusive structures, whereas bulk ceramics are mostly crystalline. The corrosion resistance of synthetic polymers, on the other hand, depends not only on their composition and structural form but also on the degree of polymerization. Unlike metallic and ceramic materials, synthetic polymers are not only dissolved but also penetrated by water and substances from biological

WWW.HIGHDENT.IR

environments. The resulting degree of alteration depends on the material property conditions for the manufactured component.

Toxicity and Consideration

Toxicity is related to primary biodegradation products (simple and complex cations and anions), particularly those of higher atomic weight metals. Factors to be considered include (1) the amount dissolved by biodegradation per time unit, (2) the amount of material removed by metabolic activity in the same time unit, and (3) the quantities of solid particles and ions deposited in the tissue and any associated transfers to the systemic system. For example, the quantity of elements released from metals during corrosion time (e.g., grams per day) can be calculated by using the following formula[15]:

$$\text{TE (g/day)} = \frac{\text{TEA(\%)} \times \text{CBR(g/cm}^2 \times \text{day)} \times \text{IS(cm}^2\text{)}}{100}$$

where *TE* = toxic element, *TEA* = toxic elements in alloy, *CBR* = corrosion biodegradation, and *IS* = implant surface.

It is of little importance for the formula whether or not the metallic substrate is exposed because the passive layer is dissolved. The critical issue is that the surface represents the "finished" form of the implant. The formula is also valid for ceramic materials and for substances transferred from synthetic polymers. Therefore it appears that the toxicity is related to the content of the materials' toxic elements and that they may have a modifying effect on corrosion rate.[15]

The transformation of harmful primary products is dependent on their level of solubility and transfer. It is known that chromium and titanium ions react locally at low concentrations, whereas cobalt, molybdenum, or nickle can remain dissolved at higher relative concentrations and thus may be transported and circulated in body fluids. Several studies have documented the relative toxicity of titanium and its alloys and are addressed within the section on titanium.

Lemons[32] reported on the formation of electrochemical couples as a result of oral implant and restorative procedures and stressed the importance of selecting compatible metals to be placed in direct contact with one another in the oral cavity to avoid the formation of adverse electrochemical couples. The electrochemical behavior of implanted materials has been instrumental in assessing their biocompatibility.[42] Zitter and Plenk[43] have shown that anodic oxidation and cathodic reduction take place in different spaces but must always balance each other through charge transfer. This has been shown to impair both cell growth and transmission of stimuli from one cell to another. Therefore an anodic corrosion site can be influenced by ion transfer but also by other possibly detrimental oxidation phenomena. Charge transfer appears to be a significant factor specific to the biocompatibility of metallic biomaterials. Passive layers along the surfaces of titanium, niobium, zirconium, and tantalum increase resistance to change transfer processes by isolating the substrate from the electrolyte, in addition to providing a higher resistance to ion transfers. On the other hand, metals based on iron, nickel, or cobalt are not as resistant to transfers through the oxidelike passive surface zones.

METALS AND ALLOYS

To date, most of the dental implant systems available within the United States are constructed from metals or alloys. These materials are reviewed in this chapter by separating the metals and alloys according to their elemental compositions, because a growing proportion have modified surface characteristics that are addressed in the second section of this chapter.

Several organizations have provided guidelines for the standardization of implant materials.[44] ASTM Committee F4 (ASTM F4) and ISO (ISOTC 106, ISOTR 10541) have provided the basis for such standards.[19,20] To date, a multinational survey by ISO indicated that titanium and its alloy are mainly used. The most widely used nonmetallic implants are oxidic, carbonitic, or graphitic oxidelike materials.[45]

The major groups of implantable materials for dentistry are titanium and alloys, cobalt chromium alloys, austenitic Fe-Cr-Ni-Mo steels, tantalum, niobium and zirconium alloys, precious metals, ceramics, and polymeric materials.

Titanium and Titanium–6 Aluminum–4 Vanadium (Ti-6Al-4V)

This reactive group of metals and alloys (with primary elements from reactive group metallic substances) form tenacious oxides in air or oxygenated solutions. Titanium oxidizes (passivates) on contact with room temperature air and normal tissue fluids. This reactivity is favorable for dental implant devices. In the absence of interfacial motion or adverse environmental conditions, this passivated (oxidized) surface condition minimizes biocorrosion phenomena. In situations in which the implant would be placed within a closely fitting receptor site in bone, areas scratched or abraded during placement would repassivate in vivo. This characteristic is one important property consideration related to the use of titanium for dental implants.[37,46-48] Some reports show that the oxide layer tends to increase in thickness under corrosion testing,[48] and that breakdown of this layer is unlikely in aerated solutions.[49]

Bothe et al.[50] studied the reaction of rabbit bone to 54 different implanted metals and alloys and showed that titanium allowed bone growth directly adjacent to the oxide surfaces. Leventhal[51] further studied the

application of titanium for implantation. Beder et al.,[52] Gross et al.,[53] Clarke et al.,[54] and Brettle[55] were able to expand indications of these materials. In all cases, titanium was selected as the material of choice because of its inert and biocompatible nature paired with excellent resistance to corrosion.[1,56-60]

Specific studies in the literature addressed the corrosion of titanium implants and are reported in the surface characteristics section. Unfortunately most are for in vitro and unloaded conditions, and few identify precisely the type of titanium and titanium surface studied.

The general engineering properties of the metals and alloys used for dental implants are summarized in Table 24-1. Titanium shows a relatively low modulus of elasticity and tensile strength when compared with most other alloys. The strength values for the wrought soft and ductile metallurgic condition (normal root forms and plate form implants) are approximately 1.5 times greater than the strength of compact bone. In most designs in which the bulk dimensions and shapes are simple, strength of this magnitude is adequate. Because fatigue strengths are normally 50% weaker or less than the corresponding tensile strengths, implant design criteria are decidedly important. The creation of sharp corners or thin sections must be avoided for regions loaded under tension or shear conditions. The modulus of elasticity of titanium is five times greater than that of compact bone, and this property places emphasis on the importance of design in the proper distribution of mechanical stress transfer. In this regard, surface areas that are loaded in compression have been maximized for some of the newer implant designs. Four grades of unalloyed titanium and titanium alloy are the most popular. Their ultimate strength and endurance limit vary as a function of their composition.

The alloy of titanium most often used is titanium-aluminum-vanadium. The wrought alloy condition is approximately six times stronger than compact bone and thereby affords more opportunities for designs with thinner sections (e.g., plateaus, thin interconnecting regions, implant-to-abutment connection screw housing, irregular scaffolds, porosities). The modulus of elasticity of the alloy is slightly greater than that of titanium, being about 5.6 times that of compact bone. The alloy and the primary element (i.e., titanium) both have titanium oxide (passivated) surfaces. Information has been developed on the oxide thickness, purity, and stability as related to implant biocompatibilities.[9,14,19] In general, titanium and alloys of titanium have demonstrated interfaces described as *osteointegrated* for implants in humans. In addition, surface conditions in which the oxide thickness has varied from hundreds of angstroms of amorphous oxide surface films to 100% titania (titanium dioxide [TiO_2] rutile form ceramic) have demonstrated osteointegration.

The possible influences of aluminum and vanadium biodegradation products on local and systemic tissue responses have been reviewed from the perspectives of basic science and clinical applications.[61] Extensive literature has been published on the corrosion rate of titanium within local tissue fluids[62-64] and the peri-implant accumulation of "black particles."[65] A few adverse effects have been reported.[66] Increased titanium concentrations were found in both peri-implant tissues and parenchymal organs,[67,68] mainly the lung and much lesser concentrations in the liver, kidney, and

WWW.HIGHDENT.IR

spleen.[25,66-70] However, alloy compositions were not well defined or controlled. Corrosion and mechanical wear have been suggested as possible causes.[48,67,68] Authors who still caution about the applicability of these results to the presently available titanium alloys have developed other alloys using iron, molybdenum, and other elements as primary alloying agents.[17] More recently, several new titanium alloys of higher strength have been introduced.[33,71]

Although many basic science questions remain, clinical applications of these alloys in dental and orthopedic surgical systems have been very positive, especially in light of improved strength, and the titanium alloys have not demonstrated significant numbers of identifiable negative sequelae.[19]

Electrochemical studies support the selection of conditions in which elemental concentrations would be relatively low in magnitude.[11] Electrochemically, titanium and titanium alloy are slightly different in regard to electromotive and galvanic potentials when compared with other electrically conductive dental materials. Results of these electrochemical potentials and how they relate to in vivo responses have been published previously.[9,42,63] In general, titanium- and cobalt-based systems are electrochemically similar; however, comparative elements imitating the conditions in an aeration cell revealed that the current flow in titanium and titanium alloys is several orders of magnitude lower than that in Fe-Cr-Ni-Mo steels or Co-Cr alloys.[15] Gold-, platinum-, and palladium-based systems have been shown to be noble, and nickel-, iron-, copper, and silver-based systems are significantly different (subject to galvanic coupling and preferential in vivo corrosion).

Mechanically, titanium is much more ductile (bendable) than titanium alloy. This feature has been a very favorable aspect related to the use of titanium for endosteal plate form devices. The need for adjustment or bending to provide parallel abutments for prosthetic treatments has caused manufacturers to optimize microstructures and residual strain conditions. Coining, stamping, or forging followed by controlled annealing heat treatments are routinely used during metallurgic processing. However, if an implant abutment is bent at the time of implantation, then the metal is strained locally at the neck region (bent), and the local strain is both cumulative and dependent on the total amount of deformation introduced during the procedure. This is one reason, other than prior loading fatigue cycling, why reuse of implants is not recommended. In addition, mechanical processes can sometimes significantly alter or contaminate implant surfaces. Any residues of surface changes must be removed before implantation to ensure mechanically and chemically clean conditions.

The emerging techniques to cast titanium and titanium alloys remain limited for dental implant application because of high melting points of the elements and propensity for absorption of oxygen, nitrogen, and hydrogen, which may cause metallic embrittlement. A high vacuum or ultrapure protective gas atmosphere allows the production of castings in titanium and its alloys at different purity levels,[72,73] although microstructures and porosity are relatively unfavorable related to fatigue and fracture strengths.[9,32] Typical strengths of cast commercially pure (CP) titanium grade 2 and Ti-6Al-4V after heat treatment and annealing can be in the range of those of wrought titanium alloys used for dental implants.[74]

Cobalt-Chromium-Molybdenum–Based Alloy

The cobalt-based alloys are most often used in an as-cast or cast-and-annealed metallurgic condition. This permits the fabrication of implants as custom designs such as subperiosteal frames. The elemental composition of this alloy includes cobalt, chromium, and molybdenum as the major elements. Cobalt provides the continuous phase for basic properties; secondary phases based on cobalt, chromium, molybdenum, nickel, and carbon provide strength (four times that of compact bone) and surface abrasion resistance (see Table 24-1); chromium provides corrosion resistance through the oxide surface; and molybdenum provides strength and bulk corrosion resistance. All of these elements are critical, as is their concentration, which emphasizes the importance of controlled casting and fabrication technologies. Also included in this alloy are minor concentrations of nickel, manganese, and carbon. Nickel has been identified in biocorrosion products, and carbon must be precisely controlled to maintain mechanical properties such as ductility. Surgical alloys of cobalt are not the same as those used for partial dentures, and substitutions should be avoided.

In general, the as-cast cobalt alloys are the least ductile of the alloy systems used for dental surgical implants, and bending of finished implants should be avoided. Because many of these alloy devices have been fabricated by dental laboratories, all aspects of quality control and analysis for surgical implants must be followed during alloy selection, casting, and finishing. Critical considerations include the chemical analysis, mechanical properties, and surface finish as specified by the ASTM F4 on surgical implants and the ADA.[19,21] When properly fabricated, implants from this alloy group have shown to exhibit excellent biocompatibility profiles.

Iron-Chromium-Nickel–Based Alloys

The surgical stainless steel alloys (e.g., 316 low carbon [316L]) have a long history of use for orthopedic and dental implant devices. This alloy, as with titanium systems, is used most often in a wrought and heat-treated metallurgic condition, which results in a high-strength and high-ductility alloy. The ramus blade, ramus frame,

WWW.HIGHDENT.IR

stabilizer pins (old), and some mucosal insert systems have been made from the iron-based alloy.

The ASTM F4 specification for surface passivation was first written and applied to the stainless steel alloys.[19] In part, this was done to maximize corrosion-biocorrosion resistance. Of the implant alloys, this alloy is most subject to crevice and pitting biocorrosion, and care must be taken to use and retain the passivated (oxide) surface condition. Because this alloy contains nickel as a major element, use in patients allergic or hypersensitive to nickel should be avoided. In addition, if a stainless steel implant is modified before surgery, then recommended procedures call for repassivation to obtain an oxidized (passivated) surface condition to minimize in vivo biodegradation.

The iron-based alloys have galvanic potentials and corrosion characteristics that could result in concerns about galvanic coupling and biocorrosion if interconnected with titanium, cobalt, zirconium, or carbon implant biomaterials.[75-77] In some clinical conditions, more than one alloy may be present within the same dental arch of a patient. For example, if a bridge of a noble or a base-metal alloy touches the abutment heads of a stainless steel and titanium implant simultaneously, then an electrical circuit would be formed through the tissues. If used independently, where the alloys are not in contact or not electrically interconnected, then the galvanic couple would not exist, and each device could function independently. As with the other metal and alloy systems discussed, the iron-based alloys have a long history of clinical applications. Long-term device retrievals have demonstrated that, when used properly, the alloy can function without significant in vivo breakdown. Clearly, the mechanical properties and cost characteristics of this alloy offer advantages with respect to clinical applications.

Other Metals and Alloys

Many other metals and alloys have been used for dental implant device fabrication. Early spirals and cages included tantalum, platinum, iridium, gold, palladium, and alloys of these metals. More recently, devices made from zirconium, hafnium, and tungsten have been evaluated.[15,78,79] Some significant advantages of these reactive group metals and their alloys have been reported, although large numbers of such devices have not been fabricated in the United States.

Gold, platinum, and palladium are metals of relatively low strength, which places limits on implant design. In addition, cost-per-unit weight and the weight-per-unit volume (density) of the device along the upper arch have been suggested as possible limitations for gold and platinum. These metals, especially gold because of nobility and availability, continue to be used as surgical implant materials. For example, the Bosker endosteal staple design represents use of this alloy system.[80]

CERAMICS AND CARBON

Ceramics are inorganic, nonmetallic, nonpolymetric materials manufactured by compacting and sintering at elevated temperatures. They can be divided into metallic oxides or other compounds. Oxide ceramics were introduced for surgical implant devices because of their inertness to biodegradation, high strength, physical characteristics such as color and minimal thermal and electrical conductivity, and a wide range of material specific elastic properties.[81,82] In many cases, however, the low ductility or inherent brittleness has resulted in limitations. Ceramics have been used in bulk forms and more recently as coatings on metals and alloys.

Aluminum, Titanium, and Zirconium Oxides

High-strength ceramics from aluminum, titanium, and zirconium oxides have been used for root form, endosteal plate form, and pin type of dental implants.[83] The overall characteristics of these ceramics are summarized in Table 24-2. The compressive, tensile, and bending strengths exceed the strength of compact bone by three to five times. These properties, combined with high moduli of elasticity, and especially with fatigue and fracture strengths, have resulted in specialized design requirements for these classes of biomaterials.[19,84] For

Table 24-2 Engineering Properties of Some Inert Ceramics Used as Biomaterials*

مرجع تخصصی دندانسازان و دندانپزشکان

example, the fabrication of a subperiosteal device from a high ceramic should not be done because of the custom nature of these devices, the lower fracture resistance, and the relative cost for manufacturing. The aluminum, titanium, and zirconium oxide ceramics have a clear, white, cream, or light-gray color, which is beneficial for applications such as anterior root form devices. Minimal thermal and electrical conductivity, minimal biodegradation, and minimal reactions with bone, soft tissue, and the oral environment are also recognized as beneficial when compared with other types of synthetic biomaterials. In early studies of dental and orthopedic devices in laboratory animals and humans, ceramics have exhibited direct interfaces with bone, similar to an osteointegrated condition with titanium. In addition, characterization of gingival attachment zones along sapphire root form devices in laboratory animal models has demonstrated regions of localized bonding.[9,85-89]

Although the ceramics are chemically inert, care must be taken in the handling and placement of these biomaterials. Exposure to steam sterilization results in a measurable decrease in strength for some ceramics; scratches or notches may introduce fracture initiation sites; chemical solutions may leave residues; and the hard and sometimes rough surfaces may readily abrade other materials, thereby leaving a residue on contact. Dry-heat sterilization within a clean and dry atmosphere is recommended for most ceramics.

One series of root form and plate form devices used during the 1970s resulted in intraoral fractures after several years of function.[90] The fractures were initiated by fatigue cycling where biomechanical stresses were along regions of localized bending and tensile loading. Although initial testing showed adequate mechanical strengths for these polycrystalline alumina materials,[91] the long-term clinical results clearly demonstrated a functional design-related and material-related limitation. This illustrates the need for controlled clinical investigation to relate basic properties to in vivo performance. The established chemical biocompatibilities, improved strength and toughness capabilities of sapphire and zirconia, and the basic property characteristics of high ceramics continue to make them excellent candidates for dental implants.

Bioactive and Biodegradable Ceramics Based on Calcium Phosphates

Bone Augmentation and Replacement

The calcium phosphate ($CaPO_4$) materials (i.e., calcium phosphate ceramics [CPCs]) used in dental reconstructive surgery include a wide range of implant types and thereby a wide range of clinical applications. Early investigations emphasized solid and porous particulates with nominal compositions that were relatively similar to the mineral phase of bone ($Ca_5[PO_4]_3OH$). Microstructural and chemical properties of these particulates were controlled to provide forms that would remain intact for structural purposes after implantation. The laboratory and clinical results for these particulates were most promising and led to expansions for implant applications, including larger implant shapes (e.g., rods, cones, blocks, H-bars) for structural support under relatively high-magnitude loading conditions.[92,93] In addition, the particulate size range for bone replacements was expanded to both smaller and larger sizes for combined applications with organic compounds. Mixtures of particulates with collagen, and subsequently with drugs and active organic compounds such as bone morphogenetic protein (BMP), increased the range of possible applications. Over the past 20 years, these types of products and their uses have continued to expand significantly.[93-96]

Endosteal and Subperiosteal Implants

The first series of structural forms for dental implants included rods and cones for filling tooth root extraction sites (ridge retainers)[97] and, in some cases, load-bearing endosteal implants.[98] Limitations in mechanical property characteristics soon resulted in internal reinforcement of the CPC implants through mechanical (central metallic rods) or physicochemical (coating over another substrate) techniques.[99,100]

The numbers of coatings of metallic surfaces using flame or plasma spraying (or other techniques) increased rapidly for the CPCs.[93] The coatings have been applied to a wide range of endosteal and subperiosteal dental implant designs, with an overall intent of improving implant surface biocompatibility profiles and implant longevities (and are addressed later in this chapter).[101-103]

Advantages and Disadvantages

Box 24-1 summarizes the advantages and disadvantages of CPCs.

Box 24-1 Advantages and Disadvantages of Calcium Phosphate Ceramics

Advantages	Disadvantages
Chemistry mimics normal biological tissue (C,P,O,H)	Variable chemical and structural characteristics (technology and chemistry related)
Excellent biocompatibility	Low mechanical tensile and shear strengths under fatigue loading
Attachment between CPC and hard and soft tissues	Low attachment between coating and substrate
Minimal thermal and electrical conductivity	Variable solubility
Moduli of elasticity closer to bone than many other implantable materials	Variable mechanical stability of coatings under load-bearing conditions
Color similar to hard tissues	Overuse
Extensive research	

CPC, Calcium phosphate ceramics.

WWW.HIGHDENT.IR

The recognized advantages associated with the CPC biomaterials are as follows[104]:

1. Chemical compositions of high purity and of substances that are similar to constituents of normal biological tissue (calcium, phosphorus, oxygen, and hydrogen)
2. Excellent biocompatibility profiles within a variety of tissues, when used as intended
3. Opportunities to provide attachments between selected CPC and hard and soft tissues
4. Minimal thermal and electrical conductivity plus capabilities to provide a physical and chemical barrier to ion transport (e.g., metallic ions)
5. Moduli of elasticity more similar to bone than many other implant materials used for load-bearing implants
6. Color similar to bone, dentin, and enamel
7. An evolving and extensive base of information related to science, technology, and application

Some of the possible disadvantages associated with these types of biomaterials are as follows:

1. Variations in chemical and structural characteristics for some currently available implant products
2. Relatively low mechanical tensile and shear strengths under condition of fatigue loading
3. Relatively low attachment strengths for some coating-to-substrate interfaces
4. Variable solubilities depending on the product and the clinical application (The structural and mechanical stabilities of coatings under in vivo load-bearing conditions—especially tension and shear—may be variable as a function of the quality of the coating.)
5. Alterations of substrate chemical and structural properties related to some available coating technologies
6. Expansion of applications that sometimes exceed the evolving scientific information on properties

Critical to applications are the basic properties of these substances. Table 24-3 provides a summary of some properties of bioactive and biodegradable ceramics. In general, these classes of bioceramics have lower strengths, hardnesses, and moduli of elasticity than the more chemically inert forms previously discussed. Fatigue strengths, especially for porous materials, have imposed limitations with regard to some dental implant designs. In certain instances, these characteristics have been used to provide improved implant conditions (e.g., biodegradation of particulates).

Calcium aluminates, sodium-lithium invert glasses with $CaPO_4$ additions (Bioglass or Ceravital), and glass ceramics (AW glass-ceramic) also provide a wide range of properties and have found extended applications.[96,100]

Bioactive Ceramic Properties

Physical properties are specific to the surface area or form of the product (block, particle), porosity (dense, macroporous, microporous), and crystallinity (crystalline or amorphous). Chemical properties are related to the calcium-phosphate ratio, composition, elemental impurities (e.g., carbonate), ionic substitution in atomic structure, and the pH of the surrounding region. These properties plus the biomechanical environment all play a role in the rate of resorption and the clinical application limits of the materials.

The atomic relationships of the basic elements, stoichiometric ratios, and the normal chemical names for several characterized CPCs are provided in Table 24-4. The general family of apatites has the following formula:

$$M_{10}^{2+}(XO_4^{3-})_6Z_2^{-1}$$

Very often, apatite atomic ratios are nonstoichiometric; that is, 1 mol of apatite may contain fewer than 10 mol of metallic ions (M^{2+}) and fewer than 2 mol of anions Z^{-1}.[105] The number of XO retains a number of 6. Multiple metals and anions can be substituted within this formulation. Most important, the relative physical, mechanical, and chemical properties of each final $CaPO_4$ material, including each of the apatites, are different from one another.[89,95] Additionally, the microstructure of any final product (solid structural form or coating) is equally important to the basic properties of the substance alone. The crystalline monolythic hydroxyapatite (HA) (fired ceramic $Ca_{10}[PO_4]_6[OH]_2$) of high density and purity (50 maximum ppm impurities)

Table 24-4 Names, Formulae, and Atomic Ratios for Some Calcium Phosphate Materials

MINERAL OR GENERAL NAME	FORMULA	CA:P RATIO	APPLICATIONS
Monetite (DVP)	$CaHPO_4$	1	Nonceramic bone substitute particulate
Brushite (DCPD)	$CaHPO_4\ 2H_2O$	1	Phase of some $CaPO_4$ biomaterials
Octacalcium phosphate (OCP)	$Ca_8(HPO_4)_2(PO_4)\ 5H_2O$	1.33	Phase of some $CaPO_4$ biomaterials
Whitlockite (WH)	$Ca_{10}(HPO_4)(PO_4)_6$	1.43	Phase of some $CaPO_4$ biomaterials
Beta-tricalcium phosphate (β-TCP)	$Ca_3(PO_4)_2$	1.48	Biodegradable $CaPO_4$ ceramic for bone substitute and coatings; also a phase of some $CaPO_4$ biomaterials
Defective hydroxyapatite (DOHA) biomaterials	$Ca_9(HPO_4)(PO_4)_5(OH)$	1.5	Component of some $CaPO_4$ biomaterials
Hydroxyapatite (HA)	$Ca_{10}(PO_4)_6(OH)_2$	1.67	Major mineral phase of bone; when fired as a ceramic, named *HA*

has provided one standard for comparison related to implant applications. The ratio of calcium to phosphorus of $Ca_{10}(PO_4)_6(OH)_2$ is 1.67, and the ceramic can be fully crystalline. Considerable differences exist between the synthetic HA ceramics (HAs) that are produced by elevated temperature processing and biological apatites (HAs).[105] Biological apatites contain trace amounts of CO_3^{2-}, sodium, magnesium, fluorine, and chlorine ions. These exist in varying ratios and distributions and of course are only one phase of calcified tissues.

The crystalline tricalcium phosphate ($\beta Ca_3[PO_4]_2$) (TCP) ceramic has also provided a high-purity (<50 ppm maximum impurities) biomaterial for comparison with other products. National standard specifications related to the basic properties and characteristics of both HA and TCP have been published.[19] These two compositions have been used most extensively as particulates for bone augmentation and replacement, carriers for organic products, and coatings for endosteal and subperiosteal implants.

One of the more important aspects of the CPCs relates to the possible reactions with water. For example, hydration can convert other compositions to HA; also, phase transitions among the various structural forms can exist with any exposure to water. This has caused some confusion in the literature, in that some CPCs have been steam autoclaved for sterilization purposes before surgical implantation. Steam or water autoclaving can significantly change the basic structure and properties of CPCs (or any bioactive surface) and thereby provide an unknown biomaterial condition at the time of implantation. This is to be avoided through the use of presterilized or clean, dry heat or gamma sterilized conditions.

Forms, Microstructures, and Mechanical Properties

Particulate HA, provided in a nonporous (<5% porosity) form as angular or spherically shaped particles, is an example of a crystalline, high-purity HA biomaterial[106] (Figure 24-2, *A*). These particles can have relatively high compressive strengths (up to 500 MPa), with tensile strengths in the range of 50 to 70 MPa. Usually, dense polycrystalline ceramics consisting of small crystallites exhibit the highest mechanical strength, apart from monocrystalline ceramics free of defects (e.g., single-crystal sapphire implants). Ceramics are brittle materials and exhibit high compressive strengths compared with tensile strengths. However, less resistance to tensile and shear stresses limit their application as dental implants because of mechanical constraints of implant form and volume. Nonresorbable, "bioinert" ceramics exhibiting satisfactory load-bearing capability are limited to dense monocrystalline and polycrystalline aluminum, zirconium, and titanium oxide ceramics. These same mechanical characteristics exist for the solid portions of several porous HA particulates and blocks. The macroporous (>50 µm), or microporous (<50 µm) particulates have an increased surface area per unit volume. This provides more surface area for solution- and cell-mediated resorption under static conditions and a significant reduction in compressive and tensile strengths (Figure 24-2, *B* and *C*; Figure 24-3). The porous materials also provide additional regions for tissue ingrowth and integration (mechanical stabilization) and thereby a minimization of interfacial motion and dynamic (wear-associated) interfacial breakdown. The strength characteristics after tissue ingrowth would then become a combination of the ceramic and the investing tissues.[107]

A number of the CPCs are phase mixtures of HA and TCP, whereas some compounds are composites or mechanical mixtures with other materials[93] (see Table 24-4). These classes of bioactive ceramics, including glasses, glass-ceramics, mixtures of ceramics, combinations of metals and ceramics, or polymers and ceramics, exhibit a wide range of properties. In general, these biomaterials have shown acceptable biocompatibility profiles from

WWW.HIGHDENT.IR

laboratory and clinical investigations. Bulk-form implant designs made from CPCs, which were contraindicated for some implant designs because of poor mechanical performance, have found a wide range of indications as coatings of stronger implant materials.

The coatings of CPCs onto metallic (cobalt- and titanium-based) biomaterials have become a routine application for dental implants. For the most part these coatings are applied by plasma spraying, have average thickness between 50 and 70 µm, are mixtures of crystalline and amorphous phases, and have variable microstructures (phases and porosities) compared with the solid portions of the particulate forms of HA and TCP biomaterials.[93,108] At this time, coating characteristics are relatively consistent, and the quality control and stricter quality assurance programs from the manufacturers have greatly improved the consistency of coated implant systems. (A more detailed discussion of surface treatment options is presented in the next section.)

Concerns continue to exist about the fatigue strengths of the $CaPO_4$ coatings and coating-substrate interfaces under tensile and shear loading conditions. There have been some reports of coating loss as a result of mechanical fracture, although the numbers reported remain small.[89] This has caused some clinicians and manufacturers to introduce designs in which the coatings are applied to shapes (geometric designs) that

minimize implant interface shear or tensile loading conditions (e.g., porosities, screws, spirals, plateaus, vents). From theoretic considerations, the coating of mechanically protected areas seems most desirable.

Density, Conductivity, and Solubility

Bioactive ceramics are especially interesting for implant dentistry because the inorganic portion of the recipient bone is more likely to grow next to a more chemically similar material. The bioactive (bioreactive) categorization includes $CaPO_4$ materials such as TCP, HA, calcium carbonate (corals), and calcium sulfate–type compounds and ceramics. A chemical-biochemical contact between the host bone and grafted material may be developed, as well as a possible stimulus of bone activity.[95] Their limitations have been associated with the material forms that have lower strengths (i.e., similar to or less than bone).[95]

The very technique-sensitive fabrication steps related to phase transition and thermal expansion during cooling might cause the final product of $CaPO_4$-type coatings to be more or less resorbable. In addition, the original categories of resorbable versus nonresorbable for these materials must be carefully weighed as a function of their particle size, porosity, chemical structure, and environmental exposure conditions.

Dissolution characteristics of bioactive ceramics have been determined for both particulates and coatings.[109,110] In general, solubility is greater for TCP than for HA. Each increase relative to increasing surface area per unit volume (porosity) and the CPC solubility profiles depend on the environment (e.g., pH, mechanical motion).

If one considers a uniform material chemistry, then the larger the particle size is, the longer the material will remain at an augmentation site. Thus 75-µm particles will be resorbed more rapidly than 3000-µm particles. In addition, the porosity of the product affects the resorption rate. Tofe et al.[111] reported on the porosity of dense, macroporous and microporous $CaPO_4$. Some of the dense HA lacks any macro- or microporosity within the particles. The longest resorption rate occurred with the dense nonporous HA type because osteoclasts may only attack the surface and cannot penetrate the nonporous material. Macroporous $CaPO_4$ (e.g., corallin HA) demonstrated 100-µm or 500-µm pores, which comprised 15% or more of the total material volume. Minimal porosity was found in the HA bulk material that surrounded the large pores. Microporous apatites often have their origin from bovine or human bone. The porosity observed in these materials is approximately 5 µm or less and comprises less than 28% of the total volume. The pores or holes are regions where blood components and organic materials can reside when placed within bone, and they represent the regions where living material existed before the processing of the implant material. The greater the porosity is, the more rapid is the resorption of the graft material. For example, clinical observation shows dense crystalline forms of HA may last longer than 15 years in the bone, the macroporous 5 years, and the microporous HA as short as 6 months (Figure 24-4).

The crystallinity of HA also affects the resorption rate of the material. The highly crystalline structure is more resistant to alteration and resorption. An amorphous product has a chemical structure that is less organized with regard to atomic structure. The hard or soft tissues of the body are more able to degrade the components and resorb the amorphous forms of grafting materials. Thus crystalline forms of HA are found to be very stable over the long term under normal conditions, whereas the amorphous structures are more likely to exhibit resorption and susceptibility to enzyme- or cell-mediated breakdown.[112] Therefore, in general, the less crystalline the material, the faster its resorption rate.[92,93,95,112,113]

The purity of the HA bone substitutes may also affect the resorption rate. The resorption of the bone substitute may be cell or solution mediated. Cell-mediated resorption requires processes associated with living cells to resorb the material, similar to the modeling and remodeling process of living bone, which demonstrates the coupled resorption and formation process. A solution-mediated resorption permits the dissolution of the material by a chemical process. Impurities or other compounds in bioactive ceramics, such as calcium carbonate, permit more rapid solution-medicated resorption, which then increases the porosity of the bone substitute. Although the coralline HA does not demonstrate micropores along the larger holes, the HA may have carbonates incorporated within the material, which hastens the resorption process.

WWW.HIGHDENT.IR

The pH in the region in which the bone substitutes are placed also affects the rate of resorption. As the pH decreases (e.g., because of chronic inflammation or infection) the components of living bone, primarily $CaPO_4$, resorb by a solution-mediated process (i.e., they become unstable chemically).

The $CaPO_4$ coatings are nonconductors of heat and electricity. This can provide a relative benefit for coated dental implants, where mixtures of conductive materials may be included in the overall prosthetic reconstruction. In combination with color (off white), these properties are considered to be advantageous.

In most applications within bone, solubilities are higher during the first few weeks, then decrease with continued in vivo exposure and the apposition of mineralized structures.[109,110] However, some investigators have shown situations in which osteoclastic resorption has removed localized zones of $CaPO_4$ coatings.[114] This raises interesting questions about long-term in vivo stabilities. At this time, clinical results have been favorable, and expanded applications have continued.

Current Status and Developing Trends

The CPCs have proved to be one of the more successful high technology–based biomaterials that have evolved within the past decades. Their advantageous properties strongly support the expanding clinical applications and the enhancement of the biocompatibility profiles for surgical implant uses.

Within the overall theme for new-generation biomaterials to be chemically (bonding to tissue) and mechanically (nonuniform, multidirectional properties) anisotropic, the CPCs could be the biomaterial surfaces of choice for many device applications.[115,116]

Carbon and Carbon Silicon Compounds

Carbon compounds are often classified as *ceramics* because of their chemical inertness and absence of ductility; however, they are conductors of heat and electricity. Extensive applications for cardiovascular devices, excellent biocompatibility profiles, and moduli of elasticity close to that of bone have resulted in clinical trials of these compounds in dental and orthopedic prostheses. One two-stage root replacement system (Vitredent) was quite popular in the early 1970s.[10] However, a combination of design, material, and application limitations resulted in a significant number of clinical failures and the subsequent withdrawal of this device from clinical use.

Ceramic and carbonitic substances continue to be used as coatings on metallic and ceramic materials. Advantages of coatings as mentioned in an earlier section include tissue attachment; components that are normal to physiological environments; regions that serve as barriers to elemental transfer, heat, or electrical current flow; control of color; and opportunities for the attachment of active biomolecules or synthetic compounds. Possible limitations relate to mechanical strength properties along the substrate-coating interface; biodegradation that could adversely influence tissue stabilities; time-dependent changes in physical characteristics; minimal resistance to scratching or scraping procedures associated with oral hygiene; and susceptibility to standard handling, sterilizing, or placing methodologies. Greater uses of surface-coated dental implants have been developed by the research and development communities.

POLYMERS AND COMPOSITES

The use of synthetic polymers and composites continues to expand for biomaterial applications. Fiber-reinforced polymers offer advantages in that they can be designed to match tissue properties, can be anisotropic with respect to mechanical characteristics, can be coated for attachment to tissues, and can be fabricated at relatively low cost. Expanded future applications for dental implant systems, beyond inserts for damping force transfers such as those used in the IMZ (Interpore, Inc.) and Flexiroot (Interdent Corp.) systems, are anticipated as interest continues in combination synthetic and biological composites.

Structural Biomedical Polymers

The more inert polymeric biomaterials include polytetrafluoroethylene (PTFE), polyethylene terephthalate (PET), polymethylmethacrylate (PMMA), ultrahigh-molecular-weight polyethylene (UHMW-PE), polypropylene (PP), polysulfone (PSF), and polydimethylsiloxane (PDS, or silicone rubber [SR]). These are summarized in Table 24-5. In general, the polymers have lower strengths and elastic moduli and higher elongations to fracture compared with other classes of biomaterials. They are thermal and electrical insulators, and when constituted as a high-molecular-weight system without plasticizers, they are relatively resistant to biodegradation. Compared with bone, most polymers have lower elastic moduli with magnitudes closer to soft tissues.

Polymers have been fabricated in porous and solid forms for tissue attachment, replacement, and augmentation and as coatings for force transfer to soft tissue and hard tissue regions. Cold-flow characteristics and creep and fatigue strengths are relatively low for some classes of polymers (e.g., SR and PMMA) and have resulted in some limitations. In contrast, some are extremely tough and fatigue cycle resistant (e.g., PP, UHMW-PE, PTFE) and afford opportunities for mechanical force transfer within selected implant designs. Most uses have been for internal force distribution connectors for osteointegrated implants, where the connector is intended to better simulate biomechanical conditions for normal tooth functions.

*Polymer properties exhibit a wide range depending on processing and structure. These values have been taken from general tables.

The indications for PTFE have grown exponentially in the last decade because of the development of membranes for guided tissue regeneration techniques. However, PTFE has a low resistance to contact abrasion and wear phenomena.

Composites

Combinations of polymers and other categories of synthetic biomaterials continue to be introduced. Several of the more inert polymers have been combined with particulate or fibers of carbon, Al_2O_3, HA, and glass ceramics. Some are porous, whereas others are constituted as solid-composite structural forms.[117,118]

In some cases, biodegradable polymers, such as polyvinyl alcohol (PVA), polylactides or glycolides, cyanoacrylates, or other hydratable forms have been combined with biodegradable $CaPO_4$ particulate or fibers.[119] These are intended as structural scaffolds, plates, screws, or other such applications. Biodegradation of the entire system, after tissues have adequately reformed and remodeled, has allowed the development significantly advantageous procedures such as bone augmentation and peri-implant defect repairs.

In general, polymers and composites of polymers are especially sensitive to sterilization and handling techniques. If intended for implant use, then most cannot be sterilized by steam or ethylene oxide. Most polymeric biomaterials have electrostatic surface properties and tend to gather dust or other particulate if exposed to semiclean air environments. Because many can be shaped by cutting or autopolymerizing in vivo (PMMA), extreme care must be taken to maintain quality surface conditions of the implant. Porous polymers can be deformed by elastic deformation, which can close open regions intended for tissue ingrowth. In addition, cleaning of contaminated porous polymers is not possible without a laboratory environment. In this regard, talc or starch on surgical gloves, contact with a towel or gauze pad, or the touching of any contaminated area must be prevented for all biomaterials.

Long-term experience, excellent biocompatibility profiles, ability to control properties through composite structures, and properties that can be altered to suit the clinical application make polymers and composites excellent candidates for biomaterial applications, as the constant expansion of the applications of this class of biomaterials can verify.

Inserts and Intramobile Elements

Relatively low moduli of elasticity (compared with metals and ceramics), high elongations to fracture, and inherent toughnesses have resulted in use of selected polymers for connectors or interpositional spacers for dental implants. One popular polymer insert system was included in Table 24-5 for general reference purposes. The most significant limitation has been the polymeric materials resistance to cyclical-load creep and fatigue phenomena. Retrieved transfer systems, in some clinical retrievals, have shown significant plastic deformation and fracture.[120] Although the desire to achieve such a stress-damping effect seems well founded, the inadequate long-term performance of the materials and high time and cost associated with maintenance of these devices have limited their field of application, and they are used less today than during the last decade.

FUTURE AREAS OF APPLICATION

Synthetic substances for tissue replacement have evolved from selected industrial grade materials such as metals, ceramics, polymers, and composites. This situation offers opportunities for improved control of basic properties. The simultaneous evolution of the biomechanical sciences also provides optimization of design and material concepts for surgical implants. Knowledge of tissue properties and

WWW.HIGHDENT.IR

computer-assisted modeling and analyses also support the present developments. The introduction of anisotropy with respect to mechanical properties; chemical gradients from device surface to center, with bonding along the tissue interfaces; and control of all aspects of manufacturing, packaging, delivering, placing, and restoring enhance the opportunities for optimal application and, it is hoped, device treatment longevities. Health care delivery would benefit from better availability and decreased per-unit costs.

Combinations to provide compositions with bioactive surfaces, the addition of active biomolecules of tissue-inductive substances, and a stable transgingival attachment mechanism could improve device systems. An integrated chemical and physical barrier at the soft tissue transition region would, at least theoretically, enhance clinical longevities. Devices that function through bone or soft tissue interfaces along the force transfer regions could be systems of choice, depending on the clinical situation.[9]

Unquestionably, the trend for conservative treatment of oral diseases will continue. Thus it can be anticipated that dental implants will frequently be a first-treatment option. Therefore increased use of root form systems is to be expected. Clearly the true efficacy of the various systems will be determined by controlled clinical studies with 10- to 20-year follow-up periods, which include statistically significant quantitative analyses.

SURFACE CHARACTERISTICS

Many aspects of biocompatibility profiles established for dental surgical implants have been shown to depend on interrelated biomaterial, tissue, and host factors. For discussion purposes, the biomaterial characteristics can be separated into categories associated with either (1) surface or (2) bulk properties. In general, the biomaterial surface chemistry (purity and critical surface tension for wetting), topography (roughness), and type of tissue integration (osseous, fibrous, or mixed) can be correlated with shorter- and longer-term in vivo host responses. Additionally, the host environment has been shown to directly influence the biomaterial-to-tissue interfacial zone specific to the local biochemical and biomechanical circumstances of healing and longer-term clinical aspects of load-bearing function. The interfacial interaction between recipient tissues and implanted material are limited to the surface layer of the implant and a few nanometers into the living tissues. The details of the integration (hard or soft tissue) and force transfer that results in static (stability) or dynamic (instability or motion) conditions have also been shown to significantly alter the clinical longevities of intraoral device constructs.

Many of the conference proceedings cited have focused on biomaterial-to-tissue interfacial interactions, which strongly supports the value of scrutinizing the surface characteristics of dental implants. This was one consistent recommendation from the 1978 and 1988 consensus conferences on the benefit and risk aspects of dental implant–based clinical treatments.[9,10,121]

The synthetic biomaterials used for the construction of dental implants and the associated abutments that contact subepithelial zones of oral tissues can be classified into *metallic*, *ceramic*, and *surface-modified* (coated, reacted, or ion-implanted) groups. It has long been recognized that synthetic biomaterials should be mechanically and chemically clean at the time of surgical placement. Surface properties are chemical in nature and have been described in terms of atomic structural characteristics with extensions to the subatomic scale. These characteristics are critical to the surface composition, corrosion resistance, cleanliness, surface energy, flexure, and tendency to interact, such as the ability to denature proteins.

Surface characteristics are the theme of this section, with emphasis on metallic, ceramic, and surface-modified dental implant biomaterials.

SURFACE CHARACTERIZATION AND TISSUE INTERACTION

Metal and Alloy Surfaces

Standard grades of alpha (unalloyed) titanium and alpha-beta and beta-base alloys of titanium exist with an oxide surface at normal temperatures, with ambient air or normal physiologic environments that act as oxidizing media. A formation of a thin oxide exists via dissociation of and reactions with oxygen or other mechanisms such as oxygen or metal ion diffusion from and to the metallic surface, especially for titanium. Independent from the fabrication process, the oxide is primarily TiO_2, with small quantities of Ti_2O_3 and TiO, with some minor variable stoichiometry.[122-126] This thin layer of amorphous oxide will rapidly reform if removed mechanically. Surface properties are the result of this oxide layer and differ fundamentally from the metallic substrate.[63,123] Therefore the oxidation parameters such as temperature, type and concentration of the oxidizing elements, and eventual contaminants all influence the physical and chemical properties of the final implant product. The type of oxide on surgical implants is primarily amorphous in atomic structure (brookite) if formed in normal-temperature air or tissue fluid environments and is usually very adherent and thin in thickness dimensions (<20 nm). In contrast, if unalloyed titanium (alpha) substrates (titanium grades 1 to 4) are processed at elevated temperatures (above approximately 350° C [660° F]) or anodized in organic acids at higher voltages (above 200 mV), then the oxide forms a crystalline atomic structure (rutile or anatase) and can be 10 to 100 times thicker. The grain structure of

WWW.HIGHDENT.IR

the metal and the oxidation conditions also condition the microstructure and morphology of the surface oxides. Porosity, density, and general homogeneity of the substrate are all related to this process. Low-temperature thermal oxides are relatively homogeneous and dense[127]; with increasing temperatures they become more heterogeneous and more likely to exhibit porosity as scale formations, and some have glasslike surface oxide conditions (semicrystalline).[125,127]

Depending on the mechanical aspects of polishing and the chemical and electrochemical aspects of cleaning and passivating, these amorphous or crystalline oxides can exhibit microscopically smooth or rough topographies at the micrometer level. However, surface macroscopic roughness is normally introduced into the substrate beneath the oxide zone by mechanical (grinding), particulate blasting (resorbable blast media or other), or chemical (acid etching) procedures. The surface topography and roughness obtained by such techniques is characteristic of each fabrication process.[11,128] The oxide dimension (thickness) along these rougher surfaces remains relatively constant and within nanometer dimensional thicknesses under normal temperature and environmental exposure conditions.

The titanium alloys used for dental implant components include microstructural phases of alpha and beta or room temperature stabilized beta (only). The alpha-phase surface regions of the alloy are similar to unalloyed titanium in atomic arrangement (close-packed hexagonal), whereas the beta phases demonstrate a different atomic structure (body-centered cubic) and elemental chemistry. However, the beta phase oxide formation kinetics, chemistry, dimensions, and environmental stabilities are relatively similar to the alpha-phase regions. Electrochemical investigations have shown that the alpha- and beta-phase oxides provide substrate coverage and a high degree of chemical and biochemical inertness (resistance to corrosion and ion transfer) for titanium and alloys of titanium. Both titanium and Ti-6Al-4V have been reported to contain small amounts of titanium nitride along their surface oxide.[124,129,130] Ions, carbon, and substances other than alloying elements may be picked up in the oxide through the preparation process, similar to that found at the surface of CP titanium.[126,131-134] Nevertheless, in the cases of titanium and titanium alloy, the oxide layer grows homogeneously and a well-controlled inert coating of very stable insoluble oxide normally contacts the living tissues.

Considerable research has been conducted on the roles of alloying elements in titanium alloys and how these elemental compositions may influence oxide properties and host tissue compatibility. This is dependent on the amount of the ions available to the tissues and relative rates of ion transfers, which could result in host tissue toxicity. In general, adequately processed and finished titanium alloys have shown integration with bone and soft tissue environments for a wide range of dental and medical implant devices.

Surface analysis studies have shown that the titanium alloy exhibits a similar oxide layer and as such is able to interact with surrounding bone in ways that are similar to unalloyed titanium.[135] Predictable results can be achieved with titanium alloy implant with a similar degree of bone integration.[136] In addition, electrochemical measurements of corrosion and ion release rates strongly support the chemical-biochemical stability properties of titanium alloys.

Some reports have expressed concerns because titanium alloy surface oxides contain significant amounts of alloying elements and exhibit different morphology and crystallization.[129,137-140] Aluminum in particular has been reported in both the outermost and the innermost layers. At the innermost layer, it was found especially over mixed (alpha) and (beta) phases grains of the alloy.[129] The different surface oxides are then argued to be responsible for a "lesser" quality of osseointegration in particular because of the potential of corrosion products containing aluminum and vanadium.[141-143] The orthopedic and dental literature specific to in vivo animal and human studies have also documented long-term success with titanium alloys that demonstrated close physical adaption of the bone to the surface of the alloy.[144-151]

Tissue Interactions

Oxide modification during in vivo exposure has been shown to result in increased titanium oxide layer thickness of up to 200 nm.[152-154] The highest oxide growth area corresponded to a bone marrow site, whereas the lowest growth was associated with titanium in contact with cortical regions of bone. Increased levels of calcium and phosphorus were found in the oxide surface layers and seemed to indicate an active exchange of ions at the interface. Hydrogen peroxide environmental conditions have been shown to interact with Ti and form a complex gel.[155-157] "Titanium gel conditions" are credited with attractive in vitro properties such as low apparent toxicity, inflammation, bone modeling, and bactericidal characteristics. The authors restricted their studies to CP titanium exclusively and not titanium alloys.

Other elements interacting with the surface layer of several implanted materials are calcium and phosphorus,[158-159] exhibiting a $CaPO_4$ structure somewhat similar to apatite on the titanium surface. However, the low percentage of these elements along the material surface indicates this was the result of transfer and adsorption of these elements from tissue fluids, not an osteointegration process per se.

The surface biointeraction processes may be slow or activated by local reactions and may cause ion release and oxide alteration of the substrate. Local and systemic increases of the ion concentration have been reported.[160-161]

WWW.HIGHDENT.IR

In vitro studies showed that both titanium or titanium alloy were released in measurable quantities of the substrate elements at the surface.[23,162] Especially high rates of ion release were observed in ethylenediamine tetraacetic acid (EDTA) and sodium citrate solutions and varied as a function of the corroding medium.[162] Ion release corresponds to an oxide layer thickness growth with inclusions of calcium, phosphorus, and sulfur in particular. This is especially a concern for larger orthopedic or porous implants, where such ion release may be a part of the origin of implant failure and allergic reactions and has even proposed to be a local or systemic reason for the formation of tumors. In addition, free-titanium ions have been shown to inhibit the growth of HA crystals (i.e., the mineralization of calcified tissues at the interface).[163-165]

Integration with Titanium and Alloys

Although titanium is known to exhibit better corrosion resistance, independent of the surface preparation, in vivo and in vitro studies have shown that titanium may interact with the recipient living tissues over several years. This interaction results in the release of small quantities of corrosion products even though a thermodynamically stable oxide film exists.

Several studies have concentrated on the behavior of titanium and titanium alloys in simulated biological environments. Williams cautioned that although titanium can demonstrate excellent properties of its tenacious oxide film, it is usually not sufficiently stable to prevent wear and galling in bearing systems under load. Some situations have resulted in metal-to-metal contact and local welding.[36] Solar et al.[166] stated that under static conditions, titanium and titanium alloy should withstand exposure to physiologic chlorine solutions at body temperature indefinitely but would be susceptible to oxide changes caused by mechanical micromotion. Bundy et al.[167] exposed implant alloys simultaneously to tensile stress and corrosive environments (stress-applied conditions). In vivo, stainless steel and titanium alloy demonstrated cracklike features when loaded to yield stress and then reimplanted under laboratory conditions for 8 weeks. Cracklike features also were seen in stainless steel and titanium alloy loaded to or beyond the yield stress and subsequently electrochemically polarized for 38 weeks in the in vitro part of the study. None of the samples actually failed by completely cracking, but the authors presumed that it would have occurred with a longer exposure time as previously suggested.[36,168] Geis Gestorfer and Weber[39] used linear polarization methods to show that titanium showed minimal breakdown in simulated tissue fluids, whereas Ni-Ti showed rapid breakdown of passivity with increased chlorine product–related concentrations in unbuffered solutions. Therefore body fluids could be responsible for the dissolution of some metallic passive oxide films.[169]

Lemons[75] studied single-stage solid implants modified by bending or cutting and showed that damage could increase corrosion. Rostoker and Pretzel[170] studied couple corrosion in vitro for alloys and found that dissimilar metals in a combined prosthesis did not create a regional breakdown of the titanium passive layer. A second in vivo study evaluated couple and crevice corrosion of prosthetic alloys in vertebral muscles of dogs for 30 weeks (non–load-bearing, nonosseointegrated).[171] It was concluded that metals of superior corrosion resistance, such as titanium alloy, and wrought cobalt alloys can be combined with titanium alloy in one prosthesis to provide superior mechanical performance without creating additional corrosion. However, repeated oxide breakdown such as sustained abrasion was likely to damage the corrosion resistance of an alloy for any type of coupling. Results from Thompson et al.[172] did not predict accelerated corrosion for titanium alloy coupled to carbon for galvanic couples under static conditions.

Marshak et al.[173] and Marshak[174] studied the potential for existence of SCC, GC, and FC in an in vitro study of titanium alloy and gold alloy abutment implants and abutment complexes simultaneously submitted to a laterally oriented 10-kg loading and a simulated tissue fluid solution at 37° C. Stress corrosion cracking was studied in the most likely area, that is the screw-to-abutment connection, which was under constant and simultaneous tension and compression stresses. These studies showed possibilities for interactions at contact regions between the cast gold and titanium alloy and components under selected environmental conditions.

Cohen and Burdairon[175] showed that odontologic fluoride gels, which create an acidic environment, could lead to the degradation of the titanium oxide layer and possibly inhibit the osseointegration process. Deposits consistent with the presence of GC byproducts were detected on various surfaces of the experimental metal.[176-177] Liles et al.[178] investigated the GC between titanium and seven crown and bridge alloys in 1% sodium chloride (NaCl) solution. The nonprecious Ni-Co complex was likely to trigger GC. Clinically, this means that in the short term, the presence of the surface impurities such as iron found on some implant parts, as well as other contaminants related to the machining process, could result in loss of bone and integration in crestal areas exposed to corrosion products. The long-term presence of corrosion reaction products and ongoing corrosion could also lead to fracture of the affected alloy-abutment interface, the abutment, or possibly the implant body itself. This combination of stress and corrosion, possibly together with factors associated with bacteria, could be one of the reasons why implants fail at the local or individual levels

WWW.HIGHDENT.IR

rather than in a generalized fashion.[179] Protocols for manufacturing and cleaning prosthetic titanium parts (specifically abutments contacting the implant body) appear less stringent than those for implant bodies. This should not be the case, and the same standards should be applied to both implant body and prosthetic components. In addition, the short and longer clinical implications of the potential GC effect could be ideally nullified by the use of electrochemically compatible alloys for the superstructure.

Cobalt and Iron Alloys

The alloys of cobalt (Vitallium) and iron (surgical stainless steel—316L) exhibit oxides of chromium (primarily Cr_2O_3 with some suboxides) under normal implant surface–finishing conditions after acid or electrochemical passivation. These chromium oxides, as with titanium and alloys, result in a significant reduction in chemical activity and environmental ion transfers. Under normal conditions of acid passivation, these chromium oxides are relatively thin (nanometer dimensions) and have an amorphous atomic structure. The oxide atomic spatial arrangement can be converted to a crystalline order by elevated temperature or electrochemical exposures.

The chromium oxides on cobalt and iron alloys are microscopically smooth, and again, roughness is usually introduced by substrate processing (grinding, blasting, or etching). Because these oxides, similar to titanium oxides, are very thin (nanometer dimensions), the reflected light color of the alloys depends on the metallic substrate under the oxide.[33] However, as mentioned, the titanium, cobalt, and iron metallic systems depend on the surface reaction zones with oxygen (oxides) for chemical and biochemical inertness.

The cobalt and iron alloy bulk microstructures are normally mixtures of the primary alloy phases with regions of metallic carbides distributed throughout the material.[33,56,76,77] Along the surfaces the chromium oxide covers the matrix phase (metallic regions), whereas the carbides stand as secondary components (usually as mounds above the surface) at the microscopic level. In contrast to homogenization-annealed alloys, the as-cast cobalt alloys exhibit multiphasic characteristics within their microstructure, with relatively extensive regions of the alloy surfaces occupied by complex metallic carbides. Thus tissue-to-oxide and tissue-to-metallic carbide zones could be used to describe tissue integration of cobalt alloy. This is uniquely different compared with titanium implant biomaterials, where tissue-to-oxide regions predominate at the interface.[76,77]

The iron-based alloy chromium oxide and substrate are more susceptible to environmental breakdown, in comparison with cobalt- and titanium-based biomaterials. This has been discussed in the literature related to crevice and pitting corrosion biodegradation phenomena for stainless steel implant systems.[59,76,77] In general, if stainless steel implant surfaces are mechanically altered during implantation, or if the construct introduces an interface that is subjected to biomechanical fretting, then the iron alloy will biodegrade in vivo, and the fatigue strength of surgical stainless steel can be significantly decreased in a corrosive environment.[180] In some cases this has resulted in implant loss. However, in the absence of surface damage, the chromium oxides on stainless steel biomaterials have shown excellent resistances to breakdown, and multiple examples of tissue and host biocompatibility have been shown for implants removed after long-term (beyond 30 years in vivo) implantations.

Dental implants and implant abutments have also been fabricated from gold alloy with many abutments fabricated from palladium or Co-Cr-Ni-Mo alloys.[37] The minimally alloyed gold and palladium systems are noble electrochemically and do not depend on surface oxides for chemical and biochemical inertness. This would be the case for the high-noble alloys (major compositions of gold, platinum, palladium, iridium, and ruthenium). However, some palladium alloys and other lower noble element content alloys gain chemical and biochemical inertness from complex metallic surface oxides.[37] As mentioned, the multicomponent (wrought) cobalt-based alloys, as with other base-metal systems, depend on chromium oxide surface conditions for inertness.

In general, the noble-metal alloys do not demonstrate the same characteristics of tissue interaction when compared with the base-metal (Ti and Co alloy) systems. The ultrastructural aspects of tissue integration have not been extensively investigated for noble-alloy systems, although some have presented results describing osteointegration of gold alloys. The noble alloys, when used in a polished condition, are resistant to debris accumulation on a relative basis compared with other alloys. This has been listed as an advantage for their use in intraoral abutment systems. In addition, mechanical finishing of the more noble alloys can result in a high degree of polish and a minimal concern about damaging or removing surface oxides.

Ceramics

Aluminum oxide ceramics have been extensively investigated related to surface properties and how these properties relate to bone and soft tissue integration.[92,93,104-117] Aluminum oxide ceramics are fully oxide materials (bulk and surface), thereby affording advantages related to tissue interface–related investigation. In addition, studies have included the polycrystalline (alumina) and single-crystalline (sapphire) forms of the oxide structure. These forms have introduced very different surface

WWW.HIGHDENT.IR

roughness values for the same material substrate plus bulk properties where ion transfer and electrochemical phenomena are minimal influences. Bone and soft tissue integration have been demonstrated for this oxide material over the long term in humans and laboratory animals. Direct relationships have been established between the interfacial events of tissue integration for metallic surface oxides of titanium and chromium and the Al_2O_3 systems. As mentioned previously, surface quality can be directly correlated with tissue integration and clinical longevity. Because the Al_2O_3 ceramics are crystalline and extend throughout the surface and bulk zones, biomechanical instabilities do not alter the chemical aspects of biomaterial properties. (No electrochemical change is introduced if the surface is removed.) Ceramic coatings (e.g., Al_2O_3) have been shown to enhance the corrosion resistance and biocompatibility of metal implants, in particular surgical stainless steel and Ni-Cr, Co-Cr alloys.[181] However, the Ni-Cr and steel alloys can be subject to crevice corrosion. Studies in orthopedics caution that the Al_2O_3 coating may cause a demineralization phenomenon caused by a high local concentration of substrate ions in the presence of metabolic bone disease.[182] This remains to be established within the use of Al_2O_3 implants for clinical applications.

Hydroxyapatite

In addition to the bulk Al_2O_3 biomaterials, $CaPO_4$–based ceramic or ceramic-like coatings have been added to titanium and cobalt alloy substrates to enhance tissue integration and biocompatibility. These coatings, for the most part, are applied by plasma spraying small-size particles of crystalline HA ceramic powders. The process of coating and the coating dimensions and property characteristics are addressed further in the next section.

The surface topography is characteristic of the preparation process. Variations in the roughness and porosity of the surface (<100 µm) can be categorized in function of the surfacing process. Machined implants exhibit an irregular surface with grooves, ridges, and pits including a nanometer scale.[183,184] Proponents of such a surface argue that it is the most conducive to cell attachment[122-124] (Figure 24-5).

Surface roughening by particulate blasting can be achieved by different media. Sandblasting provides irregular rough surfacing with <10-µm scales and a potential for impurity inclusions. Researchers used a titanium alloy Ti-6Al-4V to improve the mechanical properties and elected to electropolish the surface to reduce surface roughness to be only in the 0.1-mm scale by controlled removal of the surface layer by dissolution.[183,185,186] Titanium implants may be etched with a solution of nitric and hydrofluoric acids to chemically alter the surface and eliminate some types of contaminant products (Figure 24-6). The acids very rapidly attack metals other than titanium, and these processes are electrochemical in nature. Proponents of this technique argue that implants treated by sandblasting and acid etch provide superior radiographic bone densities along implant interfaces compared with titanium plasma-sprayed surfaces.[187] Recently, concerns have been expressed regarding embedded media from glass beading (satin finish) and grit blasting (alumina Al_2O_3) and a possible risk of associated osteolysis caused by foreign debris.[188,189] Ricci et al.[189] reported on failed retrieved implants that exhibited extensive surface inclusions consisting of silicon and/or Al_2O_3-related product, which were also present in the surrounding tissues. A relatively new process (resorbable blast media) has been said to provide a comparable roughness to an alumina grit blast finish, which can be a rougher surface than the machined, glass-beaded, or acid-etched surfaces (Figure 24-7).[190]

Porous and Featured Coatings

The implant surface may also be covered with a porous coating. These may be obtained with titanium or HA

WWW.HIGHDENT.IR

particulate–related fabrication processes. Examples of coatings and processes for producing surface-modified implants are summarized in the following sections.

Titanium Plasma Sprayed

Porous or rough titanium surfaces have been fabricated by plasma spraying a powder form of molten droplets at high temperatures. At temperatures in the order of 15,000° C, an argon plasma is associated with a nozzle to provide very high-velocity 600 m/sec partially molten particles of titanium powder (0.05- to 0.1-mm diameter) projected onto a metal or alloy substrate.[63,191] The plasma-sprayed layer after solidification (fusion) is often provided with a 0.04- to 0.05-mm thickness. When examined microscopically, the coatings show round or irregular pores that can be connected to each other (Figure 24-8). Hahn and Palich[192] first developed these types of surfaces and reported bone ingrowth in titanium hybrid powder plasma spray-coated implants inserted in animals. Karagianes et al.[193] assessed the suitability of porous titanium and titanium alloy to achieve bone-implant bonding characteristics in miniature swine and likened it to a three-dimensional surface. Kirsch[120] conducted histologic studies for plasma flame-sprayed particulate titanium coating root form specimen (IMZ) implanted and integrated to the bone in dogs, with complete integration reported at 6 weeks. In animal experiments and histologic studies, Schroeder et al.[194] concluded that the rough and porous surfaces showed a three-dimensional interconnected configuration likely to achieve bone-implant attachment for stable anchorage. Other animal studies concluded that a porous titanium surface from various fabrication methods may increase the total surface area (up to several times), produce attachment by osteoformation, enhance attachment by increasing ionic interactions, introduce a dual physical and chemical anchor system, and increase the load-bearing capability 25% to 30%.[100,120,195-200] In vitro studies of fibroblast attachment conducted by Lowenberg et al.[201] showed superior attachment to surface-ground titanium alloy disks compared with porous titanium but with a better cell orientation on porous forms of titanium.

In 1981, Clemow et al.[202] showed that the rate and percentage of bone ingrowth into the surface was inversely proportional to the square root of the pore size for sizes greater than 100 µm and that the shear properties of the interface were proportional to the extent of bone ingrowth. The optimum pore size for bone ingrowth was determined in a study of cobalt-base alloy porous implants inserted in canine femurs. The optimum pore size was deduced from the maximum fixation strength measurements. These surface porosities ranged from 150 to 400 µm and coincidentally correspond to surface feature dimensions obtained by some plasma-spraying processes.[203-206] In addition, porous surfaces can result in an increase in tensile strength through ingrowth of bony tissues into three-dimensional features. High shear forces determined by the torque-testing methods and improved force transfer into the peri-implant area have also been reported.[207,208]

In 1985 at the Brussels Osseointegration Conference, the basic science committee did not present results that showed any major differences between smooth, rough, or porous surfaces regarding their ability to achieve osteointegration. However, proponents of porous surface preparations reported that there have been results showing faster initial healing compared with noncoated porous titanium implants and that porosity allows bone formation within the porosities even in the presence of some micromovement during the healing phase.[209,210] Such surfaces were also reported to allow the successful placement of shorter-length implants when compared with noncoated implants. The basic theory was based on increased area for bone contact. Reports in the literature caution about cracking and scaling of coatings because of stresses produced by elevated temperature

WWW.HIGHDENT.IR

processing[211,212] and risk of accumulation of abraded material in the interfacial zone during implanting of titanium plasma-sprayed implants. It may be indicated to restrict the limit of coatings in lesser bone densities that cause less frictional torque transfer during implant placement process. In addition, the present technology allows metallurgic bonding of coatings and a high resistance against mechanical separation of the coating, with many coating test values exceeding the published standard requirements.[213]

Hydroxyapatite Coating

Hydroxyapatite coating by plasma spraying was brought to the dental profession by deGroot.[92] Kay et al.[214] used scanning electron microscopy (SEM) and spectrographic analyses to show that the plasma-sprayed HA coating could be crystalline and could offer chemical and mechanical properties compatible with dental implant applications.[214] Block et al.[215] and Thomas et al.[216] showed an accelerated bone formation and maturation around HA-coated implants in dogs when compared with noncoated implants. HA coating can also lower the corrosion rate of the same substrate alloys.[217] Researchers measured the HA coating thickness after retrieval from specimens inserted in animals for 32 weeks and showed a consistent thickness of 50 mm, which is in the range advocated for manufacturing.[19,89,218,219] The bone adjacent to the implant has been reported to be better organized than with other implant materials and with a higher degree of mineralization.[220] In addition, numerous histologic studies have documented the greater surface area of bone apposition to the implant in comparison with uncoated implants,[215,221,222] which may enhance the biomechanics and initial load-bearing capacity of the system. HA coating has been credited with enabling HA-coated titanium or titanium alloy implants to obtain improved bone-implant attachment compared with machined surfaces.

Studies also demonstrated that the HA-bone attachment is superior to the HA-implant interface.[216,218,223] However, proponents of such surfaces report excellent reliability of HA-coated implants.[224,225] The most significant result is the increase in bone penetrations, which enhances fixation in areas of limited initial bone contact.[37,40,41,226] However, controversies still exist, and some authors caution that HA coatings do not necessarily represent an advantage for the long-term prognosis of the system.

Implants of solid sintered HA have been shown to be susceptible to fatigue failure.[98,219,223] This situation can be altered by the use of a CPC coating along metallic substrates. Although several methods may be used to apply CPC coatings, the majority of commercially available implant systems are coated by a plasma spray technique. A powdered crystalline HA is introduced and melted by the hot, high-velocity region of a plasma gun and propelled onto the metal implant as a partially melted ceramic (Figure 24-9).[108,191] One of the concerns regarding CPC coatings is the strength of the bond between the CPC and the metallic substrate. Investigative ion beam–sputtering coating techniques for CPC or CPC-like nonresorbable coatings to varied substrates appear to produce dense, more tenacious, and thinner coatings (a few micrometers), which would minimize the problem of poor shear strength and fatigue at the coating-substrate interface.[108] Recent reports have introduced a new type of treatment for coatings, which appear primarily amorphous in nature, and further in vivo studies are needed to determine tissue response.[227,228] Other investigations include developing new biocompatible coatings based on TCP or titanium nitride.[229]

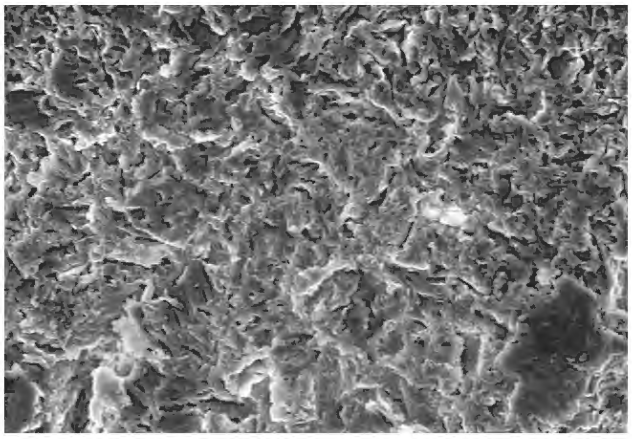

Figure 24-9 Hydroxyapatite (HA) coatings on implant surface provide several clinical properties because of the osteoconductive properties of HA. (Scanning electron microscopy [SEM] of BioHorizons D4 implant; ×500.)

It has been shown that the plasma-spraying technique can alter the nature of the crystalline ceramic powder and can result in the deposition of a variable percentage of a resorbable amorphous phase.[230] A dense coating with a high crystallinity has been listed as desirable to minimize in vivo resorption. In addition, the deposited CPC may be partially resorbed through remodeling of the osseous interface.[28,231,232] It is therefore wise to provide a biomechanically sound substructure design[230,231] that is able to function under load-bearing conditions to compensate for the potential loss of the CPC coating over years. In addition, the CPC coatings may resorb in infected or chronic inflammation areas. Animal studies also show reductions in coating thickness after in vivo function.[233] One advantage of CPC coatings is that they can act as a protective shield to reduce potential slow ion release from the Ti-6Al-4V substrate.[234] In addition, the interdiffusion between titanium and calcium (and phosphorus and other elements) may enhance the coating substrate bond by adding a chemical component to the mechanical bond.[232,235-238]

When these coatings were introduced more than two decades ago, many researchers expressed concerns about

WWW.HIGHDENT.IR

the biomechanical and gingival sulcus area biochemical stabilities. It was recommended that national and international standards for these coatings be developed, in part to provide detailed description of coating properties using consistent and uniform (standardized) test methods. Initial national standards were developed for *Beta Tricalcium Phosphate for Surgical Implantation by the ASTM Committee F4* (ASTM F4-1088). A standard specification for *Composition of Ceramic Hydroxyapatite for Surgical Implants* (ASTM F4-1185) was developed, and additional standards have been more recently approved, including *Glass and Glass-Ceramic Biomaterials for Implantation* (ASTM F4-1538), *Standard Test Method for Tension Testing of Calcium Phosphate Coatings* (ASTM F4-1501 F1147-05), *Standard Test Method for Calcium Phosphate Coatings for Implantable Materials* (ASTM F4-1609), *Test Method for Bending and Shear Fatigue Testing of Calcium Phosphate Coatings on Solid Metallic Substrates* (ASTM F4-1659 1160), and a *Standard Test Method for Shear Testing of Calcium Phosphate Coatings* (ASTM F4-1658 1044).[19] Additional standards being developed at the task group level with ASTM F4 include *Calcium Phosphate Coating Crystalline Characteristics, Mechanical Requirements for Calcium Phosphate Coatings,* and *Environmental Stability of Calcium Phosphate Coatings F1926*. An additional standard on anorganic bone (ASTM F4-1581) has also been established within the ceramics subcommittee of ASTM F4.[19]

These national and related international standards (ISO) should provide basic property information for $CaPO_4$ materials and coatings. This information should prove most useful as longer-term investigations on biocompatibility are conducted for dental implant systems. Additionally, national and international standards have been established for the surgical implant alloys, bulk ceramics, and surface finishing of metallic biomaterials.

The concerns related to $CaPO_4$ coatings have focused on (1) the biomechanical stability of the coatings and coating-substrate interface under in vivo conditions of cyclic loading and (2) the biochemical stability of these coatings and interfaces within the gingival sulcus (especially in the presence of inflammation or infection) and during enzymatic process associated with osteoclasis remodeling of the bone-coating interfacial zones. Some of these questions were addressed at an ASTM symposium on $CaPO_4$ coatings, and some researchers related that the longer-term clinical studies (less than 10 years' experience) do not support reasons for concern. It will be interesting to reevaluate these questions and answers after 20 years of clinical experience.

Other Surface Modifications

Surface modification methods include controlled chemical reactions with nitrogen or other elements or surface ion implantation procedures. The reaction of nitrogen with titanium alloys at elevated temperatures results in titanium nitride compounds being formed along the surface. These nitride surface compounds are biochemically inert (like oxides) and alter the surface mechanical properties to increase hardness and abrasion resistance. Most titanium nitride surfaces are gold in color, and this process has been extensively used for enhancing the surface properties of industrial and surgical instruments.[19] Increased hardness, abrasion, and wear resistance can also be provided by ion implantation of metallic substrates. The element most commonly used for surface ion implantation is nitrogen. Electrochemically, the titanium nitrides are similar to the oxides (TiO_2), and no adverse electrochemical behavior has been noted if the nitride is lost regionally. The titanium substrate reoxidizes when the surface layer of nitride is removed. Nitrogen implantation and carbon-doped layer deposition have been recommended to improve the physical properties of stainless steel without affecting its biocompatibility.[239] Again, questions could be raised about coating loss and crevice corrosion.

Surface Cleanliness

A clean surface is an atomically clean surface with no other elements than the biomaterial constituents. Contaminants can be particulates, continuous films (e.g., oil, fingerprints), and atomic impurities or molecular layers (inevitable) caused by the thermodynamic instability of surfaces. Even after reacting with the environment, surfaces have a tendency to lower their energy by binding elements and molecules. The typical composition of a contaminated layer depends on atmospheres and properties of surface. For example, high-energy surfaces (metals, oxides, ceramics) usually tend to bind more to this type of monolayer than polymers and carbon (amorphous).

In the earlier times of dental implantology, no specific protocol for surface preparation, cleaning, sterilization, and handling of the implants was established.[240] Researchers have respectively demonstrated adverse host responses caused by faulty preparation and sterilization, omission to eliminate adsorbed gases, and organic and inorganic debris.[122,123,137,241] According to Albrektsson,[140] implants that seem functional may fail even after years of function, and the cause may be attributed to improper ultrasonic cleaning, sterilization, or handling during the surgical placement.

A systematic study of contamination layers is not available. Lausmaa et al.[124] showed that titanium implants had large variations in carbon contamination loads (20% to 60%) in the 0.3- to 1-nm thickness range, attributed to air exposure and residues from cleaning solvents and lubricants used during fabrication. Trace amounts of Ca, P, N, Si, S, Cl, and Na were noted from other studies.[132,133,241-243] Residues of fluorine could be attributed to passivation and etching treatments; Ca, Na, and Cl to autoclaving; and Si to sand and glass beading processes.

WWW.HIGHDENT.IR

Surface Energy

Measurements of surface property values of an implant's ability to integrate within bone include contact angle with fluids, local pH, and surface topography. These are often used for the determination of surface characteristics. Numerous studies were conducted to evaluate liquid, solid, and air contact angles, wetting properties, and surface tensions as criteria to assess surface cleanliness, because these parameters have been shown to have a direct consequence on osseointegration.[12,244,245] An intrinsically high surface energy is said to be most desirable. High surface energy implants showed a threefold increase in fibroblast adhesion, and higher-energy surfaces such as metals, alloys, and ceramics are best suited to achieve cell adhesion.[12] Surface tension values of 40 dyne/cm and higher are characteristic of very clean surfaces and excellent biological integration conditions.[244] A shift in contact angle (increase) is related to the contamination of the surface by hydrophobic contaminants and decreases the surface tension parameters. Because a spontaneously deposited, host-dependent conditioning film is a prerequisite to the adhesion of any biological element, it is suggested that the wetting of the surface by blood at the time of placement can be a good indication of the high surface energy of the implant.[244]

Passivation and Chemical Cleaning

The ASTM (ASTM B600, ASTM F-86) specifications for final surface treatment of surgical titanium implants require pickling and descaling with molten alkaline base salts. This is often followed by treatment with a solution of nitric or hydrofluoric acid to decrease and eliminate contaminants such as iron. Iron or other elements may contaminate the implant surface as a result of the machining process. This type of debris can have an effect of demineralizing the bone matrix.[246,247] However, these finishing requirements remain very general. Studies of fibroblast attachment on implant surfaces showed great variations, depending on the different processes of surface preparation. Inoue et al.[144] showed fibroblasts developed a capsule or oriented fibrous attachment following the grooves in titanium disks. Contact angles are also greatly modified by acid treatment or water rinsing.[248] Machining operations, polishing, texturing process, residual chemical deposits, and alloy microstructure all inadvertently affect the surface composition. In addition, many ways exist to intentionally modify the surface of the implant. They include conventional mechanical treatment (sand blasting), wet or gas chemical reaction treatment, electroplating or vapor plating, and ion beam processing, which leaves bulk properties intact and has been newly adapted to dentistry from thin film technology. Preliminary studies by Schmidt[249] and Grabowski et al.[250] showed modified fibroblast adhesion on nitrogen and carbon-ion implanted titanium. A general rule has been that cleaner is better.

Sterilization

Manipulation with bare fingers or powdered gloves, tap water, and residual vapor-carried debris from autoclaving can all contaminate implant surfaces. Bauhammers,[240] in an SEM study of dental implants, showed contamination of the surface with acrylic materials, powder for latex gloves, and bacteria. Today, in most cases, the manufacturer guarantees precleaned and presterilized implants with high-technology procedures, with the implants ready to be inserted. If an implant needs to be resterilized, then conventional sterilization techniques are not normally satisfactory. It appears at the present time that no sterilization medium is totally satisfactory for all biomaterials and designs. Metal or alloy constituents, inorganic and organic particles, corrosion products, polymers, and precipitates can be absorbed at the surface throughout the manufacturing, polishing, cleaning, sterilization, packaging, and storage processes. Baier et al.[12] correlated the usual type of contaminant found in relation to the sterilization technique used. Baier et al.[244] showed that steam sterilization can cause deposits of organic substances resulting in poor tissue adhesion. Doundoulakis[132] submitted titanium samples to different sterilization techniques, concluded to the adverse effect of steam sterilization and degradative effect of endodontic glass bead sterilizers, found that dry heat sterilization leaves organic deposits on the surface, and suggested that ultraviolet (UV) light sterilization may become a good alternative after further evaluation. In addition, accelerated oxide growth on titanium may occur with impurity contamination leading to surface discoloration.[32,122,250] In a study by Keller et al.,[252] corrosion products and films from autoclaving, chemicals, and cytotoxic residues from solutions were identified at the surface of implants submitted to sterilization. They suggested that alteration of the titanium surface by sterilization methods may in turn affect the host response and adhesive properties of the implant. On the other hand, Schneider et al.[253] compared the surface of titanium plasma-sprayed and HA-coated titanium implants after steam or ethylene dioxide sterilization using energy dispersive radiograph analysis and concluded that these techniques do not modify the elemental composition of the surface. Keller et al.[254] studied the growth of fibroblasts on disks of CP titanium sterilized by autoclaving, ethylene oxide, ethyl alcohol, or solely passivated with 30% nitric acid and concluded that sterilization seems to inhibit cell growth, whereas passivation does not.

Presently, proteinaceous deposits and their action as films can be best eliminated by radio frequency glow discharge technique (RFGDT), which seems to

WWW.HIGHDENT.IR

be a suitable final cleaning procedure. The implants are treated within a controlled noble gas discharge at very low pressure. The gas ions bombard the surface and remove surface atoms and molecules, which are absorbed onto it or are constituents of it. However, the quality of the surface treated depends on the gas purity. Baier et al.[255] showed that RFGDT is good for cleaning and, at the same time, for granting a high-energy state to the implant, which is related to improved cell adhesion capabilities. Thinner, more stable oxide films and cleaner surfaces have been reported with RFGDT plus improved wettability and tissue adhesion.[255-257] The principal oxide at the surface is unchanged by the RFGDT process.[258] A decrease in bacteria contamination on HA-coated implant surfaces was reported after RFGDT,[259] and studies suggest that RFGDT may enhance calcium and/or phosphate affinity because of an increase in elemental zone at the surface resulting in the formation of amorphous $CaPO_4$ compounds.[257]

Recently, a modified UV light sterilization protocol was shown to enhanced bioreactivity, which was also effective for eliminating some biological contaminants. Singh and Schaaf[260] assessed the quality of UV light sterilization and its effects on irregularly shaped objects, and they established its effectiveness on spores and its ability to safely and rapidly clean the surface and to grant high surface energy. Hartman et al.[261] submitted implants to various pretreatment protocols (RFGDT, UV light, or steam sterilization) and inserted them in miniature swine. Although RFGDT and UV-sterilized implants showed rapid bone ingrowth and maturation, steam-sterilized implants seemed to favor thick collagen fibers at the surface. On the other hand, Carlsson et al.[262] inserted implants in rabbits and compared the performances of conventionally treated implants with implants treated with RFGDT, found similar healing responses, and further cautioned that the RFGDT process produces a much thinner oxide layer at the surface of the implant and may deposit silica oxide from the glass envelope.

Adequate sterilization of clean, prepackaged dental implants and related surgical components has resulted in an ever-expanding use of gamma radiation procedures. Because gamma radiation sterilization of surgical implants is a well-established methodology within the industry, facilities, procedures, and standards are well known. Most metallic systems are exposed to radiation doses exceeding 2.5 Mrad where the packaging and all internal parts of the assembly are sterilized. This is an advantage in that components remain protected, clean, and sterile until the inner containers are opened within the sterile field of the surgical procedure. The healing screws, transfer elements, wrenches, and implants are all exposed to the gamma sterilization, which reduces opportunities for contamination.

Some ceramics can be discolored and some polymers degraded by gamma radiation exposures. The limits are known for classes of biomaterials, and all types of biomaterials can be adequately sterilized within the industry. Systems control, including prepackaging and sterilization, has been an important part of the success of dental implantology.

SUMMARY

In the 1960s dental implantology as a clinical discipline was judged by some to be rather disorganized, and treatments provided were often said to be not as successful as hospital-based orthopedic and cardiovascular surgery procedures. One part of this opinion related to the use of standard intraoral dental materials for implants plus general dental operatories for surgical activities (e.g., no gloves, high-speed drills, tap water). The biomaterials discipline evolved rapidly in the 1970s. Successful uses of synthetic biomaterials have been based on experience within the field of dental implantology. The basis for many of the newer and more clinically successful surgical reconstructions evolved within dentistry, with some now recognized as the most successful types of musculoskeletal reconstructive surgery. The biomaterials discipline therefore has evolved significantly over the past decades, and synthetic biomaterials are now constituted, fabricated, and provided to health care professionals as mechanically and chemically clean devices that have a high predictability of success when used appropriately within the surgical disciplines. This chapter on biomaterials has been separated into sections related to bulk and surface properties of biomaterials, and emphasis has been placed on the published literature on how these biomaterial properties relate to interactions at the tissue interface.

Surface characterization and working knowledge about how surface and bulk biomaterial properties interrelate to dental implant biocompatibility profiles represent an important area in implant-based reconstructive surgery. This chapter has provided summary information on surface and bulk properties for metallic, ceramic, and surface-modified biomaterials. The authors strongly recommend the reference material listed, in addition to a desire to have investigators always provide biomaterial surface and bulk property information as a component of any research studies on tissue response (biocompatibility) profiles.

ACKNOWLEDGMENT

In 1970, Jack E. Lemons was attending his first American and International Associations for Dental Research (AADR/IADR) meeting and was introduced to Ralph Phillips within a group discussion on dental materials. He quickly determined that Lemons knew little about the "dental" and some about the "materials." Phillips included Lemons in the interactions with carefully

WWW.HIGHDENT.IR

placed and directed questions and comments so that he was not excluded. This happened repeatedly over the years, until Lemons had the opportunity to reverse the exchange after making a presentation on behalf of the AADR/IADR Dental Materials Group on basic biocompatibility testing, with Phillips as the overview discussant. This opportunity was to coordinate and help direct some of the emerging exchanges among those experienced in the material and biological sciences. Subsequently, ongoing interactions with Phillips fostered many wonderful times with colleagues, students, and friends throughout the world.

Contents of this chapter represent a later stage, in which Lemons provided written comments and opinions about implant biomaterials as one extension of dental biomaterials. This chapter is dedicated in part to his memory, and most especially to the long-term friendship. The dental implant field, in the author's opinion, will benefit from a continuation of a multidisciplinary approach to the science, technology, and applications. We wish that Ralph could have continued, and we certainly will miss his counsel.

Chapter 25

Clinical Biomechanics in Implant Dentistry

Martha Warren Bidez, Carl E. Misch

The discipline of biomedical engineering, which applies engineering principles to living systems, has unfolded a new era in diagnosis, treatment planning, and rehabilitation in patient care. One aspect of this field, biomechanics, concerns the response of biological tissues to applied loads. Biomechanics uses the tools and methods of applied engineering mechanics to search for structure-function relationships in living materials.[1] Advancements in prosthetic, implant, and instrumentation design have been realized because of mechanical design optimization theory and practice.[2] This chapter provides fundamental concepts and principles of dental biomechanics as they relate to long-term success of dental implants and restorative procedures.

LOADS APPLIED TO DENTAL IMPLANTS

Dental implants are subjected to occlusal loads when placed in function. Such loads may vary dramatically in magnitude, frequency, and duration, depending on the patient's parafunctional habits. Passive mechanical loads also may be applied to dental implants during the healing stage because of mandibular flexure, contact with the first-stage cover screw, and second-stage permucosal extension.

Perioral forces of the tongue and circumoral musculature may generate low but frequent horizontal loads on implant abutments. These loads may be of greater magnitude with parafunctional oral habits or tongue thrust. Finally, application of nonpassive prostheses to implant bodies may result in mechanical loads applied to the abutment, even in the absence of occlusal loads.

So many variables exist in implant treatment that it becomes almost impossible to compare one treatment philosophy with another. However, basic units of mechanics may be used to provide the tools for the consistent description and understanding of such physiologic (and nonphysiologic) loads. Two different approaches may render a similar short-term result; however, a biomechanical approach still can determine which treatment renders more risk over the long term.

MASS, FORCE, AND WEIGHT

Mass, a property of matter, is the degree of gravitational attraction the body of matter experiences. As an example, consider two cubes composed of hydroxyapatite (HA) and commercially pure titanium, respectively. If the two cubes are restrained by identical springs, then each spring will deflect by a certain amount relative to the attraction of gravity for the two cubes. The two spring deflections in this example can be made equal by removing part of the material from the titanium cube. Even though the cubes are of completely different composition and size, they can be made equivalent with respect to their response to the pull of gravity. This innate property of each cube that is related to the amount of matter in physical objects is referred to as *mass*. The unit of mass in the metric (International System of Units) system is the kilogram (kg); in the English system, it is the pound mass (lbm).[3]

In 1687, Sir Isaac Newton described a force in what is now referred to as *Newton's laws of motion*.[3] In his second law, Newton stated that the acceleration of a body is inversely proportional to its mass and directly proportional to the force that caused the acceleration. The familiar relation expresses this law:

$$F = ma$$

where F is force (newtons [N]), m is mass (kilograms), and a is acceleration (meters per second squared [m/sec^2]). In the dental implant literature, force commonly is expressed as kilograms of force. The gravitational constant (a = 9.8 m/sec^2) is approximately the same at every location on Earth; therefore mass (kilograms) is the determining factor in establishing the magnitude of a static load.

Weight is simply a term for the gravitational force acting on an object at a specified location. Weight and force can be expressed by the same units, newtons or pound force (lbf). If a titanium cube is considered as though placed on the moon, then its weight (force caused by gravity) is different from its weight on the Earth. The mass in the cube has not changed, but the

WWW.HIGHDENT.IR

acceleration caused by gravity has changed. Recalling Sir Isaac Newton's work, an apple weighs approximately 1 N (0.225 lbf). The reader will find the conversion factors in Box 25-1 useful.[4]

Box 25-1 Useful Conversion Factors

Mass

1 kg = 2.205 lbm
1 lbm = 0.45 kg

Force

1 N = 1 kg(m/s^2) = 0.225 lbf
1 lbf = 4.448 N

Area

1 m^2 = 10.764 sq ft
1 sq ft = 0.093 m^2
1 sq in = 6.452 × 10^{-4} m^2

Pressure*

1 lbf/sq in (psi) = 144 lbf/sq ft = 6894.8 Pa = 6.89 kPa = 0.0069 MPa
1 Pa = 1 N/m^2 = 1.450 x 10^{-4} psi = 0.021 lbf/sq ft

*Stress uses these same units of measurement.

FORCES

Forces may be described by magnitude, duration, direction, type, and magnification factors. Forces acting on dental implants are referred to as *vector quantities*; that is, they possess magnitude and direction. Restated, to state simply that "a force of 75 lb exists on the distal abutment" is not sufficient. The more correct statement is "a force of 75 lb exists on the distal abutment directed axially along the long axis of the implant body." The dramatic influence of load direction on implant longevity and bone maintenance is discussed later in this chapter and others. Typical maximum bite force magnitudes exhibited by adults are affected by age, sex, degree of edentulism, bite location, and especially parafunction[5-9] (Table 25-1).

A force applied to a dental implant rarely is directed absolutely longitudinally along a single axis. In fact, three dominant clinical loading axes exist in implant dentistry: (1) mesiodistal, (2) faciolingual, and (3) occlusoapical (Figure 25-1). A single occlusal contact most commonly results in a three-dimensional occlusal force. Importantly, this three-dimensional force may be described in terms of its component parts (fractions) of the total force that are directed along the other axes. For example, if an occlusal scheme on an implant restoration is used that results in a large magnitude of force component directed along the faciolingual axis (lateral loading), then the implant is at extreme risk for fatigue failure (described later in this chapter). The process by which three-dimensional forces are broken down into their component parts is referred to as *vector resolution* and may be used routinely in clinical practice for enhanced implant longevity.

Components of Forces (Vector Resolution)

Occlusion serves as the primary determinant in establishing load direction. The position of occlusal contacts on the prosthesis directly influences the type of force components distributed throughout the implant system.

The dentist should visualize each occlusal contact on an implant restoration in its component parts. Consider the example of a restored dental implant subjected to a premature contact during occlusion. When the contact is broken down into its component parts directed along the three clinical loading axes, a large, potentially dangerous lateral component is observed. Occlusal adjustments consistent with implant protective occlusion to eliminate the premature contact minimize the development of such dangerous load components.

Angled abutments also result in development of dangerous transverse force components under occlusal loads in the direction of the angled abutment. Implants should be placed surgically to provide for mechanical loading down the long axis of the implant body to the maximum extent possible. Angled abutments are used to improve esthetics or the path of insertion of a restoration, not to determine the direction of load.

Three Types of Forces

Forces may be described as compressive, tensile, or shear. Compressive forces attempt to push masses toward each other. Tensile forces pull objects apart. Shear forces on implants cause sliding. Compressive forces tend to maintain the integrity of a bone-implant interface, whereas tensile and shear forces tend to distract or disrupt such an interface. Shear forces are most destructive to implants and bone compared with other load modalities. In general, compressive forces are accommodated best by the complete implant-prosthesis system. Cortical bone is strongest in compression and weakest in shear[10] (Table 25-2). Additionally, cements and retention screws, implant components, and bone-implant interfaces all accommodate greater compressive forces than tensile or shear. For example, whereas the compressive strength of an average zinc-phosphate dental cement is 83 to 103 MPa (12,000 to 15,000 psi), the resistance to tension and shear is significantly less (500 psi) (Figure 25-2).

The implant body design transmits the occlusal load to the bone. Threaded or finned dental implants impart a combination of all three force types at

WWW.HIGHDENT.IR

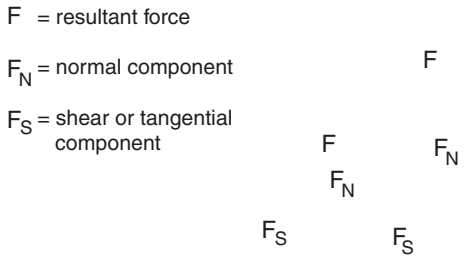

Figure 25-2 Force can be resolved into a combination of normal and shear force components in a given plane. Depending on the direction of load application, the same magnitude of force has different effects.

the interface under the action of a single occlusal load. This "conversion" of a single force into three different types of forces is controlled completely by the implant geometry. The prevalence of potentially dangerous tensile and shear forces in threaded or finned implants may be controlled optimally through careful engineering design. Cylinder implants in particular are at highest risk for harmful shear loads at the implant-tissue interface under an occlusal load directed along the long axis of the implant body. As a consequence, cylinder implants require a coating to manage the shear stress at the interface through a more uniform bone attachment along the implant length. Bone loss adjacent to cylindrical implants and coating degradation result in a mechanically compromised implant.

Offset loading on single-tooth or multiple-abutment restorations results in moment (bending) loads (described later under Force Delivery and Failure Mechanisms). As a result, an increase in tensile and shear force components is often found. Compressive forces typically should be dominant in implant prosthetic occlusion.

Multiple abutment restorations, particularly with distal cantilevers, produce a remarkably complex load profile in the prosthesis and in the bone-implant interface. These clinical realities underscore the need for optimizing dental implant design to provide the maximum functional surface area to dissipate such forces.

Stress

The manner in which a force is distributed over a surface is referred to as *mechanical stress*. Thus the familiar relation defines stress:

$$\sigma = F/A$$

where σ is stress (pounds per square inch; pascals), F is force (newtons; pound force), and A is area (square inches; square meters). The internal stresses that develop in an implant system and surrounding biological tissues under an imposed load may have a significant influence on the long-term longevity of the implants in vivo. As a general rule, a goal of treatment planning should be to minimize and evenly distribute mechanical stress in the implant system and the contiguous bone.

The magnitude of stress depends on two variables: (1) force magnitude and (2) cross-sectional area over which the force is dissipated. It is rare that a dentist can control

WWW.HIGHDENT.IR

the force magnitude completely. The magnitude of the force may be decreased by reducing these significant magnifiers of force: cantilever length, offset loads, and crown height. Night guards to decrease nocturnal parafunction; occlusal materials that decrease impact force; and overdentures, rather than fixed prostheses, that can be removed at night are further examples of force reduction strategies. The functional surface area over which the force is distributed, however, is controlled completely through careful treatment planning.

A *functional cross-sectional* area is defined as that surface that participates significantly in load bearing and stress dissipation. This area may be optimized by (1) increasing the number of implants for a given edentulous site and (2) selecting an implant geometry that has been designed carefully to maximize functional cross-sectional area. An increase in functional surface area serves to decrease the magnitude of mechanical stress imposed on the prosthesis, implant, and biological tissues.

Stress components are described as normal (perpendicular to the surface and given the symbol σ) and shear (parallel to the surface and given the symbol τ). One normal stress and two shear stresses act on each plane (x, y, z); therefore $\tau_{xy} = \tau_{yx}$, $\tau_{yz} = \tau_{zy}$, and $\tau_{xz} = \tau_{zx}$. Thus any three-dimensional element may have its stress state completely described by three normal stress components and three shear components.

The question arises as to what are the peak stresses or maximum stresses that an implant and the surrounding interfacial tissues experience. Peak stresses occur when the stress element is positioned in a particular orientation (or geometric configuration) in which all shear stress components are zero. When an element is in this configuration, the normal stresses are given a particular name, *principal stresses,* and are indicated as σ_1, σ_2, and σ_3. By convention, maximum principal (σ_1) stresses represent the most positive stresses (typically peak tensile stresses) in an implant or tissue region and minimum principal (σ_3) stresses, the most negative stresses (typically peak compressive stresses). Sigma 2 (σ_2) represents a value intermediate between σ_1 and σ_3. Determination of these peak normal stresses in a dental implant system and tissues may give valuable insights regarding sites of potential implant fracture and bone atrophy.

Deformation and Strain

A load applied to a dental implant may induce deformation of the implant and surrounding tissues. Biological tissues may be able to interpret deformation or a manifestation thereof and respond with the initiation of remodeling activity.

The deformation and stiffness characteristics of the materials used in implant dentistry, particularly the implant materials, may influence interfacial tissues, ease of implant manufacture, and clinical longevities. Elongation (deformation) of biomaterials used for surgical dental implants ranges from 0 for aluminum oxide ceramics to up to 55 for annealed 316L stainless steel[11] (Table 25-3). Related to deformation is the concept of strain, a parameter believed to be a key mediator of bone activity.

Under the action of a tensile force (F), the straight bar (of original gauge length, l_0) undergoes elongation

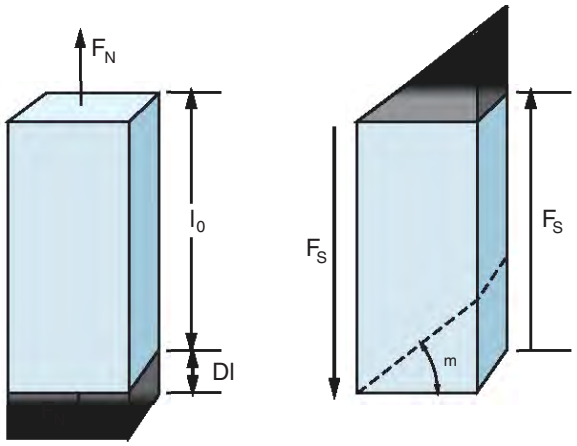

Figure 25-3 Under action of tensile force (F_N), the straight bar originally l_0 is elongated by an amount Δl. Engineering strain ε is the deformation per unit length. Shear strain γ is the change in a right angle of a body or stress element under action of a pure shearing load (F_S).

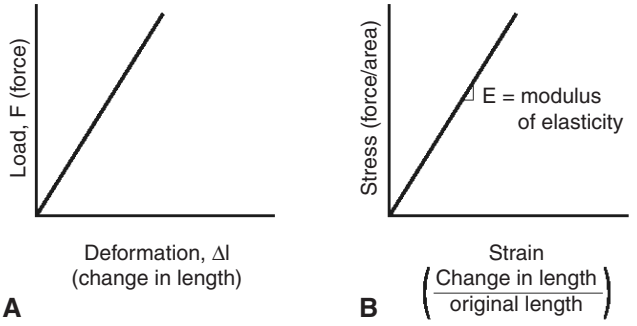

Figure 25-4 **A,** Load-versus-deformation curve may be generated for any elastic body experimentally subjected to a load. **B,** Dividing load values by the surface area and the deformation of the original gauge length of the specimen produces a stress-strain curve.

to a final length ($l_0+\Delta 1$) (Figure 25-3). Engineering strain, which is unitless, is defined as elongation per unit length and is described as:

$$\varepsilon = \frac{1\text{-}1_0}{1_0} = \frac{\Delta 1}{1_0}$$

where Δl is elongation, l_0 is original gauge length, and l is final length after elongation, Δl. Shear strain, γ, describes the change in a right angle of a body or stress element under the action of a pure shearing load. All materials (biological and nonbiological) are characterized by a maximum elongation possible before permanent deformation or fracture results. Furthermore, biological materials exhibit strain rate dependence in that their material properties (e.g., modulus of elasticity, ultimate tensile strength) are altered as a function of the rate of loading (and subsequent deformation rate).

Experimental observation also has demonstrated that lateral strain also accompanies axial strain under the action of an axial load. Within an elastic range (defined later in this section), these two strains are proportional to one another as described by Poisson's ratio, μ. For tensile loading:

$$\mu = \frac{\text{Lateral strain}}{\text{Axial strain}}$$

The material and mechanical properties described provide for the determination of implant-tissue stress-strain behavior according to established relationships in solid mechanics theory.[12]

Stress-Strain Relationship

A relationship is needed between the applied force (and stress) that is imposed on the implant and surrounding tissues and the subsequent deformation (and strain) experienced throughout the system. If any elastic body is subjected experimentally to an applied load, then a load-versus-deformation curve can be generated (Figure 25-4, *A*). Dividing the load (force) values by the surface area over which they act and the change in the length by the original length produces a classic engineering stress-strain curve (Figure 25-4, *B*). Such a curve provides for the prediction of how much strain will be experienced in a given material under the action of an applied load. The slope of the linear (elastic) portion of this curve is referred to as the *modulus of elasticity (E)*, and its value indicates the stiffness of the material under study.

The closer the modulus of elasticity of the implant resembles that of the contiguous biological tissues, the less the likelihood of relative motion at the tissue-implant interface. The cortical bone is at least five times more flexible than titanium. As the stress magnitude increases, the relative stiffness difference between bone and titanium increases. As the stress magnitude decreases, the stiffness difference becomes much less. Restated, the viscoelastic bone can stay in contact with more rigid titanium more predictably when the stress is low. In terms of full-arch kinematics, the practitioner should consider that the mandible flexes toward the midline on opening. A prosthesis and implant support system that is splinted from molar to molar must provide similar movement if the interface is to remain intact.

Once a particular implant system (i.e., a specific biomaterial) is selected, the only way for an operator to control the strain experienced by the tissues is to control the applied stress or change the density of bone around the implant (Figure 25-5). Such stress (force/area) may be influenced by the implant design, size, implant number, implant angulation, and restoration. The macrogeometry of the implant (i.e., the amount and orientation of functional surface area available to dissipate loads) has a strong influence on the nature of the force transfer at the tissue-implant interface. Surgical grafting procedures may increase the quantity and quality of bone and allow placement of a larger implant with more bone contiguous to the interface implant. The applied stress also is influenced by the restoration, including the size of occlusal tables, stress breakers, use of overdenture versus fixed prosthesis, and occlusal contact design. Generally,

WWW.HIGHDENT.IR

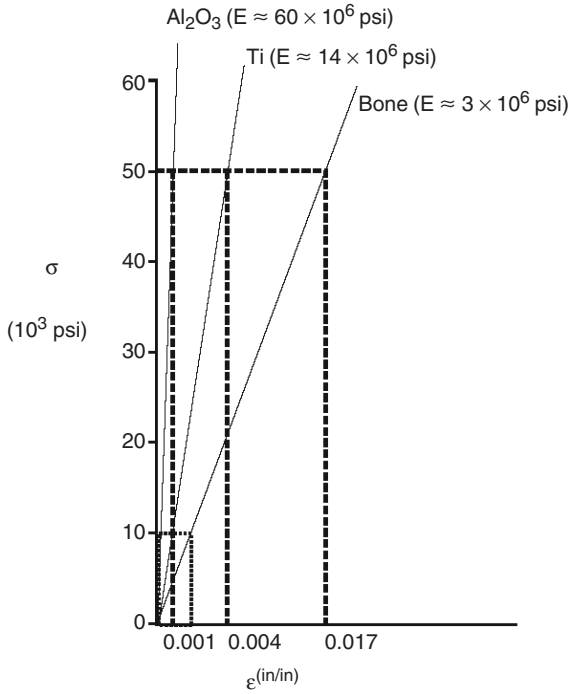

Figure 25-5 Once a particular implant system is selected, the only way to control strain (ε) on tissues is to control applied stress (σ). The greater the magnitude of stress applied to the system, the greater the difference in strain between implant material and bone. *E,* Modulus of elasticity.

the greater the magnitude of stress applied to a dental implant system, the greater the difference in strain between the implant material and bone. In such cases, the implant is less likely to stay attached to the bone, and the probability of fibrous tissue ingrowth into the interfacial region to accommodate the range of difference becomes greater. The density of bone is related not only to the bone strength but also to the modulus of elasticity (stiffness). The stiffer the bone, the more rigid it is; the softer the bone, the more flexible the bone. Therefore the difference in stiffness is less for commercially pure titanium (or its alloy) and Division 1 dense bone compared with titanium and Division 4 soft bone. Decreasing stress in softer bone is more important for two primary reasons: (1) to reduce the resultant tissue strains resulting from the elasticity difference and (2) because softer bone exhibits a lower ultimate strength.

Hooke's law is the name given to the relationship between stress and stain; in its simplest form, the law is described mathematically as the following:

$$\sigma = E\varepsilon$$

where σ is normal stress (pascal or pounds per square inch), *E* is the modulus of elasticity (pascal or pounds per square inch), and ε is normal strain (unitless). A similar relationship exists for shear stress and shear strain, where the constant of proportionality is the modulus of rigidity *(G)* expressed by the following:

$$\tau = G\gamma$$

where τ is shear stress (pascal or pounds per square inch), *G* is the modulus of rigidity (pascal or pounds per square inch), and γ is shear strain (unitless).

Impact Loads

When two bodies collide in a small interval of time (fractions of a second), large reaction forces develop. Such a collision is described as *impact*. In dental implant systems subjected to occlusal implant loads, deformation may occur in the prosthodontic restoration, in the implant itself, and in the contiguous interfacial tissues. The nature of the relative stiffness of these components in the overall implant system largely controls the response of the system to impact load. The higher the impact load, the greater the risk of implant and bridge failure and bone fracture.

Rigidly fixed implants generate a higher interfacial impact force with occlusion compared with natural teeth, which possess a periodontal ligament. Soft tissue–borne prostheses have the least impact force because the gingival tissues are resilient. Occlusal material fracture is a significant complication of fixed prostheses on natural teeth. The incidence of occlusal material fracture is greater on implants and may approach rates as high as 30%.

Various methods have been proposed to address the issue of reducing implant loads. Skalak[13] has suggested the need for using acrylic teeth along with osteointegrated fixtures partially to mitigate high-impact loads that might damage bony tissues adjacent to the implant. Weiss[14] has proposed that a fibrous tissue-implant interface provides for physiologic shock absorption in a fashion similar to that exhibited by a functioning periodontal ligament. At least one implant design has attempted to incorporate shock absorption capability in the design itself by the use of an "intramobile element" of lower stiffness compared with the rest of the implant.[15] Misch[16] advocates an acrylic provisional restoration with a progressive occlusal loading to improve the bone-implant interface before the final restoration, occlusal design, and masticatory loads are distributed to the system. Only limited data exist concerning impact forces on natural dentition and tooth-supported bridgework.[17,18]

FORCE DELIVERY AND FAILURE MECHANISMS

The manner in which forces are applied to implant restorations within the oral environment dictates the likelihood of system failure. The duration of a force may affect the ultimate outcome of an implant system. Relatively low-magnitude forces, applied repetitively over a long time, may result in fatigue failure of an implant or prosthesis. Stress concentrations and, ultimately, failure may develop if insufficient cross-sectional area is

WWW.HIGHDENT.IR

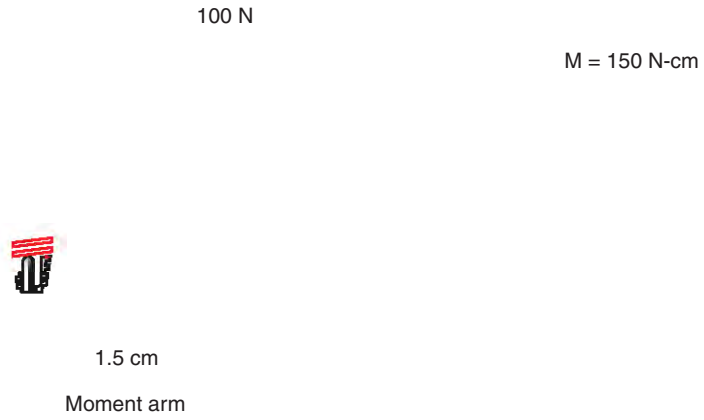

Figure 25-6 The moment of a force is defined as a vector *(M)*, the magnitude of which equals the product of the force magnitude multiplied by the perpendicular distance (moment arm) from the point of interest to the line of action of the force.

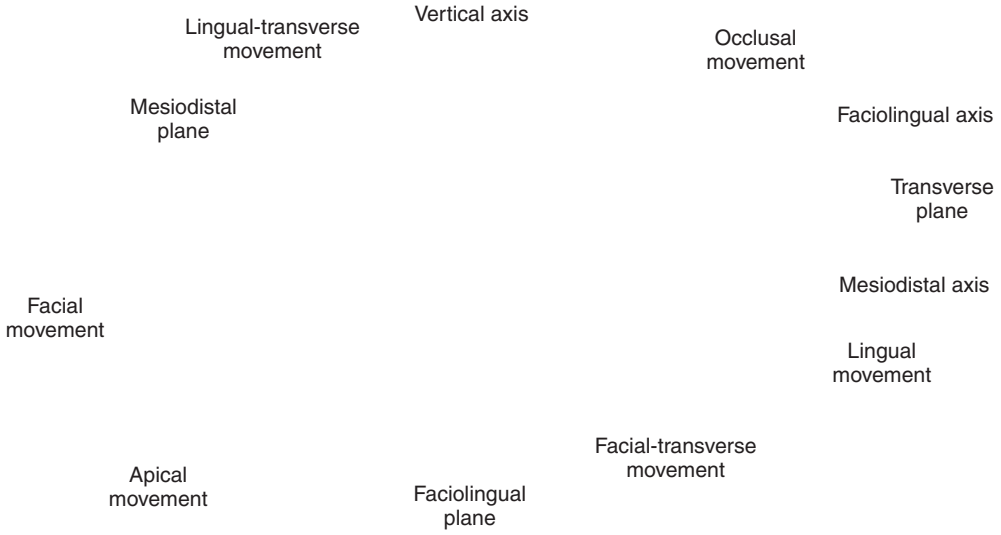

Figure 25-7 Moment loads tend to induce rotations in three planes. Clockwise and counterclockwise rotations in these three planes result in six moments: lingual-transverse, facial-transverse, occlusal, apical, facial, and lingual.

present to dissipate high-magnitude forces adequately. If a force is applied some distance away from a weak link in an implant or prosthesis, then bending or torsional failure may result from moment loads. An understanding of force delivery and failure mechanisms is critically important to the implant practitioner to avoid costly and painful complications.

Moment Loads

The moment of a force about a point tends to produce rotation or bending about that point. In Figure 25-6, the moment is defined as a vector *(M)* (vectors are described in terms of magnitude and direction), the magnitude of which equals the product of the force magnitude multiplied by the perpendicular distance (also called the *moment arm*) from the point of interest to the line of action of the force. This imposed moment load also is referred to as a *torque* or *torsional load* and may be destructive to implant systems. Torques or bending moments imposed on implants because of, for example, excessively long cantilever bridge or bar sections may result in interface breakdown, bone resorption, prosthetic screw loosening, or bar or bridge fracture. The negative effect of cantilevers has been reported for more than 30 years.[19,20] Proper restorative design must include consideration of forces and the moment loads caused by those forces.

Clinical Moment Arms

A total of six moments (rotations) may develop about the three clinical coordinate axes previously described (occlusoapical, faciolingual, and mesiodistal axes) (Figure 25-7). Such moment loads induce microrotations and stress concentrations at the crest of the alveolar ridge

WWW.HIGHDENT.IR

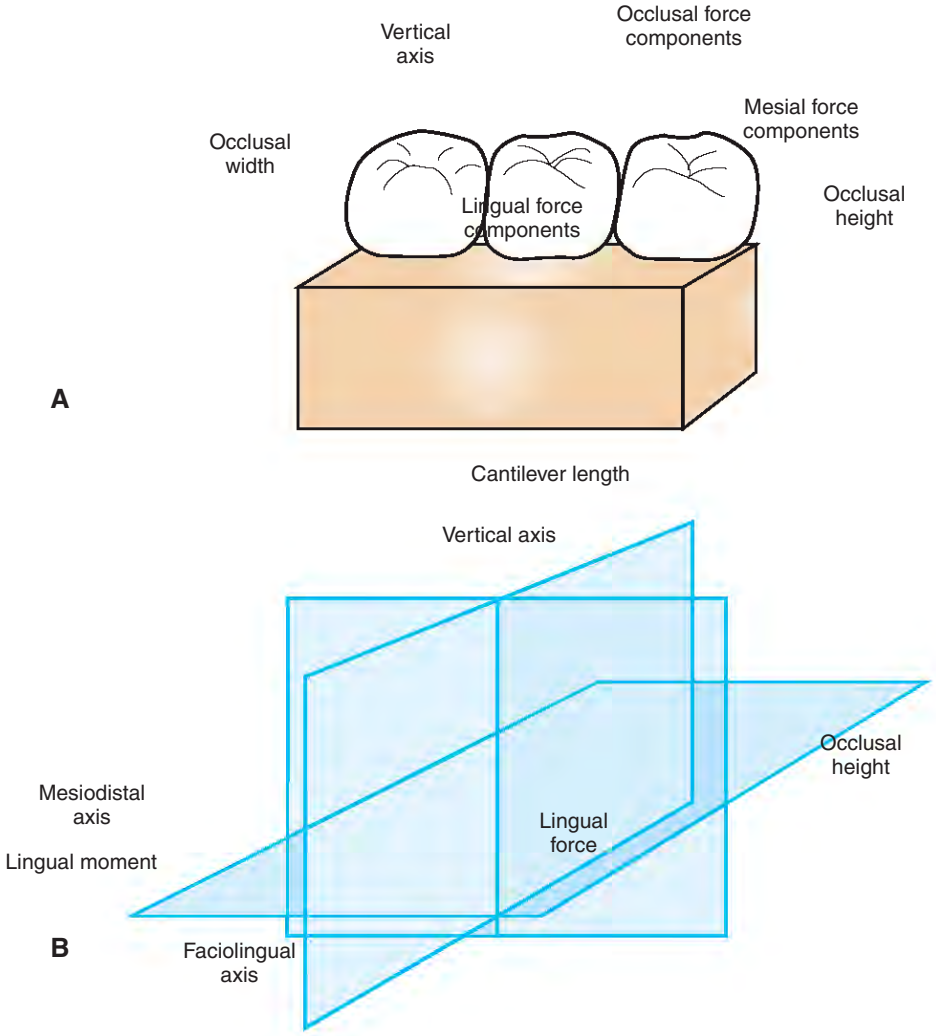

Figure 25-8 **A,** Three clinical moment arms contribute to torsional (moment) loads on dental implants: occlusal height, occlusal width, and cantilever length. **B,** Occlusal height serves as moment arm for force components directed along faciolingual axis and force components directed along mesiodistal axis **(C).** *Continued*

at the implant-tissue interface, which lead inevitably to crestal bone loss.

Three clinical moment arms exist in implant dentistry: (1) occlusal height, (2) cantilever length, and (3) occlusal width. Minimization of each of these moment arms is necessary to prevent unretained restorations, fracture of components, crestal bone loss, or complete implant system failure.

Occlusal Height

Figure 25-8 shows that the occlusal height serves as the moment arm for force components directed along the faciolingual axis—working or balancing occlusal contacts, tongue thrusts, or in passive loading by cheek and oral musculature (Figure 25-8, *B*), as well as force components directed along the mesiodistal axis (Figure 25-8, *C*).

In Division A bone, initial moment load at the crest is less than in Division C or D bone because the crown height is greater in C and D bone. Treatment planning must take into account this initially compromised bio-mechanical environment (Table 25-4). The moment contribution of a force component directed along the vertical axis is not affected by the occlusal height because no effective moment arm exists. Offset occlusal contacts or lateral loads, however, introduce significant moment arms (see Figure 25-8, *E*).

Cantilever Length

Large moments may develop from vertical axis force components in prosthetic environments designed with cantilever extensions or offset loads from rigidly fixed implants. A lingual force component also may induce a twisting moment about the implant neck axis if applied through a cantilever length (Figure 25-8, *D*).

An implant with a cantilevered mesobar extending 1, 2, and 3 cm has significant ranges of moment loads. A 100-N force applied directly over the implant does not induce a moment load or torque because no rotational forces are applied through an offset distance. This same 100-N force applied 1 cm from the implant results

WWW.HIGHDENT.IR

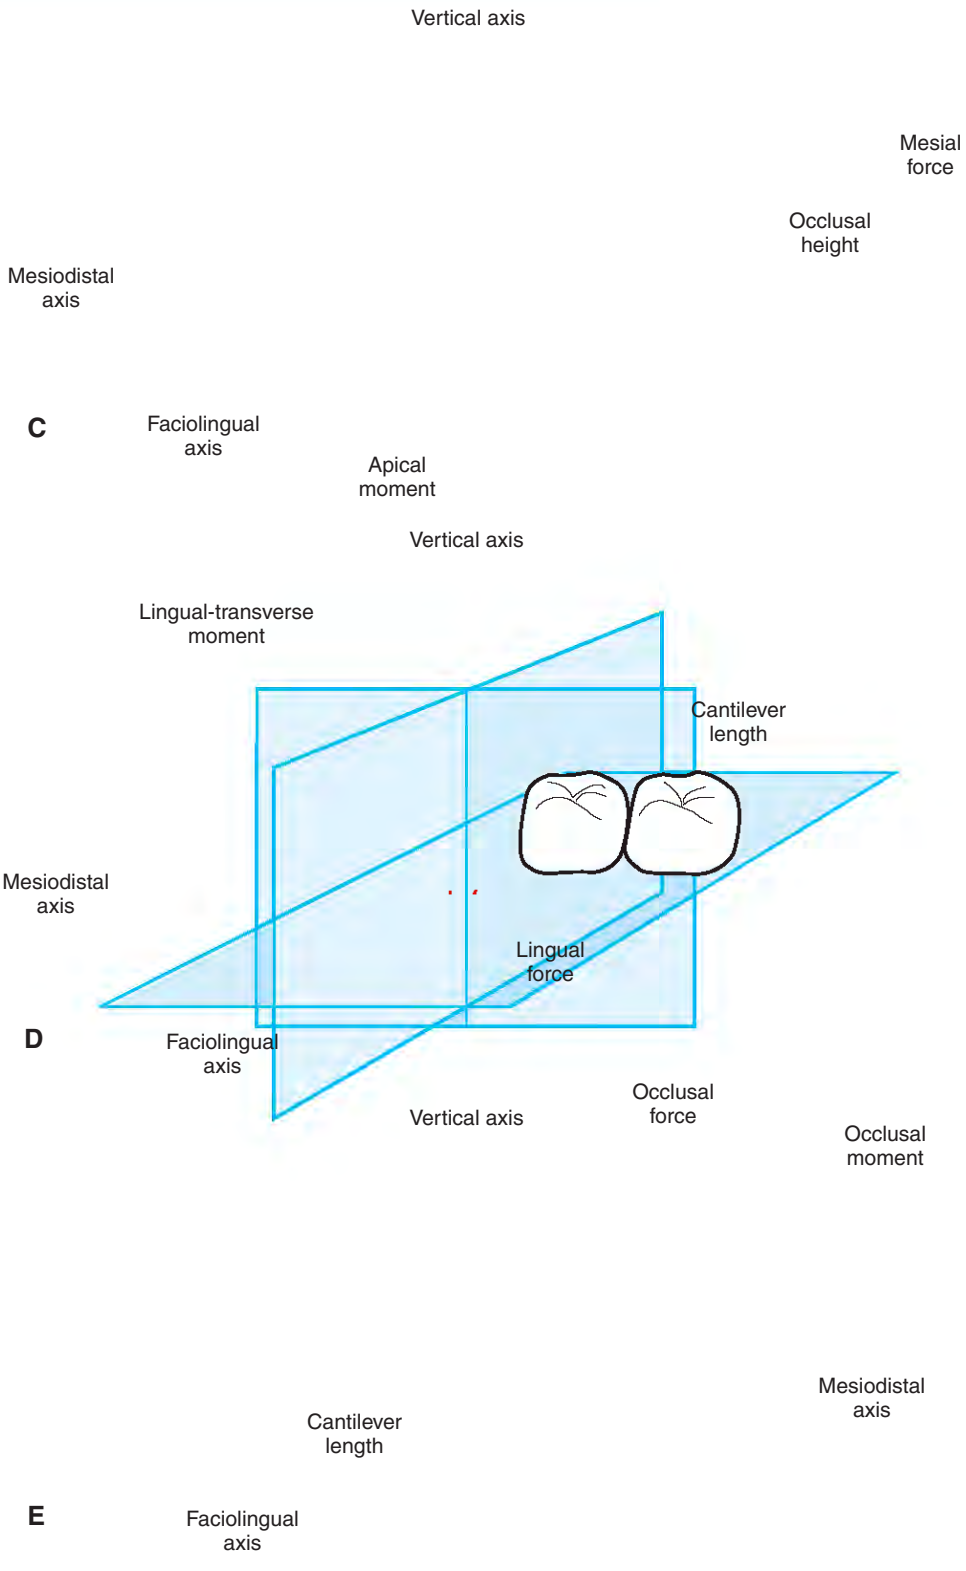

Figure 25-8, cont'd **D,** Lingual force component also may induce twisting moment about the implant neck if applied through the cantilever length. **E,** Moment of force along the vertical axis is not affected by occlusal height because its effective moment arm is zero if positioned centrically.

10	20	100	0	50	400	0	200
10	30	100	0	50	600	0	300
20	10	200	0	100	200	0	100
20	20	200	0	100	400	0	200
20	30	200	0	100	600	0	300

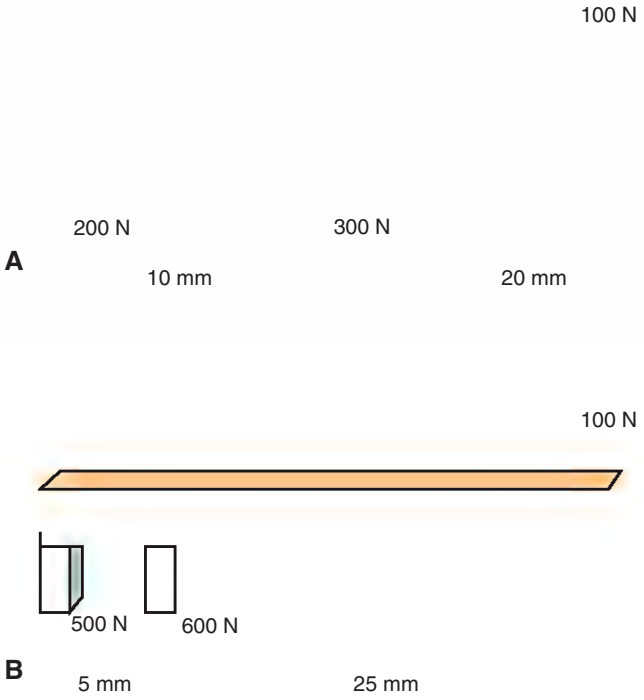

Figure 25-9 **A,** If two implants are designed 10 mm apart and splinted together with a 20-mm distal cantilever, then a 100-N load is resisted by a 200-N force by the mesial implant, and the distal implant acts as a fulcrum with a 300-N load. **B,** If implants are 5 mm apart, then the anterior implant must resist a 500-N force and the distal fulcrum implant receives a 600-N force.

in a 100 N-cm moment load. Similarly, if the load is applied 2 cm from the implant, then a 200 N-cm torque is applied to the implant-bone region, and at 3 cm a 300 N-cm moment load results. For comparison, recall that implant abutments typically are tightened with 30 N-cm of torque.

Cantilever prostheses attached to splinted implants result in a complex load reaction. In its simplest form, a Class 1 lever action may be expressed. If two implants 10 mm apart are splinted together, and a 20-mm distal cantilever is designed with a 100-N load, then the following forces result. The 100-N load is resisted with a 200-N tensile force by the mesial implant, and the distal implant acts as a fulcrum with a 300-N compressive load (Figure 25-9, *A*). If the position and amount of distal load remain the same, but the distal implant is positioned 5 mm anterior, then the resultant loads on the implants change (Figure 25-9, *B*). The anterior implant must resist a 500-N tensile force and the distal, fulcrum implant receives a 600-N compressive force. Therefore the tensile force is increased 2.5 times on the anterior implant, whereas the compressive force is increased twofold. Because bone and screws are weaker under the action of tensile forces, both implants become more at risk for complications.

Similar principles regarding Class 1 lever forces apply to cantilever loads with anterior splinted implants placed on a curve with distal extended prostheses. The Nobel Biocare prosthetic protocol uses four to six anterior implants placed in front of the mental foramen or maxillary sinuses and uses a full-arch fixed prosthesis with cantilevered segments.[21-23] Specific cantilever lengths are not stated, although two to three premolars are recommended. The cantilever length is suggested to be reduced when four rather than six implants are used to support the restoration[24] or when implants are in the softer bone of the maxilla.[25] A line is drawn from the distal of each posterior implant. The distance to the center of the most anterior implant is called the *anteroposterior distance* (A-P spread).[26] The greater the A-P spread is between the center of the most anterior implant or implants and the most distal aspect of the posterior implants, the smaller is the resultant loads on the implant system from cantilevered forces because of the stabilizing effect of the A-P distance. According to Misch,[25] the amount of stress applied to the system determines the length of this distal cantilever. Because stress equals force divided by area, both aspects must be considered. The magnitude and direction of force are determined by parafunction, crown height, masticatory dynamics, gender, age, and arch location. The functional surface area is determined by the number of implants, width, length, design, and bone density, which determines

WWW.HIGHDENT.IR

the area of contact and bone strength. Clinical experiences suggest that the distal cantilever should not extend 2.5 times the A-P spread under ideal conditions (e.g., parafunction absent or five Division A implants). One of the greatest determinants for the length of the cantilever is the magnitude of the force. Patients with severe bruxism should not be restored with any cantilevers, regardless of other factors.

A square arch form involves smaller A-P spreads between splinted implants and should have shorter-length cantilevers. A tapered arch form has the largest distance between anterior and posterior implants and may have the longest cantilever design. The maxilla has less dense bone than the mandible and more often has an anterior cantilever with the prosthesis. As a result, more distal implants may be required in the maxilla to increase the A-P spread for the anterior or posterior cantilever than in the mandible, and sinus augmentation may be required to permit posterior placement of the implant.

Occlusal Width

Wide occlusal tables increase the moment arm for any offset occlusal loads. Faciolingual tipping (rotation) can be reduced significantly by narrowing the occlusal tables or adjusting the occlusion to provide more centric contacts.

In summary, a vicious, destructive cycle can develop with moment loads and result in crestal bone loss. As crestal bone loss develops, occlusal height automatically increases. With an increased occlusal height moment arm, the faciolingual microrotation and rocking increases and causes even more crestal bone loss. Unless the bone increases in density and strength, the cycle continues to spiral toward implant failure if the biomechanical environment is not corrected.

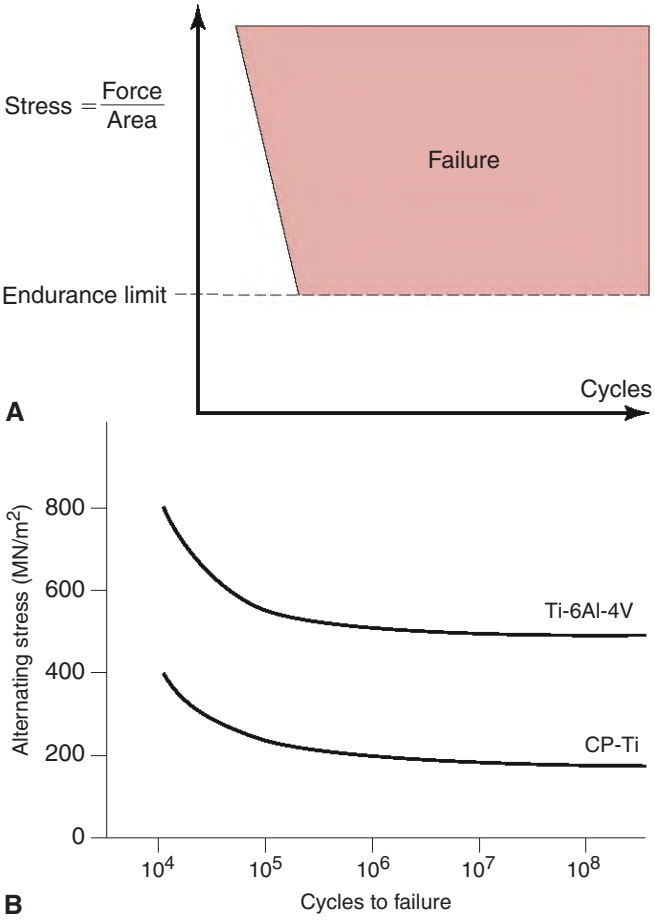

Figure 25-10 **A,** Fatigue behavior of biomaterials is characterized by a plot of applied stress versus number of loading cycles, an S-N curve. **B,** Endurance limit defines the stress level below which an implant biomaterial may be loaded indefinitely without failure. Titanium alloy is two to four times stronger in fatigue conditions compared with commercially pure titanium.

Fatigue Failure

Fatigue failure is characterized by dynamic, cyclic loading conditions. Four fatigue factors significantly influence the likelihood of fatigue failure in implant dentistry: (1) biomaterial, (2) macrogeometry, (3) force magnitude, and (4) number of cycles.

Fatigue behavior of biomaterials is characterized graphically in what is referred to as an *S-N curve* (a plot of applied stress versus number of loading cycles) (Figure 25-10, *A*). If an implant is subjected to an extremely high stress, then only a few cycles of loading can be tolerated before fracture occurs. Alternatively, an infinite number of loading cycles can be maintained at low stress levels. The stress level below which an implant biomaterial can be loaded indefinitely is referred to as its *endurance limit*. Titanium alloy exhibits a higher endurance limit compared with commercially pure titanium (Figure 25-10, *B*).

The geometry of an implant influences the degree to which it can resist bending and torsional loads and ultimately fatigue fracture. Implants rarely, if ever, display fatigue fracture under axial compressive loads. Morgan et al.[27] reported fatigue fractures of Brånemark dental implants caused by cyclical buccolingual loads (lateral loading) in an area of weak bending strength within the fixture (i.e., reduced moment of inertia [defined later]). The fracture of the implant body occurred in three of the patients studied, and fracture of the abutment screws for the Brånemark implant occurred in less than three patients. Fifteen acrylic or composite tooth fractures occurred on 10 to 20 of the fixed prostheses supported by implants over a 1- to 5-year period.[28-31]

The geometry also includes the thickness of the metal or implant. The fatigue fracture is related to the fourth power of the thickness difference. A material two times thicker in wall thickness is approximately 16 times stronger. Even small changes in thickness can result in significant differences. Often the weak link in an implant body design is affected by the difference in the inner and outer diameter of the screw and the abutment screw space in the implant.[32]

WWW.HIGHDENT.IR

To the extent that an applied load (stress) can be reduced, the likelihood of fatigue failure is reduced. As described previously, the magnitude of loads on dental implants can be reduced by careful consideration of arch position (i.e., higher loads in the posterior compared with anterior mandible and maxilla), elimination of moment loads, and increase in surface area available to resist an applied load (i.e., optimize geometry for functional area, or increase the number of implants used).

Finally, fatigue failure is reduced to the extent that the number of loading cycles is reduced. Thus aggressive strategies to eliminate parafunctional habits and reduce occlusal contacts serve to protect against fatigue failure.

MOMENT OF INERTIA

Moment of inertia is an important property of cylindrical implant design because of its importance in the analysis of bending and torsion. The bending stress in a cylinder is given by the following equation:

$$\sigma = \frac{My}{I}$$

where M is moment (newton-centimeters), y is the distance from the neutral axis of bending (centimeters), and I is the moment of inertia (centimeters to the fourth power).

Root form implants have varying cross-sectional geometries. The root form implant may be modeled as a hollow circle, because a channel exists in the implant body to allow for abutment screw engagement. In the distal (apical) region of a root form implant, the cross-sectional geometry may more closely represent a solid circle. In some designs, vents that penetrate transversely through the cross-sectional geometry may interrupt the apical geometry.

The bending stress (and likelihood of bending fracture) decreases with increasing moment of inertia. Consider the mathematical formulations for the solid versus hollow cylindrical cross-sectional geometry:

Solid circle (cylinder in the middle region): $4\ I = \pi R^4$

Hollow circle (cylinder in apical region): $4\ I = \pi(R^4 - R_i 4)$

where R is the outer radius (centimeters) and R_i is the inner wall radius.

SUMMARY

The most common complications in implant-related reconstruction are related to biomechanical conditions. Implant healing failures may result from micromovement of the implant from too much stress. Early crestal bone loss may be related to occlusal overload conditions. Prostheses or abutment screws may become loose from bending or moment forces. Implant or component fracture may occur from fatigue conditions. Prosthesis failure may result from all of the foregoing or bending fracture resistance. In addition, the manifestation of biomechanical loads on dental implants (moments, stress, and strain) controls the long-term health of the bone-implant interface. Knowledge of basic biomechanical principles is thus required for the dentist.

Chapter 26

Bone Physiology, Metabolism, and Biomechanics

W. Eugene Roberts

Consistent success with implant-supported prostheses requires a thorough knowledge of the physiology, metabolism and biomechanics of bone as a tissue, and bones as musculoskeletal organs. Bone is a vital mineralized tissue and bones are unique morphologic organs, composed of calcified and soft tissues that provide structural and metabolic support for a wide variety of interactive functions (Figure 26-1).

Understanding the clinical manipulation of bone begins with an appreciation of the fundamental genetic and environmental mechanisms of osseous development and adaptation. The genome codes for growth factors, ischemic agents, vascular induction/invasion mechanisms, and mechanically induced inflammation. These biological mechanisms interact with the physical factors of diffusion limitation and mechanical loading to produce bone morphology (Figure 26-2). Fundamental principles control the quality and quantity of bone that directly and indirectly supports stomatognathic function. A firm grasp of the modern concepts of bone physiology, metabolism, and biomechanics is an essential prerequisite for innovative clinical practice. These principles are an objective basis for designing a realistic treatment plan that has a high probability of meeting the esthetic and functional expectations of the patient.

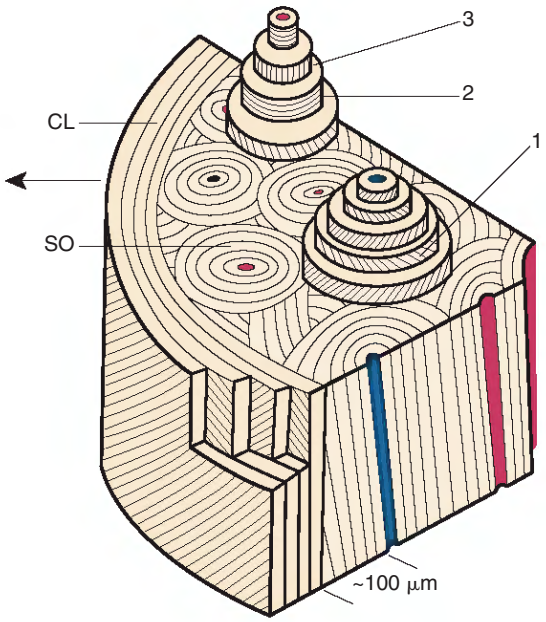

Figure 26-1 A schematic drawing of a wedge of a cortical bone that is growing to the left demonstrates the morphology of circumferential lamellae *(CL)* and secondary osteons *(SO)*. Depending on the mechanical loading at the time the matrix is formed, bone lamellae may have a collagen orientation that is an alternating bias *(1)* or alternating horizontal *(2)* and vertical *(3)* orientations. *(From Roberts WE, Hartsfield JK Jr: Bone development and function: genetic and environmental mechanisms,* Semin Orthod *10:100-122, 2004.)*

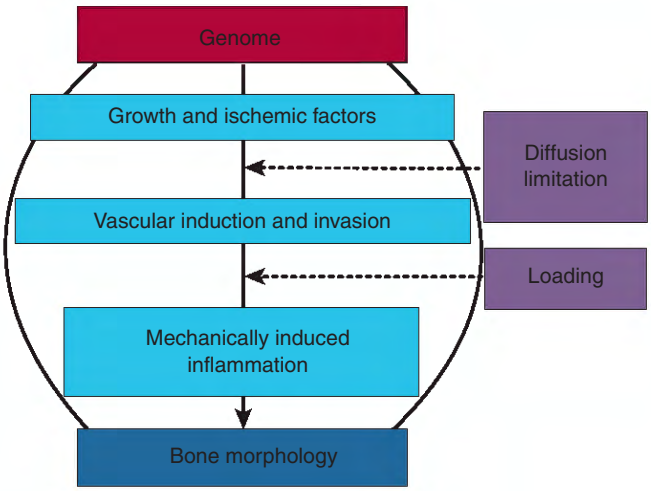

Figure 26-2 The genome dictates bone morphology by a sequence of three genetic mechanisms: (1) growth and ischemic factors, (2) vascular induction and invasion, and (3) mechanically induced inflammation. The latter two are influenced by two major physical influences: (1) diffusion limitation for maintaining viable osteocytes and (2) mechanical loading history. *(From Roberts WE, Hartsfield JK Jr: Bone development and function: genetic and environmental mechanisms,* Sem Orthod *10:100-122, 2004.)*

WWW.HIGHDENT.IR

Bone is a dynamic structure that is adapting constantly to its environment. Because the skeleton is the principal reservoir of calcium, bone remodeling (physiologic turnover) performs a critical life support role in mineral metabolism (Figure 26-3). Collectively, bones are essential elements for locomotion, antigravity support, and life-sustaining functions such as mastication. Mechanical adaptation of bone is the physiologic basis of stomatognathic reconstruction with implant-supported prostheses. A detailed knowledge of the dynamic nature of bone physiology and biomechanics is essential to enlightened clinical practice.

OSTEOLOGY

In defining the physiologic basis of orthodontics, the initial consideration is bone morphology (osteology) of the craniofacial complex. Via the systematic study of a personal collection of more than 1000 human skulls, Spencer Atkinson[1] provided the modern basis of craniofacial osseous morphology as it relates to the biomechanics of stomatognathic function. A frontal section of an adult skull shows the bilateral symmetry of bone morphology and functional loading (Figures 26-4 and 26-5). Because the human genome contains genes to pattern the structure of only half of the body, the contralateral side is a mirror image. Consequently, normal development of the head is symmetrical. Thus unilateral structures are on the midline, and bilateral structures are equidistant from it. As shown in Figure 26-5, the vertical components of the cranium tend to be loaded in compression (negative stress), and the horizontal components are loaded in tension (positive stress). From an engineering perspective, the internal skeletal structure of the midface is similar to that of a ladder: vertical rails loaded in compression connected by rungs loaded in tension. This is one of the most efficient structures for achieving maximal compressive strength with minimal mass in a composite material.

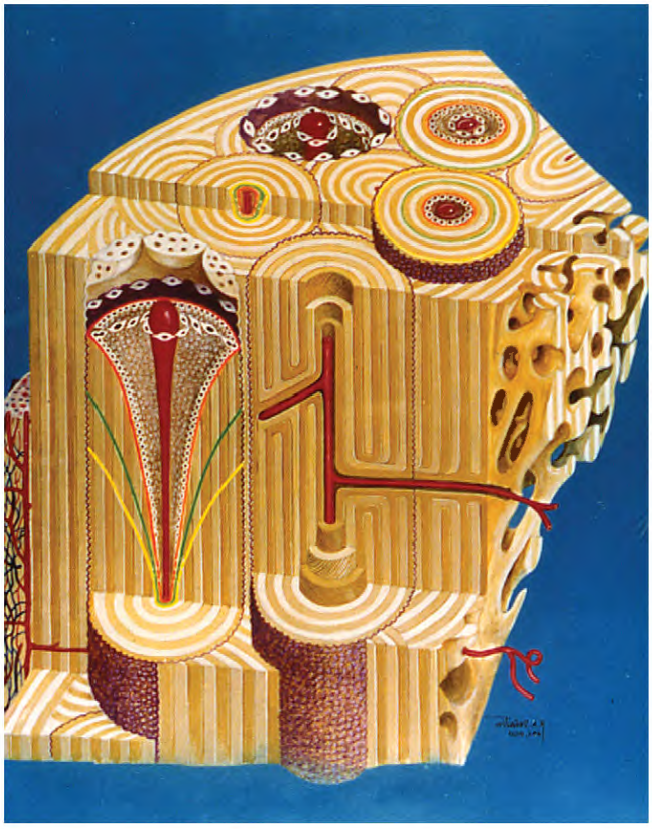

Figure 26-3 This artist's rendition of the dynamic principles of cortical bone remodeling was produced by the renowned dental illustrator Rolando De Castro. Remodeling is a vascularly mediated process of bone turnover that maintains the integrity of structural support and is a source of metabolic calcium. Osteoblasts are derived from preosteoblasts circulating in the blood, and perivascular mesenchymal cells give rise to osteoblasts. Note the three colored chevrons (yellow, green, and orange) progressively marking the mineralization front of the evolving second osteon that is moving superiorly on the left. *(From Roberts WE, Arbuckle GR, Simmons KE: What are the risk factors of osteoporosis? Assessing bone health,* J Am Dent Assoc *122:59-61, 1991.)*

Differential Osteology of the Maxilla and Mandible

Although equal and opposite functional loads are delivered to the maxilla and mandible, the maxilla transfers stress to the entire cranium, whereas the mandible must absorb the entire load. Consequently, the mandible is much stronger and stiffer than the maxilla.

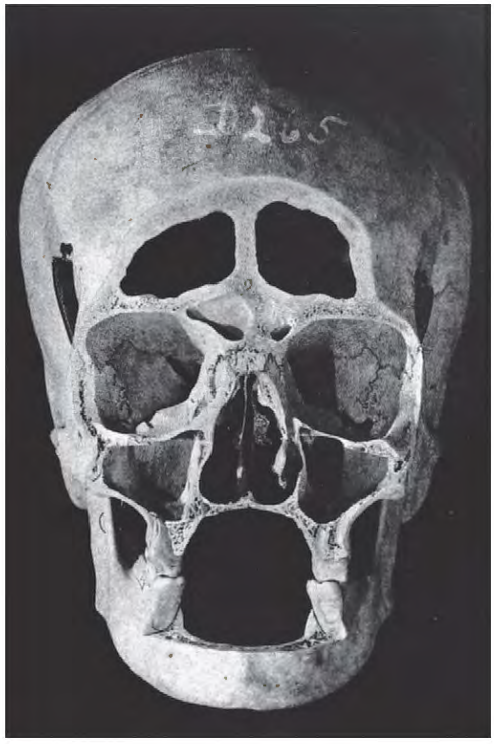

Figure 26-4 Frontal section of a human skull in the plane of the first molars. *(From Atkinson SR: Balance: the magic word,* Am J Orthod *50:189, 1964.)*

WWW.HIGHDENT.IR

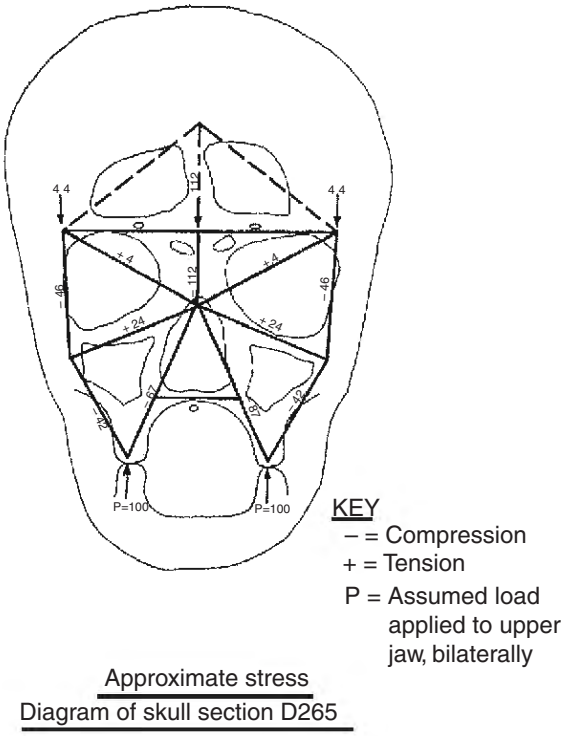

Figure 26-5 Two-dimensional vector analysis of stress in the frontal section of the human skull depicted in Figure 26-4. Relative to a bilateral biting force of 100 arbitrary units, the load is distributed to the vertical components of the midface as compressive (negative) stress. The horizontal structural components are loaded in tension. In a nongrowing individual the stress across the midpalatal suture is 0. When masticating, loads increase and the midpalatal suture is subjected to a tensile load, resulting in an increase in maxillary width. *(From Atkinson SR: Balance: the magic word,* Am J Orthod *50:189, 1964.)*

Figure 26-6 Midsagittal section of a human skull shows that the maxilla primarily is composed of trabecular (spongy) bone. The opposing mandible has thick cortices connected by relatively coarse trabeculae. *(From Atkinson SR: Balance: the magic word,* Am J Orthod *50:189, 1964.)*

A midsagittal section through the incisors (Figure 26-6) and a frontal section through the molar region (Figure 26-7) show the distinct differences in the osseous morphology of the maxilla and mandible. The maxilla has relatively thin cortices that are interconnected by a network of trabeculae (see Figures 26-4, 26-6, and 26-7).

Figure 26-7 Frontal section of the maxilla and mandible in the plane of the first molars. Because it transmits masticatory loads to the entire cranium, the maxilla has thin cortices connected by relatively fine trabeculae. The mandible, however, is loaded in bending and torsion; it therefore is composed of thick cortical bone connected by coarse, oriented trabeculae. *(From Atkinson SR: Balance: the magic word,* Am J Orthod *50:189, 1964.)*

Because it is loaded primarily in compression, the maxilla is structurally similar to the body of a vertebra.

The mandible, however, has thick cortices and more radially oriented trabeculae (see Figures 26-6 and 26-7). The structural array is similar to the shaft of a long bone and indicates that the mandible is loaded predominantly in bending and torsion. This biomechanical impression based on osteology is confirmed by in vivo strain gauge studies in monkeys. Hylander[2,3] demonstrated substantial bending and torsion in the body of the mandible associated with normal masticatory function (Figure 26-8). A clinical correlation consistent with this pattern of surface strain is the tendency of some humans to form tori in the areas of maximal bending and torsion (Figure 26-9). The largest tori are on the side on which the individual habitually chews (preferential working side).

Temporomandibular Articulation

The temporomandibular joint (TMJ) is the principal adaptive center for determining the intermaxillary relationship in all three planes of space. Figure 26-10 shows optimal skeletal development consistent with normal morphology of the TMJ. Figure 26-11 shows aberrant skeletal and dental relationships consistent with degeneration of the fossa and mandibular condyle (i.e., the enlarged mushroom shape of the condylar process, the roughened topography of the articulating

WWW.HIGHDENT.IR

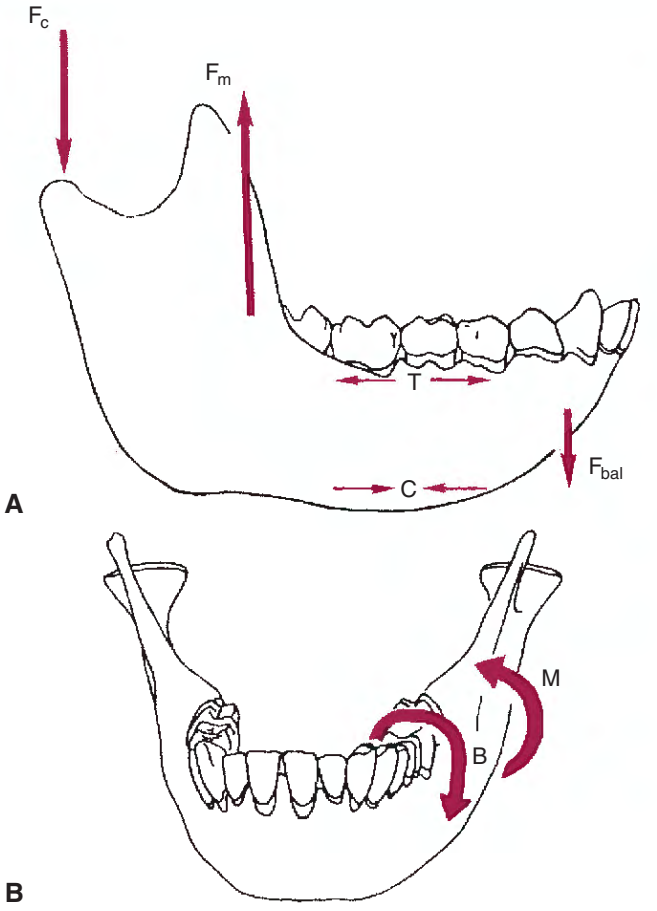

Figure 26-8 Stress patterns in the primate mandible during unilateral mastication. F_c and F_m are the condyla reaction and the resultant muscle forces on the balancing side, respectively. F_{bal} is the force transmitted through the symphysis from the balancing to the working side. T and C indicate the location of tensile stress and compressive stress, respectively. **A,** During the power stroke, the mandibular corpus on the balancing side is bent primarily in the sagittal plane, resulting in tensile stress along the alveolar process and compressive stress along the lower border of the mandible. **B,** On the working side, the corpus is twisted primarily about its long axis (it also experiences direct shear and is slightly bent). The muscle force on this side tends to evert the lower border of the mandible and invert the alveolar process *(curved arrow M).* The twisting movement associated with the bite force has the opposite effect *(curved arrow B).* The portion of the corpus between these two twisting movements experiences maximal twisting stress. *(From Hylander WL: Patterns of stress and strain in the macaque mandible. In Carlson DS, editor:* Craniofacial biology, *Ann Arbor, Mich, 1981, Center for Human Growth and Development.)*

Figure 26-9 Occlusal view of the mandibular dentition of a male patient with extensive buccal and lingual tori. Note that the exostoses are most extensive in the area of the second premolar and first molar, the area of maximal torsion in the posterior segment of the mandible.

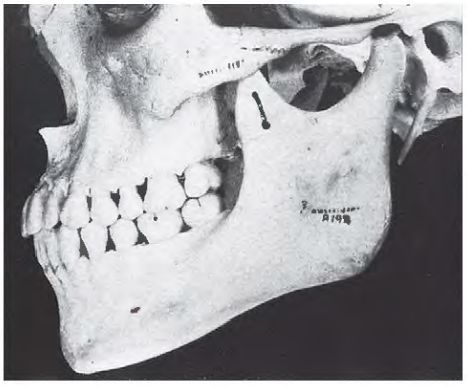

Figure 26-10 Adult human skull with ideal occlusion and osseous form of the maxilla and mandible. Note the ideal anatomical form of the condyle and articular fossa of the temporomandibular joint. *(From Atkinson SR: Balance: the magic word,* Am J Orthod *50:189, 1964.)*

Figure 26-11 Adult human skull with a severe Class II malocclusion. Note the degeneration of the temporomandibular joint (i.e., the large, mushroom-shaped condyle and the enlarged, roughened articular fossa). *(From Atkinson SR: Balance: the magic word,* Am J Orthod *50:189, 1964.)*

surfaces, the loss of articular cartilage and subchondral plate). Progressive degeneration or hyperplasia of one or both mandibular condyles may result in substantial intermaxillary discrepancies in the sagittal, vertical, and frontal dimensions. Adaptation of the TMJ allows for substantial growth change to occur without disturbing the intermaxillary relationship of the dentition (e.g., Class I occlusion remains Class I). In the adult years the intermaxillary relationship continues to change but at a slower rate. The face lengthens and may rotate anteriorly as much as 10 mm over the adult lifetime.[4] The mandible adapts to this change by lengthening and maintaining the intermaxillary dental relationship (Figure 26-12). However, if the TMJs of an adult undergo bilateral degenerative change, whether

WWW.HIGHDENT.IR

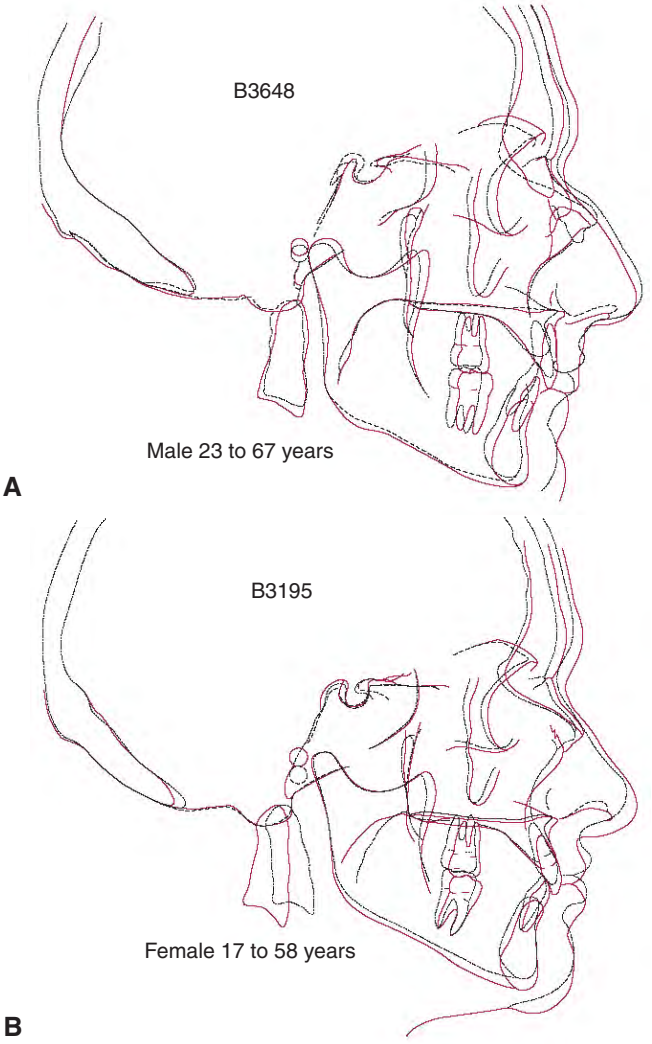

Figure 26-12 **A,** Superimposed cephalometric tracings of a male patient at ages 23 and 67 years (black and red tracings, respectively). Note the downward and forward growth of the mandible and the substantial increase in the length of the face. The nasal form was altered by a rhinoplasty in the intervening years. **B,** Superimposed cephalometric tracings of an adult female at ages 17 and 58 years (black and red tracings, respectively). Note the downward growth of the mandible and the substantial increase in the length of the face. *(From Behrents RG: Adult facial growth. In Enlow DH, editor:* Facial growth, *ed 3, Philadelphia, 1990, WB Saunders.)*

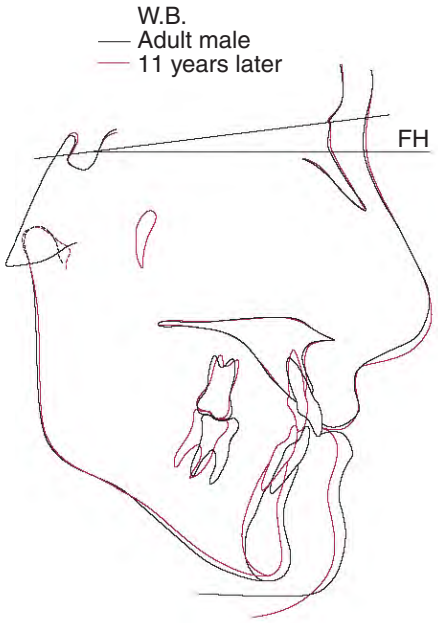

Figure 26-13 Superimposed cephalometric tracings of a middle-aged man over an 11-year period. Although the soft tissue changes are similar to those seen in other adult males (see Figure 26-12, *A*), the less prominent mandible and more convex skeletal profile are consistent with a shortened mandible. This man had a history of bilateral temporomandibular internal derangement that progressed to crepitus. However, despite the substantial change in facial form and occlusal compensation, no appreciable pain was reported.

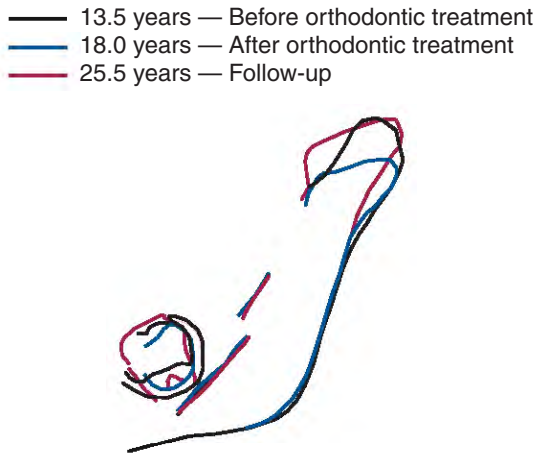

Figure 26-14 Superimposed tracings of a series of panoramic radiographs documenting the degeneration of a mandibular condyle between 13.5 and 18 years of age. Between the ages of 18 and 25.5 years, the degenerative condyle "grew," restoring the original length of the mandible. *(From Peltola JS, Kononen M, Nystrom M: A follow-up study of radiographic findings in the mandibular condyles of orthodontically treated patients and associations with TMD,* J Dent Res *74:1571, 1995.)*

symptomatic or not, the mandible can decrease in length, resulting in a shorter, more convex face (Figure 26-13).

Within physiologic limits, the TMJ has remarkable regenerative and adaptive capabilities allowing for spontaneous recovery from degenerative episodes (Figure 26-14). Unlike other joints in the body, the TMJ has the ability to adapt to altered jaw structure and function. After a subcondylar fracture, the condylar head is pulled medially by the superior pterygoid muscle and resorbs. If the interocclusal relationship is maintained, a new condyle forms from the medial aspect of the ramus and assumes normal function. Unilateral subcondylar fractures usually result in regeneration of a new functional condyle with no significant deviation of the mandible.[5] However, about one fourth of subcondylar fractures result in a mandibular deviation toward the injured side, resulting in an asymmetrical Class II malocclusion with a midline deviation. Another sequela of mandibular trauma is internal derangement such as a unilateral closed lock (a condyle distally

WWW.HIGHDENT.IR

displaced relative to the disk). If the range of motion is reduced in a growing patient, the compromised function may inhibit mandibular growth, resulting in a cant of the occlusal plane. Progressive dysfunction and pain may ensue, particularly when associated with occlusal trauma. Reestablishing normal bilateral function allows the compromised condyle or condyles to adapt favorably.

BONE PHYSIOLOGY

The morphology of bone has been well described, but its physiology is elusive because of the technical limitations inherent in the study of mineralized tissues. Accurate assessment of the orthodontic or orthopedic response to applied loads requires time markers (bone labels) and physiologic indexes (DNA labels, histochemistry, and in situ hybridization) of bone cell function. Systematic investigation with these advanced methods has defined new concepts of clinically relevant bone physiology.

Specific Assessment Methodology

Physiologic interpretation of the response to applied loads requires the use of specially adapted methods, as follows:

- Mineralized sections are an effective means of accurately preserving structure and function relationships.[6]
- Polarized light birefringence detects the preferential orientation of collagen fibers in the bone matrix.[7]
- Fluorescent labels (e.g., tetracycline) permanently mark all sites of bone mineralization at a specific point in time (anabolic markers).[7]
- Microradiography assesses mineral density patterns in the same sections.[8]
- Autoradiography detects radioactively tagged precursors (e.g., nucleotides, amino acids) used to mark physiologic activity.[9-11]
- Nuclear volume morphometry differentially assesses osteoblast precursors in a variety of osteogenic tissues.[12]
- Cell kinetics is a quantitative analysis of cell physiology based on morphologically distinguishable events in the cell cycle (i.e., DNA synthesis [S] phase, mitosis, and differentiation-specific change in nuclear volume).[12,13]
- Finite element modeling is an engineering method of calculating stresses and strains in all materials, including living tissue.[14-17]
- Microelectrodes inserted in living tissue such as the periodontal ligament (PDL) can detectelectrical potential changes associated with mechanical loading.[13,18]
- Backscatter emission is a variation of electron microscopy that assesses relative mineral density at the microscopic level in a block specimen.[19]
- Microcomputed tomography is an in vitro imaging method for determining the relative mineral density of osseous tissue down to a resolution of approximately 5 µm (about the size of an osteoblast nucleus).[20]
- Microindentation testing is a method for determining the mechanical properties of bone at the microscopic level.[21]

Mineralized Sections

Fully mineralized specimens are superior to routine demineralized histologic sections for most critical analyses of teeth, periodontium, and supporting bone because fully mineralized specimens experience less processing distortion. Furthermore, the inorganic mineral and organic matrix can be studied simultaneously.[6-8,22] For tissue-level studies, sections 100 µm thick are appropriate because they can be studied by means of several analytic methods. Even without bone labels, microradiographic images of polished mineralized sections provide substantial information about the strength, maturation, and turnover rate of cortical bone (Figure 26-15, *A*). Reducing the thickness of the section to less than 25 µm considerably enhances cellular detail and resolution of bone labels. Specific stains are useful for enhancing the contrast of cellular and extracellular structures. The disadvantages of thin mineralized sections are (1) bone labels quench more rapidly and (2) tissue density is inadequate for microradiographic analysis.

Polarized Light

Birefringence of polarized light (see Figure 26-15, *B*) has particular biomechanical significance. The lamellar fringe patterns revealed with polarized light indicate the preferential collagen orientation within the matrix.[23] Most lamellar bone has alternating layers of collagen fibers at right angles. However, two specialized collagen configurations can be seen in the same or adjacent osteons: (1) longitudinally aligned collagen fibers efficiently resist tension and (2) transverse or circumferential collagen fibers are preferential supports for compression.[24] Loading conditions at the time of bone formation appear to dictate the orientation of the collagen fibers to best resist the loads to which the bone is exposed. The important point is that bone formation can adapt to different loading conditions by changing the internal lamellar organization of mineralized tissue.

Fluorescent Labels

Administered in vivo, calcium-binding labels are anabolic time markers of bone formation. Histomorphometric analysis of label incidence and inter-label distance is an effective method of determining the mechanisms of bone growth and functional adaptation (see Figure 26-15, *C*). Because they fluoresce at different wavelengths (colors), six bone labels can be used: (1) tetracycline (10 mg/kg, bright yellow); (2) calcein green

WWW.HIGHDENT.IR

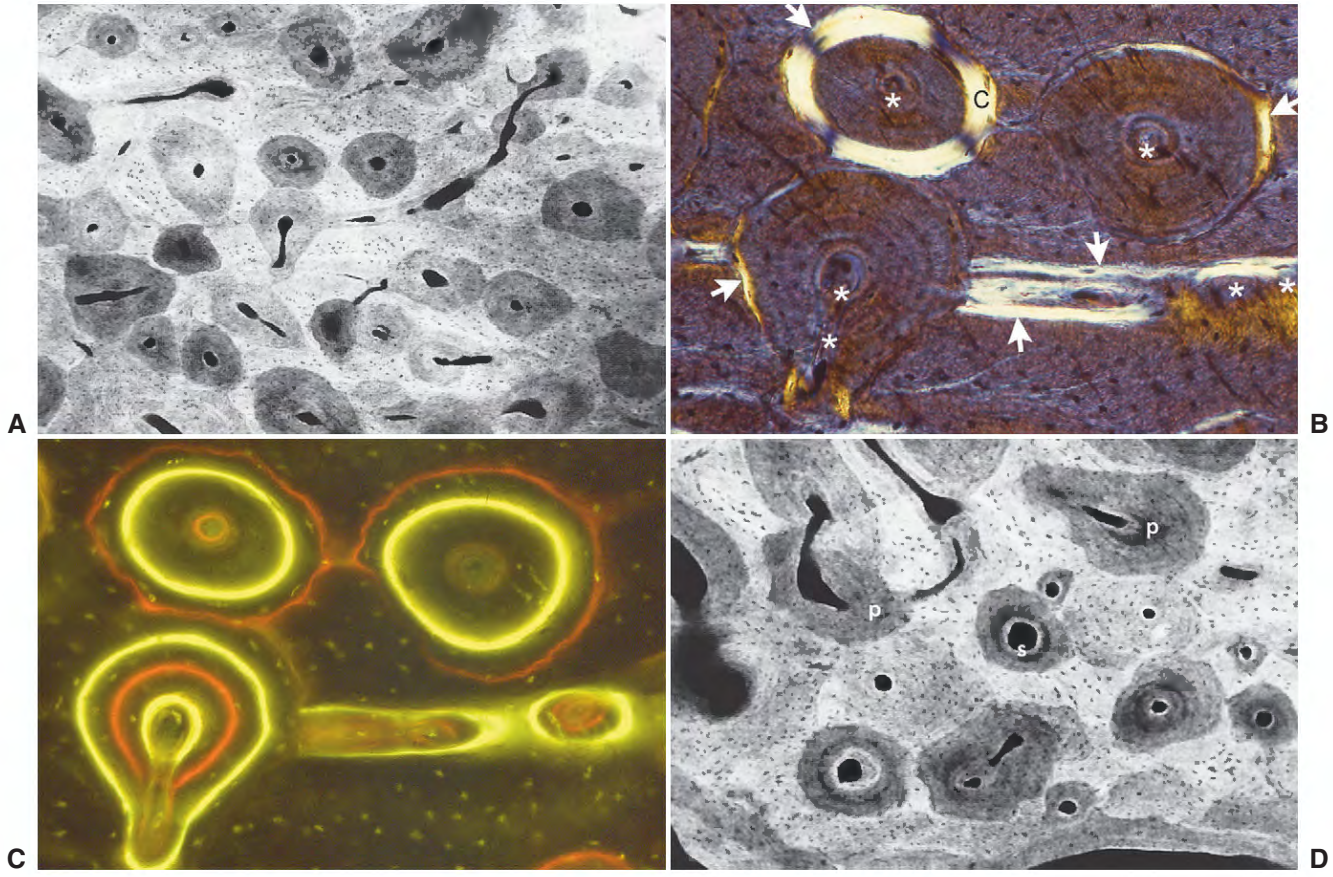

Figure 26-15 **A,** Microradiography provides a physiologic index of bone turnover and relative stiffness. The more radiolucent (dark) osteons are the youngest, the least mineralized, and the most compliant. Radiodense (white) areas are the oldest, most mineralized, and rigid portions of the bone. **B,** Polarized light microscopy shows the collagen fiber orientation in bone matrix. Lamellae with a longitudinally oriented matrix *(C)* are particularly strong in tension, whereas a horizontally oriented matrix (dark) has preferential strength in compression (arrows mark resorption arrest lines, and asterisks mark vascular channels). **C,** Multiple fluorochrome labels administered at 2-week intervals demonstrate the incidence and rates of bone formation. **D,** This microradiograph shows an array of concentric secondary osteons (haversian systems) characteristic of rapidly remodeling cortical bone. Primary *(p)* and beginning secondary *(s)* mineralization are more radiolucent and radiodense, respectively. *(From Roberts WE et al:* Bone biodynamics in orthodontic and orthopedic treatment: craniofacial growth series*, vol 27, Ann Arbor, 1991, University of Michigan Press.)*

(5 mg/kg, bright green); (3) xylenol orange (60 mg/kg, orange); (4) alizarin complexone (20 mg/kg, red); (5) demeclocycline (10 mg/kg, gold); and (6) oxytetracycline (10 mg/kg, dull or greenish yellow). The multiple-fluorochrome method (sequential use of a variety of different colored labels) is a powerful method of assessing bone growth, healing, functional adaptation, and response to applied loads.[7,25]

Microradiography

High-resolution images require polished sections approximately 100 µm thick. Differential radiographic attenuation shows that new bone is less mineralized than mature bone. Newly formed bone matrix is osteoid and requires about 1 week of maturation to become mineralized bone matrix. Depending on the collagen configuration of the bone matrix, osteoblasts deposit 70% to 85% of the eventual mineral complement by a process called *primary mineralization.*[7,24] Secondary mineralization (mineral maturation) completes the maturation process in about 8 months by a crystal growth process (see Figure 26-15, *D*). Because the strength of bone tissue is related directly to mineral content, the stiffness and strength of an entire bone depends on the distribution and relative degree of mineralization of its osseous tissue.[26] The initial strength of new bone is the result of the cell-mediated process of primary mineralization, but its ultimate strength is dictated by secondary mineralization, which is the physiochemical process of crystal growth. This concept has important clinical value in orthodontics. Fully mineralized lamellar bone (i.e., bone in steady state with respect to modeling and remodeling) is expected to be less susceptible to relapse tendencies than its woven and composite bone predecessors.[6,27] After active orthodontic therapy, retaining dental corrections for at least 6 to 8 months is important to allow for mineral maturation of the newly formed bone (Figure 26-16).

Endosseous implants can be placed in the nasal bones of rabbits to serve as anchorage units to load the nasal suture. Slow sutural expansion (Figure 26-17) produces high-quality lamellar bone along the osseous

Figure 26-16 Periapical radiographs comparing bone maturation at the end of active orthodontic treatment and 2 years later. **A,** At the end of treatment, large amorphous areas of relatively immature bone can be seen. **B,** After retention and restorative treatment, including endodontics, distinct definition of cortices and trabeculae is evident. *(From Roberts WE et al:* Bone biodynamics in orthodontic and orthopedic treatment: craniofacial growth series*, vol 27, Ann Arbor, Mich, 1991, University of Michigan Press.)*

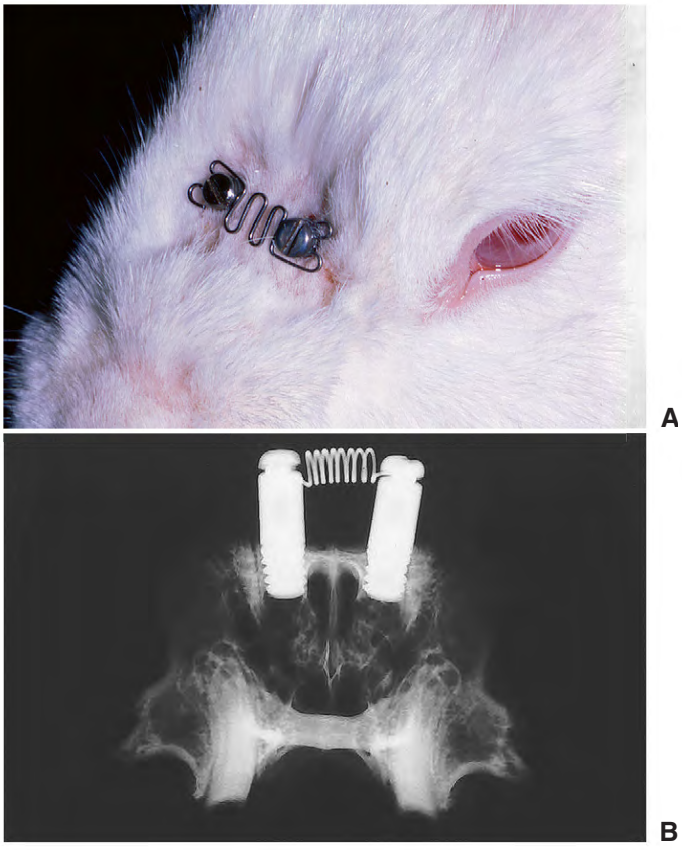

Figure 26-17 **A,** Endosseous implants in rabbit nasal bones are loaded in tension to expand the suture between the nasal bones. **B,** Radiograph of a postmortem specimen of rabbit maxilla and nasal bones shows two bilateral endosseous implants used as abutments for a coil spring that delivers a compressive load across the internasal suture. *(From Don MT:* Orthopedic anchorage with endosseous implants in rabbit nasal bones *[master's thesis], San Francisco, 1988, University of the Pacific.)*

margins of the suture and the periosteal (superior) surface of the nasal bones (Figure 26-18). Compression of the nasal bones (see Figure 26-17, *A*) is manifested by resorption along the margins of the suture (Figure 26-19). Compressive and tensile loading of the suture are associated with extensive bone modeling and remodeling of the adjacent bones. Sutural adaptation to physiologic and therapeutic loads is associated with a regional acceleration of modeling and remodeling in the adjacent bones.

The PDL is the adaptive connective tissue interface between a tooth and its supporting bone. The overall quality and relative maturation of alveolar bone supporting a rat maxillary molar is shown by a microradiographic image of a histologic section (Figure 26-20, *A*). If the same section is viewed with fluorescent light, the pattern of osteogenic activity in the bone directly supporting the PDL is visible. Sharp labels mark lamellar bone, and diffuse labels indicate woven bone. Extensive turnover (remodeling) of the alveolar process is shown by uptake of internal labels (Figure 26-20, *B*). These data reveal that the entire alveolar process responds to tooth movement. Uncoupled anabolic and catabolic modeling occurs along bone surfaces that border the periosteum and PDL. Remodeling (coupled foci of bone resorption and formation) is the process of internal turnover and adaptation.

To a limited extent the temporal fossa can adapt to growth and functional loading, primarily in an anteroposterior direction, but the principal site of skeletal growth and adaptation is the mandibular condyle. In one study, multifluorochrome labeling and microradiography were used to compare bone in growing adolescent rabbits (Figure 26-21) with that in adult female rabbits who had completed growth (Figure 26-22). The adolescent primary spongiosa, the layer of endochondral bone immediately beneath the articular cartilage, is predominantly woven bone (marked by the diffuse labels in Figure 26-22). More inferiorly, the primary spongiosa is remodeled to secondary spongiosa (broad, distinct labels). Progressing deeper into the secondary spongiosa (trabecular bone), continuing remodeling of lamellar bone is shown by the sharp labels (see Figure 26-21). This progressive pattern

of bone modeling and remodeling is characteristic of the skeletal mechanism of long bone growth.

In contrast, the nongrowing condyles of adult animals have a much thinner subchondral plate composed primarily of woven bone (see Figure 26-22). The supporting metaphysis is composed entirely of secondary spongiosa. Bone label uptake documents a high rate of remodeling of lamellar bone.

These data suggest that the mandibular condyle has a high rate of remodeling consistent with heavy functional loading. All things considered, the substantial histologic variance of functioning condyles in adolescent and adult animals indicates that the TMJ is highly adaptable. However, the presence of woven bone and diffuse labels in the thin subchondral plate of adults suggests that the mandibular condyle may be fragile

and susceptible to degenerative changes if overloaded. Nevertheless the high rate of physiologic activity in the mandibular condyle of young and old animals may explain the remarkable ability of this joint to heal and even regenerate after injury (see Figure 26-14).

Microindentation, Backscatter Imaging, and Microcomputed Tomography

Huja et al.[21] developed a microindentation method for determining the material properties of bone in a block specimen and demonstrated that the lamellar bone within 1 mm of the surface of an implant is more compliant than the supporting bone of the jaw. Polarized microscopy demonstrates the more irregular collagen pattern of the compliant lamellar bone near the interface (Figure 26-23). Backscatter emission imaging[19] recently has been refined as a high-resolution method for assessing the bone mineral density and surface topography patterns of the osseous interface of dental implants (Figure 26-24). In another important technologic advancement, Yip et al.[20] developed a special tuning sequence for the microcomputed tomography that allows three-dimensional detection of bone mineral density patterns to a resolution of 5 µm (Figure 26-25).

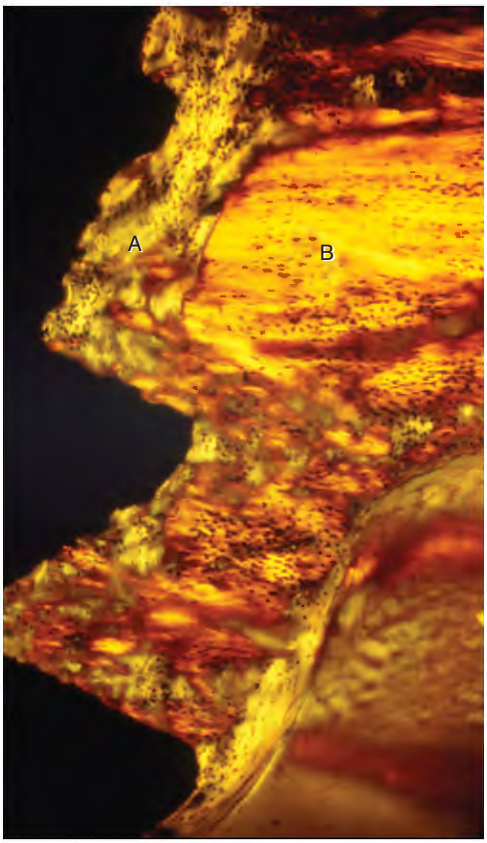

Figure 26-23 A polarized illumination photomicrograph shows the healed interface of a titanium implant in rabbit cortical bone. Note the layer of newly formed lamellar bone *(A)* formed by multidirectional remodeling within about 1 mm of the implant surface. Compare the more compliant layer of primarily mineralized lamellar bone *(A)* with the fully mineralized lamellar bone *(B)* supporting the interfacial layer.

Furthermore, this exciting new method can detect bone remodeling foci within intact specimens (Figure 26-26) and can differentiate between primary and secondary lamellar bone along the metallic surfaces of endosseous implants. Collectively, these new methods have been valuable for assessing the material properties and mineral density of bone integrating endosseous implants that are used for orthodontic and dentofacial orthopedic anchorage. However, these advanced technologies offer the promise of considerably exceeding the capability of previous histologic methods for defining the adaptive

Figure 26-24 Backscatter emission imaging of the bone surface immediately adjacent to an implant (removed) reveals the mineral density of surface topography of the rapidly remodeling interfacial layer. *(From Huja SS, Roberts WE: Mechanism of osseointegration: characterization of supporting bone with indentation testing and backscattered imaging,* Semin Orthod *10:162-173, 2004.)*

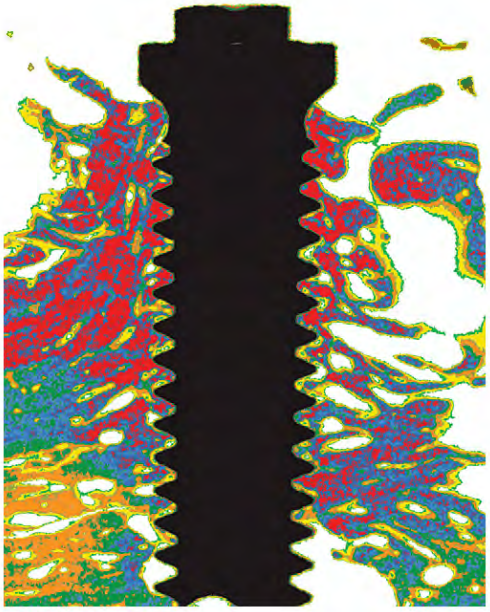

Figure 26-25 Microcomputed tomography of a section through an implant placed in canine cortical bone reveals a broad array of mineralized tissues. The original gray-level distribution has been color coded gold, blue, red, and yellow to demonstrate decreasing levels of mineral density. The method can resolve structures as small as an osteoblast. *(From Yip G, Schneider P, Roberts WE: Mechanism of osseointegration: characterization of supporting bone with indentation testing and backscattered imaging,* Semin Orthod *10:174-187, 2004.)*

WWW.HIGHDENT.IR

response of the oral and craniofacial structures to therapeutic loads.

Autoradiography

Radioactive precursors for structural and metabolic materials can be detected in tissue by coating histologic sections with a nuclear track emulsion. By localizing radioactive disintegrations, one can determine the location of the radioactive precursors (Figure 26-27). Specific radioactive labels for proteins, carbohydrates, and nucleic acids are injected at a known interval before tissue sampling is done. Qualitative and quantitative assessment of label uptake is a physiologic index of cell activity. The autoradiographic labeling procedures most often used in bone research are ^{3}H-thymidine labeling of cells synthesizing DNA (S phase cells) and ^{3}H-proline labeling of newly formed bone matrix. Bromodeoxyuridine immunocytochemistry, a nonradioactive method of labeling S phase cells in vivo (Figure 26-28), shows promise of becoming an important bone cell kinetic method of the future.[14]

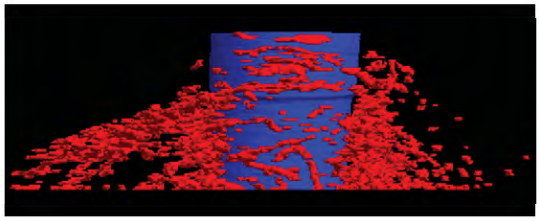

Figure 26-26 A three-dimensional microcomputed tomography view of the peri-implant radiolucent areas reveals an uneven distribution of vascular areas and remodeling foci. This image of the cervical half of a cylindric implant is consistent with the intense bone remodeling pattern focused within the center of the endosseous portion. This image was tuned to demonstrate less mineralized structures: internal vascularity including remodeling foci (cutting/filling cones). *(From Yip G, Schneider P, Roberts WE:* Semin Orthod *10:174-187, 2004.)*

Nuclear Volume Morphometry

Measuring the size of the nucleus is a cytomorphometric procedure for assessing the stage of differentiation of osteoblast precursor cells. This method has been particularly useful for assessing the mechanism of osteogenesis in orthodontically activated PDLs (Figure 26-29). Preosteoblasts (C and D cells) have significantly larger nuclei than committed osteoprogenitor (A′) cells or their less differentiated precursors (A cells). The B cell compartment is a group of fibroblast-like cells that appear to have little or no osteogenic potential.[28] Careful cytomorphometric assessment of the size of the nucleus (Figure 26-30, *A*) has proved to be an effective means of determining the relative differentiation of PDL and other bone-lining cells.

Classification of Bone Tissue

Orthodontic tooth movement involves a cytokine-mediated bone adaptation response similar to wound healing; therefore, tooth movement is a good experimental model for understanding the types of bone formed during the postoperative bone modeling and long-term remodeling response to bone manipulative therapy. The first bone formed is relatively immature woven bone (Figure 26-31). Woven bone is compacted to form composite bone (primary ostons) and subsequently is remodeled to lamellar bone. To appreciate the biologic mechanism of bone healing and adaptation, the practitioner must have knowledge of bone types.

Woven Bone

Woven bone varies considerably in structure; it is realtively weak, disorganized, and poorly mineralized. However, it serves a crucial role in wound healing by (1) rapidly filling osseous defects; (2) providing initial continuity for fractures, osteotomy segments, and endos-

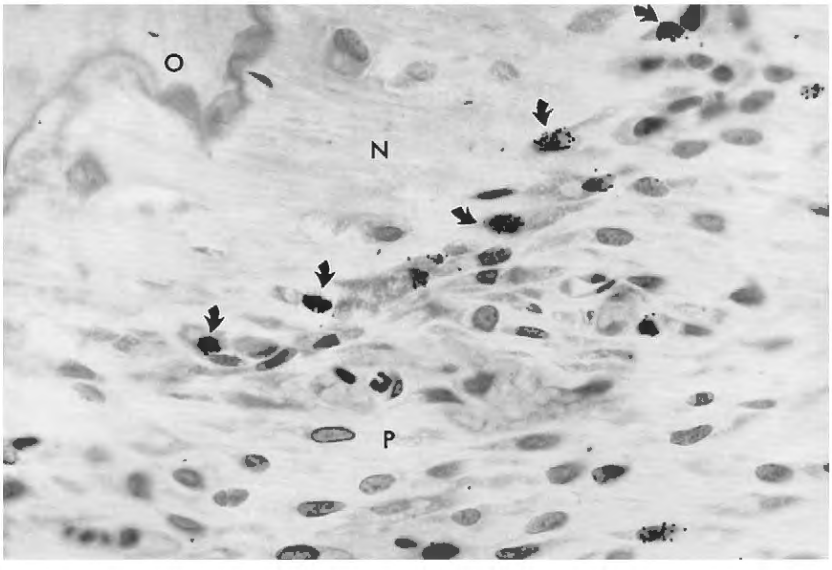

Figure 26-27 At 56 hours after initiation of orthodontic force, new bone *(N)* is forming on the original *(O)* alveolar bone surface. The ^{3}H-thymidine–labeled osteoblasts *(arrows)* are derived from preosteoblasts in the periodontal ligament *(P)* (×450).

seous implants; and (3) strengthening a bone weakened by surgery or trauma. The first bone formed in response to wound healing is the woven type. Woven bone is not found in the adult skeleton under normal, steady-state conditions; rather, it is compacted to form composite bone, remodeled to lamellar bone, or rapidly resorbed if prematurely loaded.[8,29] The functional limitations of woven bone are an important aspect of orthodontic retention (see Figure 26-16), as well as postoperative healing of implants and orthognathic surgery segments.[30]

Lamellar Bone

Lamellar bone, a strong, highly organized, well-mineralized tissue, makes up more than 99% of the adult human skeleton. When new lamellar bone is formed, a portion of the mineral component (hydroxylapatite) is deposited by osteoblasts during primary mineralization (see Figure 26-15, *D*). Secondary mineralization, which completes the mineral component, is a physical process (crystal growth) that requires many months. Within physiologic limits, the strength of bone

WWW.HIGHDENT.IR

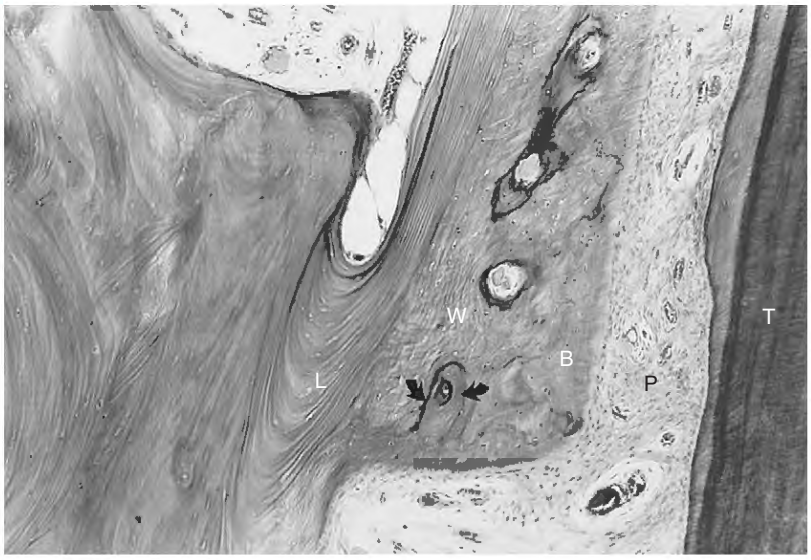

Figure 26-31 A section of human periodontium from the lower first molar region shows a typical histologic response to orthodontic tooth movement. With respect to the mature lamellar bone *(L)* on the left, the tooth *(T)* is being moved to the right. The first bone formed adjacent to the periodontal ligament *(P)* is of the woven type *(W)*. Subsequent lamellar compaction forms primary osteons of composite bone *(arrows)*. Bundle bone *(B)* is formed where ligaments, such as the periodontal ligament, are attached. *(From Roberts WE Turkey PK, Breznia KN et al: Implants: bone physiology and metabolism,* Calif Dent Assoc *J 15:54-61, 1987.)*

is related directly to its mineral content.[24,26] The relative strengths of different histologic types of osseous tissue are such that woven bone is weaker than new lamellar bone, which is weaker than mature lamellar bone.[30] Adult human bone is almost entirely of the remodeled variety: secondary osteons and spongiosa.[7,8,24] The full strength of lamellar bone that supports an endosseous implant is not achieved until about 1 year postoperatively. This is an important consideration in planning the functional loading of an implant-supported prosthesis.

Composite Bone

Composite bone is an osseous tissue formed by the deposition of lamellar bone within a woven bone lattice, a process called *cancellous compaction.*[6,31] This process is a rapid means of producing relatively strong bone in a short period.[26] Composite bone is an important intermediary type of bone in the physiologic response to functional loading (see Figure 26-31), and it usually is the predominant osseous tissue for stabilization during the early process of postoperative healing. When the bone is formed in the fine compaction configuration, the resulting composite of woven and lamellar bone forms structures known as *primary osteons.* Although composite bone may be high-quality, load-bearing osseous tissue, it is eventually remodeled into secondary osteons.[7,30]

Bundle Bone

Bundle bone is a functional adaptation of lamellar structure to allow attachment of tendons and ligaments. Perpendicular striations, called *Sharpey's fibers,* are the major distinguishing characteristics of bundle bone. Distinct layers of bundle bone usually are seen adjacent to the PDL (see Figure 26-31) along physiologic bone-forming surfaces.[32] Bundle bone is the mechanism of ligament and tendon attachment throughout the body. First-generation blade implants were thought to form a ligamentous attachement to bone, which was deemed a *pseudoperiodontium.* However, histologic studies could not demonstrate any bundle bone attaching fibrous conective tissue to bone at the interface. Because the fibrous tissue encapsulation had no physiologic role, it was actually scar tissue, which was equivalent to a nonunion in a failed facture repair.

SKELETAL ADAPTATION: MODELING AND REMODELING

Skeletal adaptation to the mechanical environment is achieved through changes in (1) bone mass, (2) geometric distribution, (3) matrix organization, and (4) collagen orientation of the lamellae. In addition to these adaptive mechanisms that influence bone formation, the mechanical properties of osseous structures change as a result of maturation, function, aging, and pathologic processes. A few physiologic and pathologic examples are (1) secondary mineralization, (2) mean bone age, (3) fatigue damage, and (4) loss of vitality (pathologic hypermineralization).[33]

Trabecular and cortical bone grow, adapt, and turn over by means of two fundamentally distinct mechanisms: modeling and remodeling. In bone modeling, independent sites of resorption and formation change the form (shape, size, or both) of a bone. In bone remodeling, a specific, coupled sequence of resorption and formation occurs to replace previously existing bone (Figure 26-32). The mechanism for internal remodeling (turnover) of dense compact bone involves axially oriented cutting and filling cones (Figure 26-33).[6] From an orthodontic perspective the biomechanical response to tooth movement involves an integrated array of bone modeling and remodeling events (Figure 26-34, *A*).

WWW.HIGHDENT.IR

Bone modeling is the dominant process of facial growth and adaptation to applied loads such as headgear, rapid palatal expansion, and functional appliances. Modeling changes can be seen on cephalometric tracings (see Figure 26-34, *B*), but remodeling events, which usually occur at the same time, are apparent only at the microscopic level. True remodeling usually is not imaged on clinical radiographs,[34] but can be detected with clinical scintillation scans. Constant remodeling (internal turnover) mobilizes and redeposits calcium by means of coupled resorption and formation: bone is resorbed and redeposited at the same site. Osteoblasts, osteoclasts, and possibly their precursors are thought to communicate by chemical messages known as *coupling factors.* Transforming growth factor β is thought to be a coupling factor.[35]

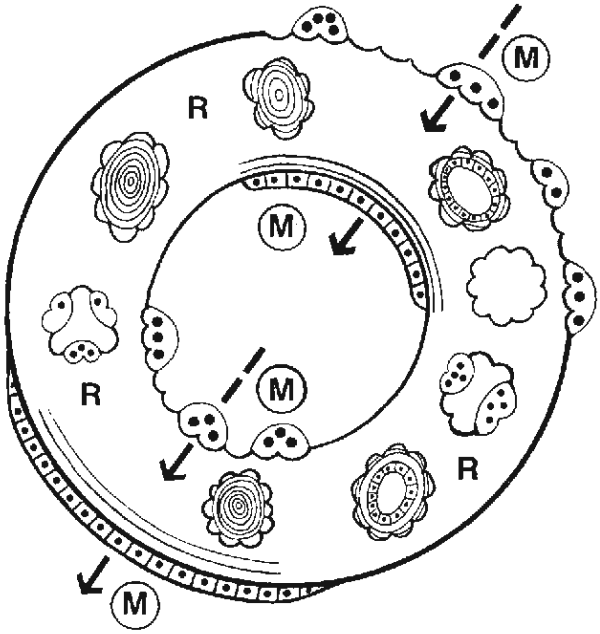

Figure 26-32 A schematic cross section of cortical bone shows surface modeling *(M),* which is the process of uncoupled resorption and formation. Remodeling *(R)* is the turnover of existing bone. *(From Roberts WE et al: Remodeling of devitalized bone threatens periosteal margin integrity of endosseous titanium implants,* Indiana Dent Assoc J *68:19, 1989.)*

CORTICAL BONE GROWTH AND MATURATION

Enlow[31] sectioned human skulls and histologically identified areas of surface apposition and resorption. The overall patterns of bone modeling ("external remodeling") helped define the mechanisms of facial growth. Although the method could not distinguish between active and inactive modeling sites, it was adequate for determining the overall direction of regional activity in the maxilla and mandible. This method of osseous topography was a considerable advance in the understanding of surface modeling of facial bones.

Melsen[36] used microradiographic images of mineralized sections to extend the capability of the osseous topography method. Patterns of primary and secondary mineralization (as described in Figure 26-15) identified active appositional sites and provided a crude index of bone formation rates. Through the systematic study of autopsy specimens of 126 normal males and females from birth to 20 years of age, the most stable osseous structures in the anterior cranial base of growing children and adolescents were defined anatomically (Figure 26-35, *A*). This research established that the three most stable osseous landmarks for superimposition of cephalometric radiographs are (1) the anterior curvature of the sella turcica, (2) the cribriform plate, and (3) the internal curvature of the frontal bone (see Figure 26-35, *B*). In effect, this research established the gold standard for reliable superimposition on the anterior cranial base. This information is valuable for implantologists because a superimposed tracing of serial cephalometric radiographs is the most reliable means for determining when postadolescent growth is complete. The latter is essential for treatment planning implant placement during the late adolescent and early adult periods.

Roberts et al.[6,7,25] introduced simultaneous use of multiple fluorochrome labels and microradiography to assess modeling and remodeling patterns over extended periods of time. Noorda[37] applied these methods for a three-dimensional assessment of subcondylar growth of the mandible of adolescent rabbits. Twenty-week-old rabbits (early adolescents) were labeled every 2 weeks

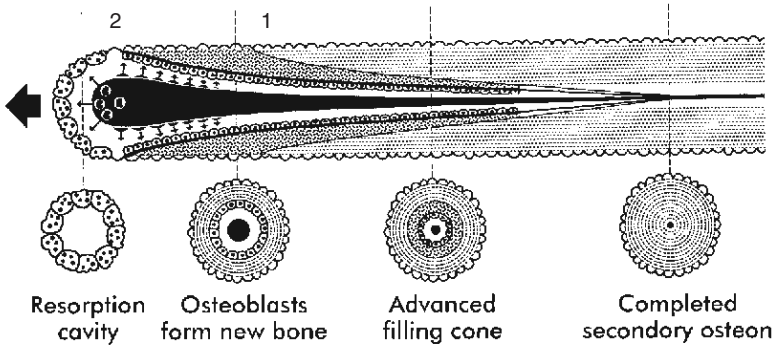

Figure 26-33 The cutting/filling cone has a head of osteoclasts that cut through the bone and a tail of osteoblasts that form a new secondary osteon. The velocity through bone is determined by measuring between two tetracycline labels (1 and 2) administered 1 week apart. *(Adapted from Roberts WE Garetto LP, Arbuckle GR et al: What are the risk factors of osteoporosis? Assessing bone health,* J Am Dent Assoc *122:59-61, 1991.)*

WWW.HIGHDENT.IR

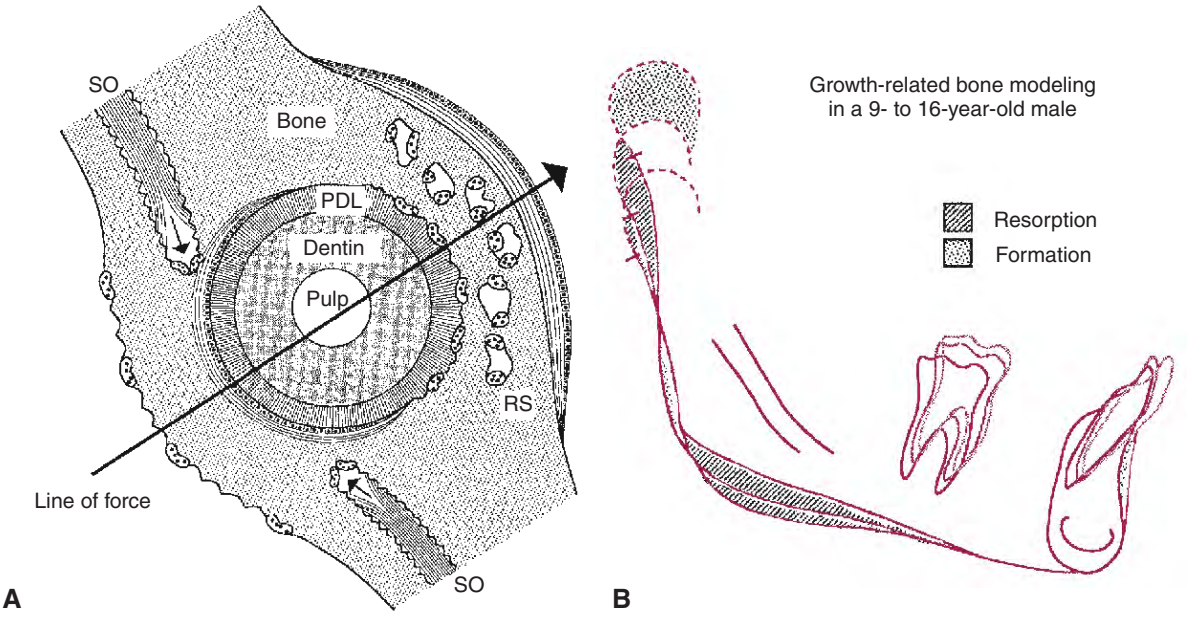

Figure 26-34 **A,** Orthodontic bone modeling, or site-specific formation and resorption, occurs along the periodontal ligament (PDL) and periosteal surfaces. Remodeling, or turnover, occurs withinalveolar bone along the line of force on both sides of the tooth. **B,** Orthopedic bone modeling related to growth in an adolescent male involves several site-specific areas of bone formation and resorption. Although extensive bone remodeling (i.e., internal turnover) also is underway, itis not evident in cephalometric radiographs superimposed on stable mandibular structures.

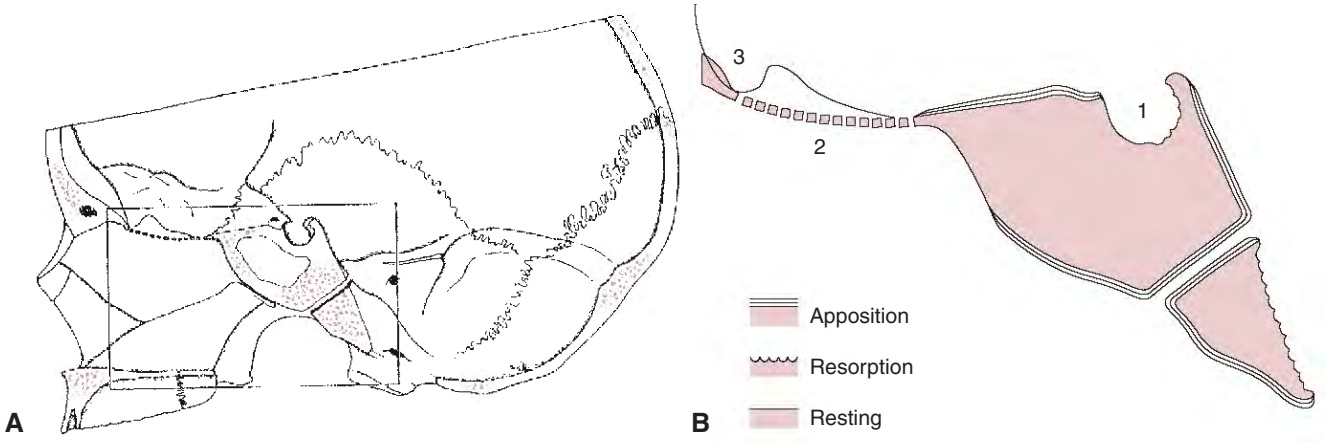

Figure 26-35 **A,** Schematic drawing of a skull showing the tissue block removed at autopsy from a series of growing children and adolescents from birth to 20 years of age. **B,** Diagrammatic representation of the bone modeling patterns of the cranial base in growing children. Histologic and microradiographic analysis established that the three most stable anatomical landmarks are *(1)* the anterior curvature of the sella turcica, *(2)* the cribriform plate, and *(3)* the internal curvature of the frontal bone. *(From Melsen B: The cranial base,* Acta Odontol Scand *32(suppl 62):103, 1974.)*

with a rotating series of six different multifluorochrome labels for 18 weeks. Cross sections of the subcondylar region (Figure 26-36, *A*) were superimposed on original, oldest-labeled, and newest-labeled bone according to fluorescent time markers (see Figure 26-36, *B*). Because all three sections were at the same relative level at a point in time, superimposition on original (unlabeled) bone and the oldest labeled bone (see Figure 26-36, *C*) provided an index of the relative amounts of bone resorbed and formed as the mandible grew superiorly (see Figure 26-36, *D*). This method provides the most accurate assessment to date of cortical bone drift over time. The major mechanism of the increase in interramal width during adolescent growth in rabbits is lateral drift of the entire subchondral region.

The Noorda study also produced important quantitative data on the rates of surface modeling (apposition and resorption) of primary bone (Figure 26-37). During the last 18 weeks of growth to adult stature, the surface apposition rate decreased from more than 25 µm per day to less than 5 µm per day (Figure 26-38, *A*). The secondary osteon census peaked at about 8 to 10 weeks (see Figure 26-38, *B*). Therefore under conditions of relatively rapid growth, primary cortical bone is

WWW.HIGHDENT.IR

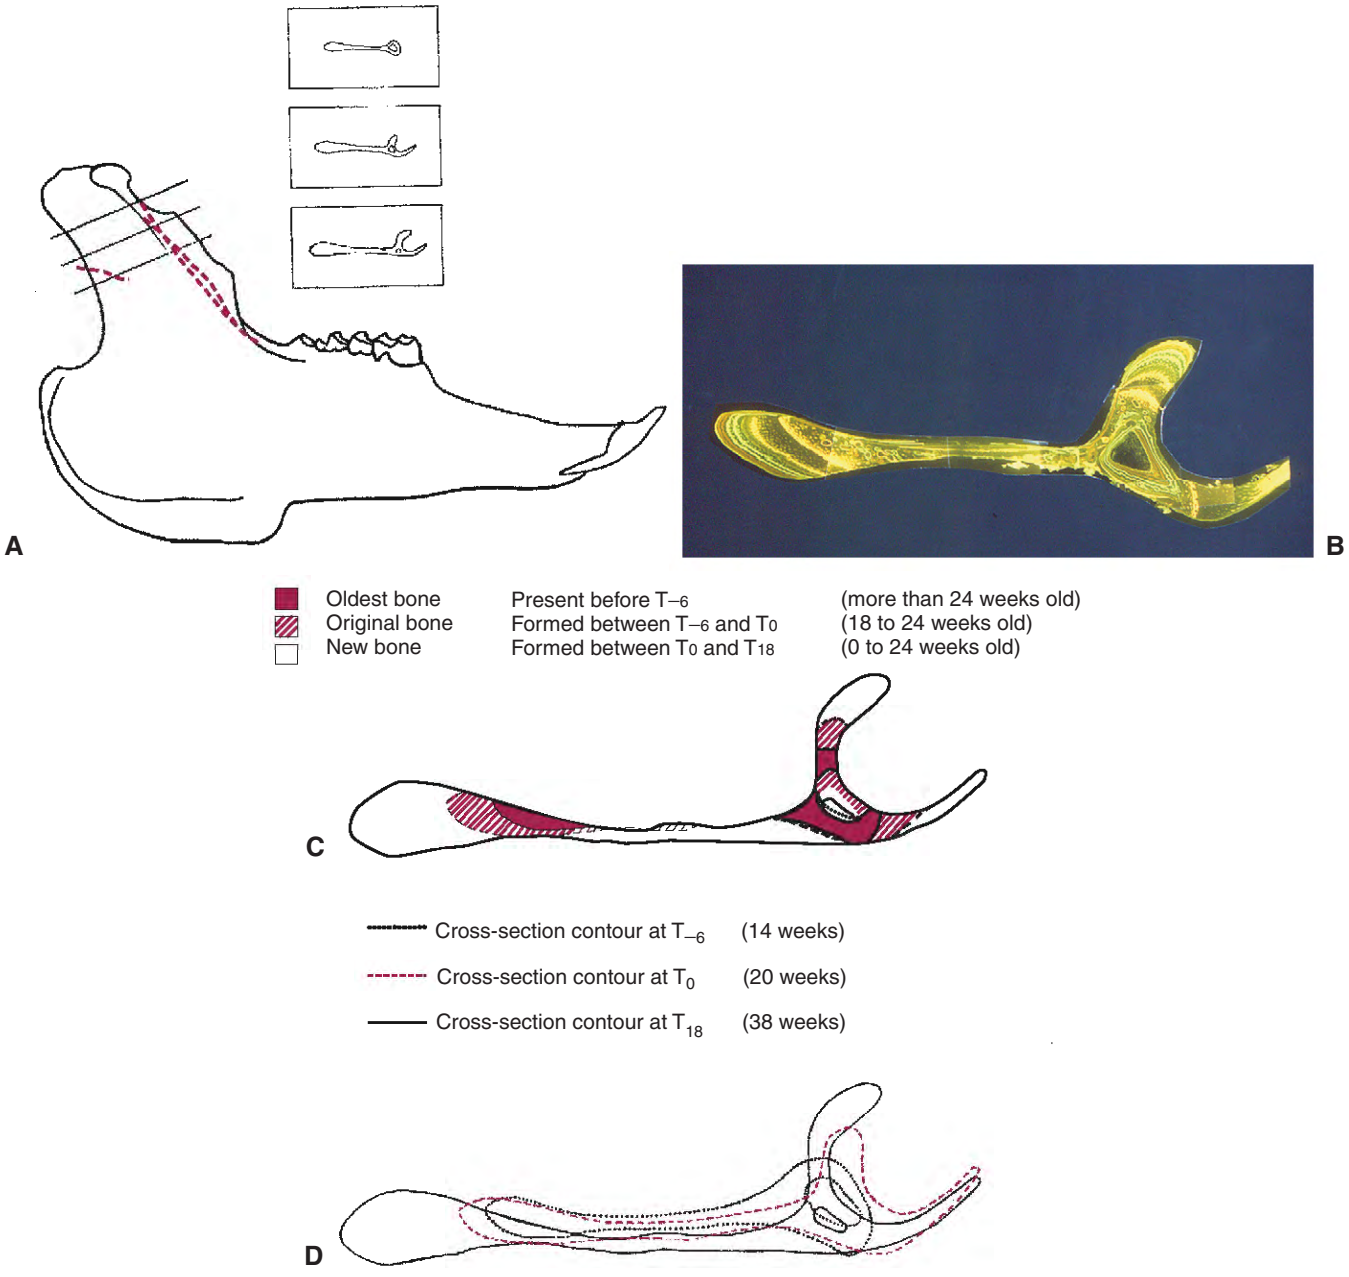

Figure 26-36 **A,** Schematic drawing of a rabbit mandible showing the plane of sectioning in the subcondylar region of the ramus. **B,** Fluorescent light photomicrographs of the most inferior section are arranged in a composite. The weekly deposition of bone labels over 4 months shows the patterns of bone modeling and remodeling associated with the growth and development of the subcondylar region. **C,** Based on the uptake of bone labels, the age of specific areas in a given cross section can be determined accurately. **D,** Because the subcondylar region of the ramus is growing superiorly, superimposition of the three sections on the oldest bone gives an estimation of the patterns of bone resorption (catabolic modeling) associated with growth of the mandibular ramus. *(From Noorda CB:* Modeling and remodeling in the cortical bone of both growing and mature rabbits *[master's thesis], San Francisco, 1986, University of the Pacific.)*

remodeled to secondary osteons in about 2 months. Remodeling therefore is a time-dependent maturation of primary cortical bone.[6,7]

There is little long-term documentation of the bone remodeling response to functional loading of implant-supported restorations. The same methods used for defining the growth and development of the rabbit mandible would provide valuable new information for the field of implantology.

Cutting and Filling Cones

The rate at which cutting and filling cones progress through compact bone is an important determinant of turnover. The progression is calculated by measuring the distance between initiation of labeled bone formation sites along the resorption arrest line in longitudinal sections.[6] Using two fluorescent labels administered 2 weeks apart in adult dogs, the velocity was 27.7 ± 1.9 µm

WWW.HIGHDENT.IR

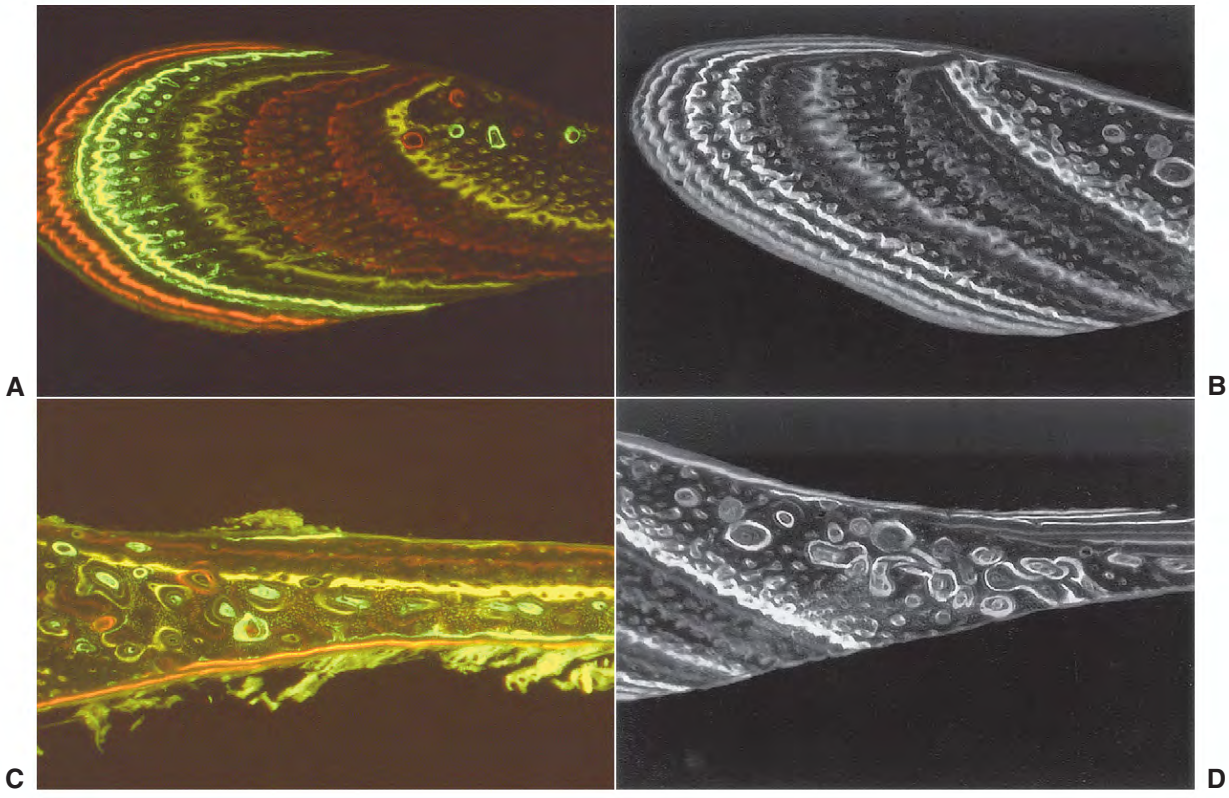

Figure 26-37 **A,** Fluorescent microscopy of weekly bone labels shows the patterns of anabolic modeling (bone apposition) in a rabbit. Note the diminishing space between the labels as growth slows and the animal achieves an adult skeletal form. **B,** A similar section from another rabbit in the same study shows the consistency of the growth pattern. **C,** In the first rabbit the adjacent microscopic field shows several sites of bone remodeling in primary cortical bone formed about 6 to 12 weeks earlier. **D,** In the second rabbit the adjacent microscopic field shows a consistent pattern of remodeling of new cortical bone at about 6 to 12 weeks after formation. *(From Noorda CB:* Modeling and remodeling in the cortical bone of both growing and mature rabbits *[master's thesis], San Francisco, 1986, University of the Pacific.)*

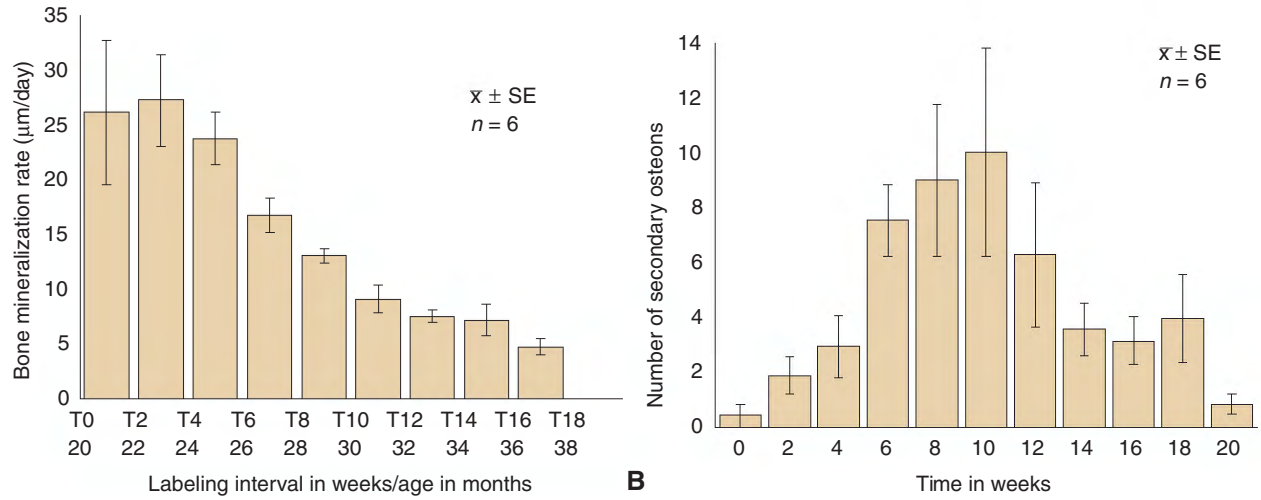

Figure 26-38 **A,** Age-related changes in the rate of periosteal apposition that occur in the posterior border of the mandibular ramus of the rabbit. Note the progressive decrease in the rate of periosteal bone apposition as the adolescent animals mature. **B,** Remodeling of new cortical bone. The highest incidence of remodeling to secondary osteons occurs when new cortical bone is 6 to 12 weeks old. *(From Noorda CB:* Modeling and remodeling in the cortical bone of both growing and mature rabbits *[master's thesis], San Francisco, 1986, University of the Pacific.)*

WWW.HIGHDENT.IR

per day (mean ± SEM [standard error of the mean], n = 4 dogs, 10 cutting and filling cones sampled from each). At this speed, evolving secondary osteons travel about 1 mm in 36 days. Newly remodeled secondary osteons (formed within the experimental period of the dog study) contained an average of 4.5 labels (administered 2 weeks apart); the incidence of resorption cavities is about one third the incidence of labeled osteons.[25] These data are consistent with a remodeling cycle of about 12 weeks in dogs[25] compared with 6 weeks in rabbits[6] and 17 weeks in humans.[7,8] This relationship is useful for extrapolating animal data to human applications. More recent experimental studies have shown that new secondary osteons may continue to fix bone labels for up to 6 months, indicating that terminal filling of the lumen is slow.[38]

Traumatic or surgical wounding usually results in intense but localized modeling and remodeling responses. After an osteotomy or placement of an endosseous implant, callus formation and resorption of necrotic osseous margins are modeling processes; however, internal replacement of the devitalized cortical bone surrounding these sites is a remodeling activity. In addition, a gradient of localized remodeling disseminates through the bone adjacent to any invasive bone procedure. This process, called *regional acceleratory phenomenon*, is an important aspect of postoperative healing.[8,39]

Modeling and remodeling are controlled by an interaction of metabolic and mechanical signals. Bone modeling is largely under the integrated biomechanical control of functional applied loads (Table 26-1). However, hormones and other metabolic agents have a strong secondary influence, particularly during periods of growth and advanced aging. Paracrine and autocrine mechanisms, such as local growth factors and prostaglandins, can override the mechanical control mechanism temporarily during wound healing.[40] Remodeling responds to metabolic mediators such as parathyroid hormone (PTH) and estrogen, primarily varying the rate of bone turnover (Box 26-1). Bone scans with ^{99}Te-bisphosphate, a marker of bone activity, indicate that the alveolar processes, but not the basilar mandible, have a high remodeling rate.[41,42] Uptake of the marker in alveolar bone is similar to uptake in trabecular bone of the vertebral column. The latter is known to remodel at a rate of about 20% to 30% per year compared with most cortical bone, which turns over at a rate of 2% to 10% per year.[43] Metabolic mediation of continual bone turnover provides a controllable flow of calcium to and from the skeleton.

Table 26-1 Control Factors for Bone Modeling

FACTOR	PEAK LOAD IN MICROSTRAIN (με)*
Mechanical†	
Disuse atrophy	<200
Bone maintenance	200 to 2500
Physiologic hypertrophy	2500 to 4000
Pathologic overload	>4000
Endocrine	
Bone metabolic hormones: PTH, vitamin D, calcitonin	
Growth hormones: somatotropin, IGF-I, IGF-II	
Sex steroids: testosterone, estrogen	
Paracrine and autocrine	
Wide variety of local agents	

PTH, Parathyroid hormone; *IGF,* insulin-like growth factor.
*με = percent deformation $\times 10^{-4}$.
†Frost's mechanostat theory (Frost HM: Skeletal structural adaptations to mechanical usage [SATMU]. 2. Redefining Wolff's law: the remodeling problem, Anat Rec 226:414, 1990).

Structural and Metabolic Fractions

The structural fraction of cortical bone is the relatively stable outer portion of the cortex; the metabolic fraction is the highly reactive inner aspect (Figure 26-39, *A*). The primary metabolic calcium reserves of the body are found in trabecular bone and the endosteal half of the cortices. Analogous to orthodontic wires, the stiffness and strength of a bone are related directly to its cross-sectional area. Diaphyseal rigidity quickly is enhanced by adding a circumferential lamella at the periosteal surface. Even a thin layer of new osseous tissue at the periosteal surface greatly enhances bone stiffness because it increases the diameter of the bone. In engineering terms, cross-sectional rigidity is related to the second moment of the area. The same general relationship of round wire diameter and stiffness (strength) is well known to orthodontists. The rigidity of a wire increases as the fourth power of diameter.[44] Therefore when a relatively rigid material (bone or wire) is doubled in diameter, the stiffness increases 16 times.

The addition of new osseous tissue at the endosteal (inner) surface has little effect on overall bone strength. Structurally, the long bones and mandible are modified

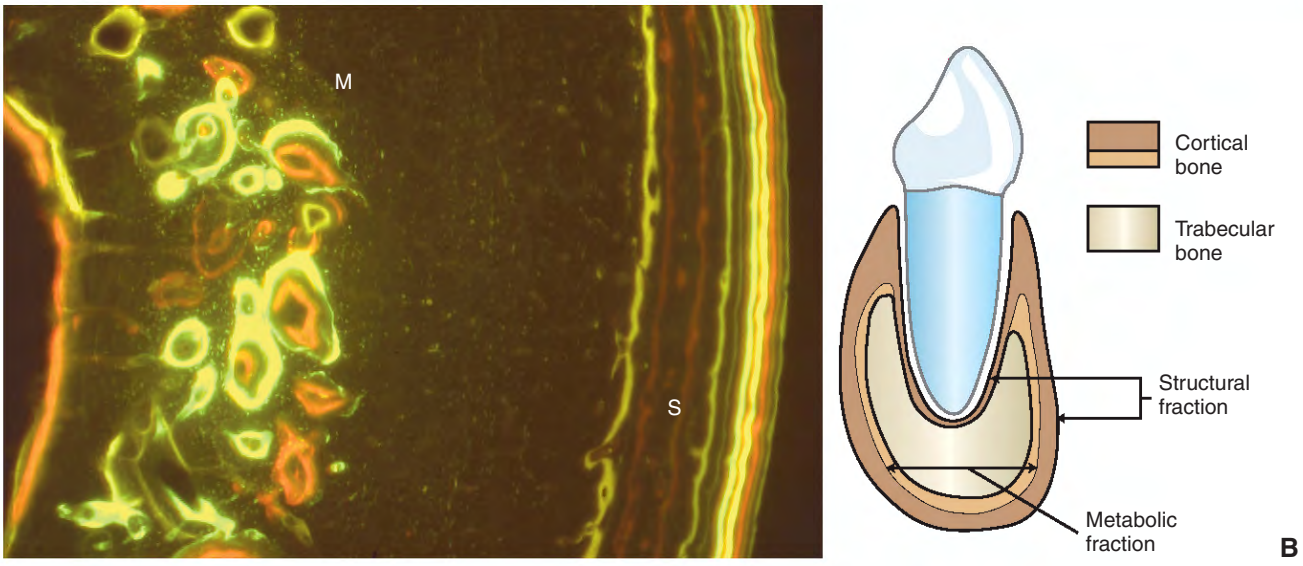

Figure 26-39 **A,** The structural *(S)* and metabolic *(M)* fractions of cortical bone are revealed by multiple fluorochrome labeling of a rabbit femur during the late growth and early adult periods. Continuing periosteal bone formation (right) contributes to structural strength, and high remodeling of the endosteal half of the compacta provides a continual supply of metabolic calcium. **B,** Structural and metabolic fractions of bone in the mandible. *(Adapted from Roberts WE et al:* Bone dynamics in orthodontic and orthopedic treatment: craniofacial growth series, *vol 27, Ann Arbor, Mich, 1991, University of Michigan Press.)*

tubes—an optimal design for achieving maximal strength with minimal mass.[26] Within limits, loss of bone at the endosteal surface or within the inner third of the compacta has little effect on bone rigidity. The inner cortex can be mobilized to meet metabolic needs without severely compromising bone strength (see Figure 26-39, *B*); this is the reason patients with osteoporosis have bones with a normal diameter but thin cortices. Even under severe metabolic stress, the body follows a cardinal principle of bone physiology: *maximal strength with minimal mass.*[45]

BONE METABOLISM

Restoration of esthetics and function with implant-supported prostheses requires substantial bone manipulation. The biomechanical response to altered function and applied loads depends on the metabolic status of the patient. Bone metabolism is an important aspect of clinical medicine that is directly applicable to implant dentistry. This section discusses the fundamentals of bone metabolism with respect to clinical practice.

The skeletal system is composed of highly specialized mineralized tissues that have structural and metabolic functions. Structurally, lamellar, woven, composite, and bundle bone are unique types of osseous tissue adapted to specific functions. Bone modeling and remodeling are distinct physiologic responses to integrated mechanical and metabolic demands. Biomechanical manipulation of bone is the physiologic basis of stomatognathic reconstruction. However, before addressing dentofacial considerations, the clinician must assess the patient's overall health status. Implantology is bone-manipulative therapy, and favorable calcium metabolism is an important consideration. Because of the interaction of structure and metabolism, a thorough understanding of osseous structure and function is fundamental to patient selection, risk assessment, treatment planning, and retention of desired dentofacial relationships.[45,46]

Bone is the primary calcium reservoir in the body (Figure 26-40). Approximately 99% of the calcium in the body is stored in the skeleton. The continual flux of bone mineral responds to a complex interaction of endocrine, biomechanical, and cell-level control factors that maintain the serum calcium level at about 10 mg/dL (10 mg%).

Calcium homeostasis is the process by which mineral equilibrium is maintained. Maintenance of serum calcium levels at about 10 mg/dL is an essential life support function. Life is thought to have evolved in the sea; calcium homeostasis is the mechanism of the body for maintaining the primordial mineral environment in which cellular processes evolved.[45] Calcium metabolism is one of the fundamental physiologic processes of life support. When substantial calcium is needed to maintain the critical serum calcium level, bone structure is sacrificed (see Figure 26-40). The alveolar processes and basilar bone of the jaws also are subject to metabolic bone loss.[47] Even in cases of severe skeletal atrophy, the outer cortex of the alveolar process and the lamina dura around the teeth are preserved. This preservation is analogous to the thin cortices characteristic of osteoporosis.

Calcium homeostasis is supported by three temporally related mechanisms: (1) rapid (instantaneous) flux of

WWW.HIGHDENT.IR

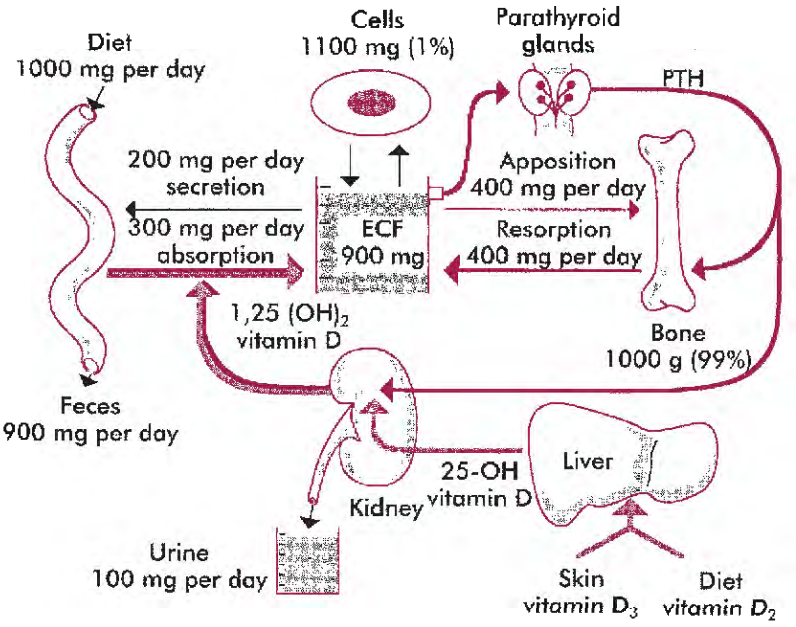

Figure 26-40 Calcium metabolism is a complex physiologic process. Maintaining zero calcium balance requires optimal function of the gut, parathyroid glands, bone, liver, and kidneys. Parathyroid hormone (PTH) and the active metabolite of vitamin D, 1,25 dihydroxycholecalciferol, are the major hormones involved. *(Adapted from Roberts WE et al:* Bone dynamics in orthodontic and orthopedic treatment: craniofacial growth series, *vol 27, Ann Arbor, Mich, 1991, University of Michigan Press.)*

calcium from bone fluid (which occurs in seconds); (2) short-term response by osteoclasts and osteoblasts (which extends from minutes to days); and (3) long-term control of bone turnover (over weeks to months) (Figure 26-41). Precise regulation of serum calcium levels at about 10 mg/dL is essential for nerve conductivity and muscle function. A low serum calcium level can result in tetany and death. A sustained high serum calcium level often is a manifestation of hyperthyroidism and some malignancies. Hypercalcemia may lead to kidney stones and dystrophic calcification of soft tissue. Normal physiology demands precise control of the serum calcium level.[45,46,48]

Instantaneous regulation of calcium homeostasis is accomplished in seconds by selective transfer of calcium ions into and out of bone fluid (see Figure 26-41, *B*). Bone fluid is separated from extracellular fluid by osteoblasts or relatively thin bone-lining cells (the latter are thought to be atrophied remnants of osteoblasts). A decrease in the serum calcium level stimulates secretion of PTH, which enhances transport of calcium ions from bone fluid into osteocytes and bone-lining cells. The active metabolite of vitamin D (1,25-dihydroxycholecalciferol [1,25DHCC]) enhances pumping of calcium ions from bone-lining cells into the extracellular fluid. By means of this sequence of events, calcium is transported across the bone-lining cells, resulting in a net flux of calcium ions from bone fluid to extracellular fluid. Within physiologic limits, support of calcium homeostasis is possible without resorption of bone. Radioisotope studies have confirmed that bone contains a diffuse mineral component that can be mobilized or redeposited without osteoblastic and osteoclastic activity.[24] However, a sustained negative calcium balance can be compensated for only by removing calcium from bone surfaces.[45,46]

Short-term control of serum calcium levels affects rates of bone resorption and formation within minutes through the action of the three calcific hormones: PTH, 1,25-DHCC, and calcitonin. Calcitonin, a hormone produced by interstitial cells in the thyroid gland, is believed to help control hypercalcemia by transiently suppressing bone resorption. Parathyroid hormone, acting in concert with 1,25-DHCC, accomplishes three important tasks: it (1) enhances osteoclast recruitment from promonocyte precursors[49]; (2) increases the resorption rate of existing osteoclasts; and (3) may suppress the rate at which osteoblasts form bone.[45,46]

Long-term regulation of metabolism has profound effects on the skeleton. Biomechanical factors (e.g., normal function, exercise, posture, habits), noncalcific hormones (e.g., sex steroids, growth hormone), and the metabolic mechanisms previously discussed (see Figures 26-40 and 26-41) dictate mass, geometric distribution, and the mean age of bone (Figure 26-42). Mass and geometric distribution of bone are influenced strongly by load history (biomechanics) and sex hormone status. Parathyroid hormone is the primary regulator of the frequency of remodeling (see Box 26-2). Because the adult skeleton is composed almost entirely of secondary (remodeled) bone, the PTH-mediated activation frequency determines mean bone age. Bone age is an important determinant of fragility because old bone presumably has been weakened by fatigue damage.[45,46]

CALCIUM CONSERVATION

Calcium conservation is the aspect of bone metabolism that involves preservation of skeletal mass. A failure in calcium conservation because of one problem or a

WWW.HIGHDENT.IR

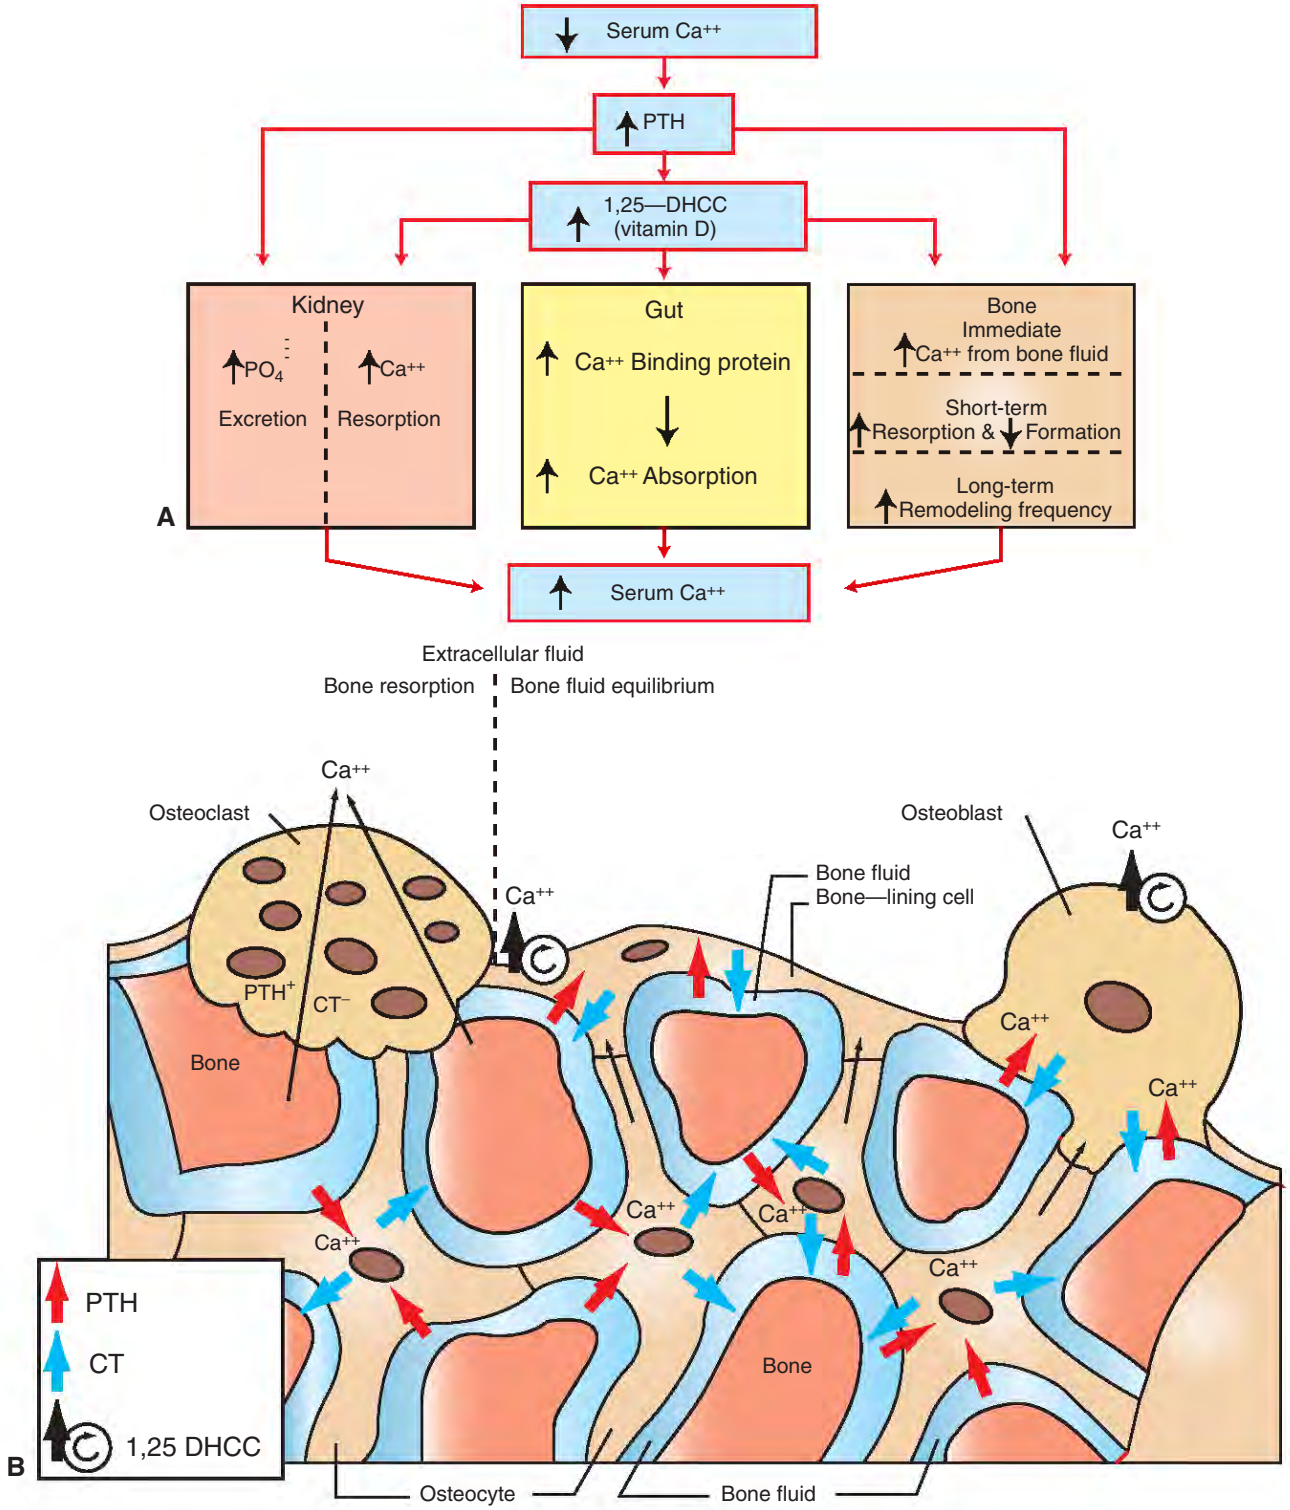

Figure 26-41 **A,** A flowchart of calcium homeostasis shows the roles of parathyroid hormone (PTH), vitamin D, and the kidneys, gut, and bone in maintaining serum calcium levels. Note that bone has immediate, short-term, and long-term responses. **B,** PTH, the active metabolite of vitamin D (1,25 DHCC), and calcitonin (CT) play active roles in transporting ionic calcium(Ca^{++}) between the bone fluid and extracellular fluid compartments. This is the mechanism of immediate homeostatic control of the serum calcium level. *(Redrawn from Roberts WE, Simmons KE, Garetto LP et al: Bone physiology and metabolism in dental implantology: risk factors for osteoporosis and other metabolic bone diseases,* Implant Dent *1:11, 1992.)*

combination of metabolic and biomechanical problems may leave a patient with inadequate bone mass for reconstructive dentistry.

The kidney is the primary calcium conservation organ in the body. Through a complex series of excretion and endocrine functions, the kidney excretes excess phosphate while minimizing the loss of calcium (see Figures 26-40 and 26-41, *A*). A patient with impaired renal function often is a high risk for osseous manipulative procedures such as endosseous implants or orthognathic surgery. Because of its components of secondary hyperparathyroidism and impaired vitamin D metabolism, kidney disease may result in poor bone quality, a condition often referred to as *renal osteodystrophy.*[45,46,50]

Absorption from the small intestine is the primary source of exogenous calcium and phosphate. Phosphate is absorbed passively and rarely is deficient. Optimal calcium uptake, however, requires an active absorption mechanism. A unique factor involved in the gut absorption process is calcium-binding protein, formed in response to the active metabolite of vitamin D.[51] Common clinical profiles associated with poor calcium absorption include a diet deficient in dairy products, vitamin D deficiency, liver disease, and kidney problems.[16,45,46]

Under normal physiologic conditions, the body expends about 300 mg of calcium per day, primarily as a result of secretory processes in the intestines and kidneys. To maintain the serum calcium level, this 300-mg deficit must be recovered by absorption from the gut. However, absorption of calcium from the gut depends on vitamin D and is only about 30% efficient. If less than about 300 mg per day of calcium is absorbed from the intestine, the serum calcium level drops, PTH secretion ensues, and the necessary calcium is removed from the bones (see Figure 26-40).

Positive calcium balance normally occurs during the growing period and for about 10 years thereafter. The skeletal mass of prepubertal children can be enhanced with regular calcium supplements.[52] Peak skeletal mass is attained between 25 and 30 years. After the early adult years, natural aging is associated with a slightly negative calcium balance that progressively erodes bone volume throughout life. Zero calcium balance (see Figure 26-40) is the ideal metabolic state for maintaining skeletal mass. Preservation of bone requires a favorable diet, endocrine balance, and adequate exercise.[45,46]

Diet

Animal studies have documented endosteal bone loss of the alveolar processes of dogs maintained on a low-calcium diet.[47] These data indicate that a low-calcium diet may have severe effects on the bones of the oral cavity. In adult humans the current recommended daily allowance of calcium is 1000 to 1500 mg per day (Table 26-2). Growing adolescents, pregnant or lactating women, and particularly pregnant teenagers need as much as 1500 mg per day. Postmenopausal women who are not receiving estrogen replacement therapy should get 1500 mg of calcium per day. In the United States, dairy products supply about 70% of dietary calcium. As previously mentioned, dietary phosphate deficiency is a rare problem.[16,27,45,46]

Obesity has few health benefits; however, it is a protective factor against osteoporosis. This most probably is a result of the high rates of mechanical loading needed to support an overweight body. Slight stature, however, is a risk factor for osteoporosis. Because weight control is a concern for the population at risk, the calcium-to-calorie ratio is an important consideration in dietary counseling (Table 26-3). The most favorable dairy products with respect to the calcium-to-calorie

*Food or foods with most favorable calcium-to-calorie ratios in each category. Data provided by the American Dairy Association.

ratio are nonfat milk, part-skim mozzarella cheese, Swiss cheese, and plain, low-fat yogurt. Typical servings of these products have about 300 mg of calcium and 100 to 200 calories. Some adults avoid milk because of intolerance to lactose. These patients often assume that they have a milk allergy, which should be determined according to symptoms. Lactose intolerance usually is manifested by an upset stomach rather than a classic anaphylaxis. Even patients who are intolerant of milk usually can tolerate cultured products such as buttermilk, cheese, and yogurt. Calcium supplements are indicated if a patient is allergic to milk or fails to achieve a calcium-sufficient diet for any other reason. Other foods, particularly green, leafy vegetables (e.g., turnip greens, spinach), contain substantial amounts of calcium, but the calcium is tightly bound and little ionic calcium is absorbed. In effect, to consume adequate calcium in a diet that excludes dairy products is difficult.[45,46] Calcium supplements of many varieties are available in pharmacies and health food stores, and most provide adequate calcium when used as directed. However, consumers should beware of toxic contaminants in some natural supplements, such as bone meal and dolomite, which may contain significant amounts of lead, arsenic, or other heavy metals. Among the least expensive, readily tolerated supplements are calcium carbonate (e.g., Tums, calcium-rich Rolaids). To determine the amount of elemental calcium in a

WWW.HIGHDENT.IR

supplement, consumers must remember to use the molecular weight. For instance, calcium carbonate is only 40% calcium; this means that a 500-mg tablet provides only 200 mg of calcium.[45,46]

Endocrinology

Peptide hormones (e.g., PTH, growth hormone, insulin, calcitonin) bind receptors at the cell surface and may be internalized with the receptor complex. Steroid hormones (e.g., vitamin D, androgens, estrogens) are lipid soluble and pass through the plasma membrane to bind receptors in the nucleus.[45,46] PTH increases serum calcium by direct and indirect vitamin D–mediated effects. Vitamin D (cholecalciferol) originally was thought to be an essential dietary factor. However, vitamin D is not a vitamin at all; it is a hormone. Cholecalciferol is synthesized in skin irradiated by ultraviolet light, hydroxylated in the liver at the No. 25 position, and then hydroxylated in the kidney at the No. 1 position to produce the active metabolite 1,25-DHCC. The last step is feedback controlled; hydroxylation at the No. 1 position is induced by a low serum calcium level, probably through PTH (see Figure 26-40). Clinically a major effect of 1,25-DHCC is induction of active absorption of calcium from the gut. Because of the complexity of vitamin D synthesis and the metabolic pathway, calcium adsorption may be inhibited at many levels; some of these inhibitors are (1) lack of skin exposure to adequate sunlight of the proper wavelength; (2) failure to consume vitamin D through the diet, thereby not compensating for the lack of vitamin D synthesis; (3) a genetic defect in the skin; (4) liver disease; and (5) kidney failure.[45,46]

Sex hormones have profound effects on bone. Androgens (testosterone and other anabolic steroids) build and maintain musculoskeletal mass. The primary hypertrophic effect of androgens is to increase muscle mass. The anabolic effect on bone is a secondary biomechanical response to increase loads generated by the enhanced muscle mass. Estrogen, however, has a direct effect on bone; it conserves skeletal calcium by suppressing the activation frequency of bone remodeling.[53] At menopause, enhanced remodeling activation increases turnover.[54] Because a slight negative calcium balance is associated with each remodeling event, a substantial increase in the turnover rate can result in rapid bone loss, leading to symptomatic osteoporosis. Even young women are susceptible to significant bone loss if the menstrual cycle (menses) stops.[55] Bone loss is a common problem in women who have low body fat and who exercise intensely (e.g., running, gymnastics) and in women who are anorexic.[56] Clearly, estrogen protects the female skeleton from bone loss during the childbearing years. Lack of menses in women of any age is a high-risk factor for the development of osteoporosis later in life.[45,46]

Estrogen replacement therapy is widely recommended for calcium conservation and the prevention of osteoporosis in postmenopausal women.[57,58] A major concern of many patients and of some physicians is the relationship of estrogen therapy to the incidence and progression of breast cancer.[59] It generally is accepted that estrogen replacement therapy increases the risk of breast cancer by about 2% but decreases the risk of osteoporosis, heart disease, colon cancer, and Alzheimer disease by as much as 50%. For many women, estrogen replacement therapy remains a wise health measure.

The antiestrogen tamoxifen is used to treat some forms of breast cancer. Fortunately, in postmenopausal women, tamoxifen has a beneficial effect on bone similar to that of estrogen.[60] Recently raloxifene (Evista) has been shown to reduce the risk of osteoporosis and heart disease without increasing the risk of breast cancer. Some studies have even shown a substantial anticancer protective effect.[61]

SKELETAL COMPROMISE

Skeletal health is related to diet, exercise, lifestyle, and proper functioning of numerous organ systems. To provide optimal support over a broad spectrum of conditions, the skeletal system has evolved complex mechanical, endocrine, and cell-level regulatory mechanisms. A failure of one or more of these homeostatic mechanisms can result in metabolic bone disease. Low skeletal mass and/or poor osteogenic capability may make some patients poor candidates for orthodontic or orthognathic procedures. Skeletally compromised patients who seek unrelated dental treatment provide dentists with unique diagnostic opportunities. Timely medical referral of individuals with high-risk profiles can result in substantial health benefits. If osteopenia is confirmed, corrective medical therapy can be started before the onset of the debilitating symptoms associated with osteoporosis.[45,46]

The concept of structural and metabolic fractions (see Figure 26-39) has considerable clinical significance. The dietary requirement for calcium increases during the growing years. A high dietary calcium intake (1200 mg per day) is essential during the adolescent period (see Table 26-2) to provide structural strength without compromising the metabolic reserve. Pregnancy and lactation before the age of 19 may be precipitating factors for osteopenia later in life. Multiple births during the teenage years are of particular concern. Under these circumstances, young women may fail to deposit sufficient skeletal reserves to withstand the sustained negative calcium balance that follows menopause.[45,46,61]

Although the metabolic fraction of cortical bone can make a substantial contribution, the major source of serum calcium under steady-state conditions is trabecular bone. The primary reason for this is the differential

WWW.HIGHDENT.IR

remodeling rates. Cortical bone turns over about 2% to 10% per year, whereas trabecular bone, which is much more active, remodels at 20% to 30% per year.[62] Because it is more labile, trabecular bone is more susceptible to loss under conditions of negative calcium balance. For this reason, patients with osteoporosis have a tendency to suffer structural failure at sites primarily dependent on trabecular bone: the spine (compression fracture), the wrist (Colles' fracture), and the hip (femoral neck fracture). Degenerative changes in the TMJ have not been related directly to skeletal atrophy. However, some relationship is likely because these problems tend to affect the same high-risk group—postmenopausal women.[45,46,63]

Women depend on estrogen to maintain skeletal mass. Lack of normal menses, even in young women, usually indicates an estrogen deficiency and probable negative calcium balance. Numerous national and international consensus conferences[64,57] have recommended that most postmenopausal Caucasian and Asian women be treated with estrogen to prevent osteoporosis. Surveys indicate that some physicians fail to prescribe estrogen for their postmenopausal patients[65]; however, the most common problem is the failure of many women to comply despite the recommendations of their physicians. For this reason many women in Western society are estrogen deficient. About 20% will develop frank osteoporosis, and as many as 50% will have some signs or symptoms.[46] All health care providers should be concerned particularly about the skeletal status of postmenopausal white and Asian women. However, even low-risk groups, such as men and black women, have an incidence of osteoporosis that approaches 5%. Osteopenia and osteoporosis therefore are significant health risks for almost everyone. Bone metabolic evaluation is an important diagnostic concern for all patients being considered for dental implants or any other bone-manipulative therapy.[16,45,66]

METABOLIC BONE DISEASE

Osteoporosis is a generic term for low bone mass (osteopenia). The most important risk factor for the development of osteoporosis is age: after the third decade, osteopenia is related directly to longevity. Other high-risk factors are (1) a history of long-term glucocorticoid treatment, (2) slight stature, (3) smoking, (4) menopause or dysmenorrhea, (5) lack of or little physical activity, (6) low-calcium diet, (7) excessive consumption of alcohol, (8) vitamin D deficiency, (9) kidney failure, (10) liver disease (cirrhosis), and (11) a history of fractures. These risk factors are effective in identifying 78% of those with the potential for osteopenia.[61,67] This is a particularly good screening method for skeletally asymptomatic dental patients. However, one must realize that more than 20% of individuals who eventually develop osteoporosis have a negative history for known risk factors. Any clinical signs or symptoms of low bone mass (e.g., low radiographic density of the jaws, thin cortices, excessive bone resorption) are grounds for referral. A thorough medical workup, including bone mineral density measurement, usually is necessary to establish the diagnosis of osteopenia. The term *osteoporosis* usually is reserved for patients with evidence of fracture or other osteoporotic symptoms. The treatment of metabolic bone diseases such as osteoporosis depends on the causative factors. Medical management of these often complex disorders is best handled by physicians specifically trained in bone metabolism.[45,46]

Because the loss of teeth is an important risk factor for osteoporosis, dental patients, especially adult women, are at high risk for developing osteoporosis. A sampling of all adult female dental patients at a midwestern dental school showed that about 65% were at high risk for developing osteoporosis (estrogen deficient or had at least two other risk factors).[68]

See Box 26-1 for a relevant case study.

BIOMECHANICS

Gravitational loads have a substantial influence on normal skeletal physiology. Osteoblast differentiation that leads to new bone formation is stimulated by mechanical loading[12] but inhibited by weightlessness.[28,69] Space flight studies have established that gravity helps maintain skeletal mass.[70,71] A substantial part of the physiologic loading of the mandible is related to antigravity posturing. In erect posture, gravity tends to open the mouth; muscular force is used to hold the mouth closed. Apparently, growth of the rat mandibular condyle may be inhibited during space flight because of weightlessness and the decrease in functional loading.[72] Gravity may prove to be an important factor in the secondary growth mechanism of the mandible.

Mechanical loading is essential to skeletal health. Control of most bone modeling (see Table 26-1) and some remodeling processes (see Box 6-1) are related to strain history, which usually is defined in microstrain (με).[73] Repetitive loading generates a specific response, which is determined by the peak strain.[74-78] In an attempt to simplify the often conflicting data, Frost[79] proposed the mechanostat theory. Reviewing the theoretical basis of this theory, Martin and Burr[24] proposed that (1) subthreshold loading of less than 200 με results in disuse atrophy, manifested as a decrease in modeling and an increase in remodeling; (2) physiologic loading of about 200 to 2500 με is associated with normal, steady-state activities; (3) loads exceeding the minimal effective strain (about 2500 με) result in a hypertrophic increase in modeling and a concomitant decrease in remodeling; and (4) after peak strains exceed about 4000 με, the

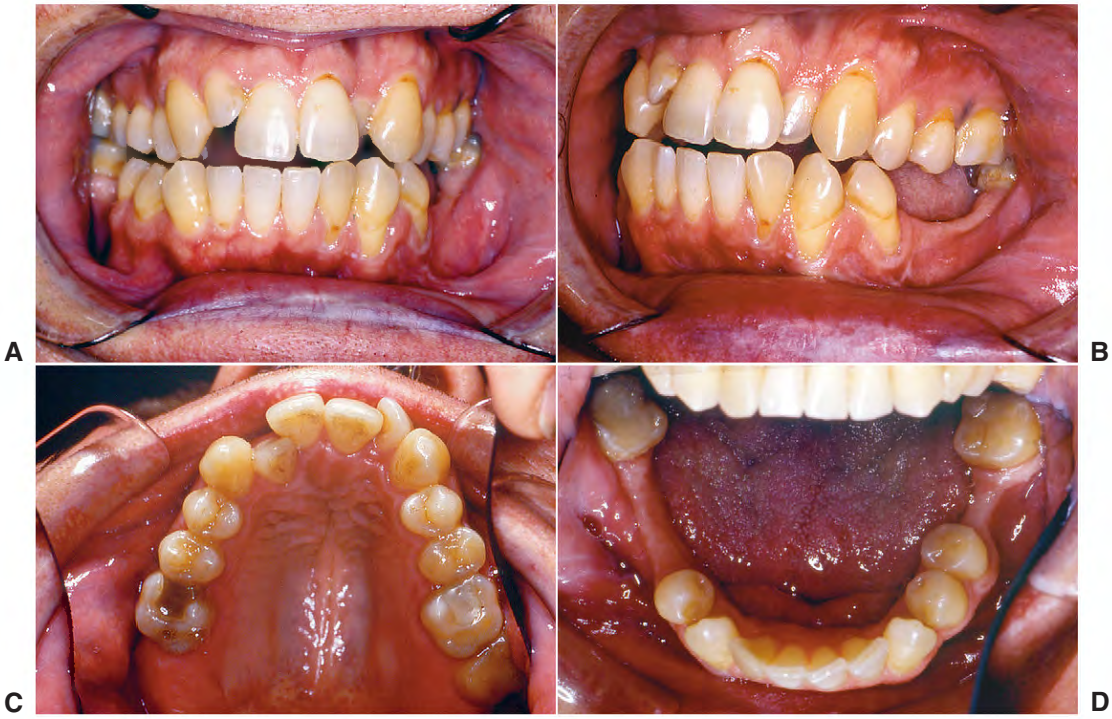
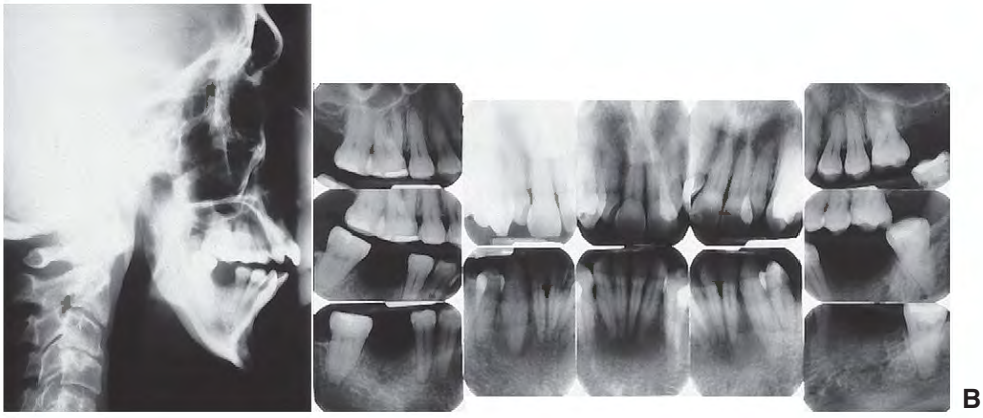
Box 26-2 Temporomandibular Discrepencies: A Case Study

A 52-year-old man sought treatment for a long history of facial pain, occlusal dysfunction, and an internal derangement of the right mandibular condyle (see figures). Intracapsular surgery was performed on the right temporomandibular (TMJ) accelerated, the pain increased, and a progressive anterior open bite malocclusion developed. Masticatory function deteriorated, and an internal derangement of the left TMJ was noted. Bilateral intracapsular surgery was performed to restore "normal jaw function." After the second surgical procedure, the patient suffered for 10 years with chronic pain and progressive bilateral degeneration of both TMJs. Orthodontic and orthotic (splint) therapy failed to relieve the pain and functional debilitation. The patient declined further treatment and is being managed with pain medication. From a physiologic perspective, intracapsular surgery usually is contraindicated because it inhibits the natural ability of the joint to adapt to changing biomechanical demands. The TMJ is remarkably regenerative and adaptive joint if its physiologic limits are respected.



Frontal view **(A),** lateral view **(B),** maxillary occlusal view **(C),** and mandibular occlusal view **(D)** of the dentition of a 52-year-old man with a partly edentulous open bite malocclusion. Note the atrophic extraction sites and gingival rescession. *(From Roberts WE: Adjunctive orthodontic therapy in adults over 50 years of age: clinical management of compensated, partially edentulous malocclusion,* J Indiana Dent Assoc *76:33-41, 1997.)*



A, Cephalometric radiograph of the patient shown above, shows a skeletal open bite with a steep mandibular plane and a relatively short ramus. The thin symphyseal cortex is consistent with a systemic osteopenia. **B,** A full-mouth radiographic survey shows a generalized lack of cortical bone at the alveolar crest and a pattern of indistinct lamina dura and trabeculae. This generalized ground-glass approach of the alveolar bone is consistent with high-turnover metabolic bone disease. *(From Roberts WE: Adjunctive orthodontic therapy in adults over 50 years of age: clinical management of compensated, partially edentulous malocclusion,* J Indiana Dent Assoc *76:33-41, 1997.)*

WWW.HIGHDENT.IR

structural integrity of bone is threatened, resulting in pathologic overload. Figure 26-43 is a representation of the mechanostat. Many of the concepts and microstrain levels are based on experimental data.[24] The strain range for each given response probably varies between species and may be site specific in the same individual.[16,24,74,76,78] However, the mechanostat provides a useful clinical reference for the hierarchy of biomechanical responses to applied loads.

Normal function helps build and maintain bone mass. Suboptimally loaded bones atrophy as a result of increased remodeling frequency and inhibition of osteoblast formation.[80] Under these conditions, trabecular connections are lost and cortices are thinned from the endosteal surface. Eventually the skeleton is weakened until it cannot sustain normal function. Assuming that the negative calcium balance is corrected and adequate bone structure remains, patients with a history of osteoporosis or other metabolic bone disease are viable candidates for reconstructive dental procedures. The crucial factor is the residual bone mass in the area of interest after the disease process has been arrested (Figure 26-44).

When flexure (strain) exceeds the normal physiologic range, bones compensate by adding new mineralized tissue at the periosteal surface. Adding bone is an essential compensating mechanism because of the inverse relationship between load (strain magnitude) and the fatigue resistance of bone.[81] When loads are less than 2000 με, lamellar bone can withstand millions of loading cycles, more than a lifetime of normal function. However, increasing the cyclic load to 5000 με, about 20% of the ultimate strength of cortical bone, can produce fatigue failure in 1000 cycles, which is achieved easily in only a few weeks of normal activity. Repetitive overload at less than one fifth of the ultimate strength of lamellar bone (25,000 με, or 2.5% deformation) can lead to skeletal failure, stress fractures, and shin splints.

From a dental perspective, occlusal prematurities or parafunction may lead to compromise of periodontal bone support. Localized fatigue failure may be a factor in periodontal clefting, alveolar recession, tooth oblation (cervical ditching), or TMJ arthrosis. Guarding against occlusal prematurities and excessive tooth mobility, while achieving an optimal distribution of occlusal loads, are important objectives for orthodontic treatment. The human masticatory apparatus can achieve a biting strength of more than 2200 N, or more than 500 lb of force.[82,83] Because of the high magnitude and frequency of oral loads, functional prematurities during reconstructive treatment could contribute to isolated incidences of alveolar clefting (Figure 26-45, *A*) and root resorption (see Figure 26-45, *B*). Excessive tooth mobility should be monitored carefully. Prevention of

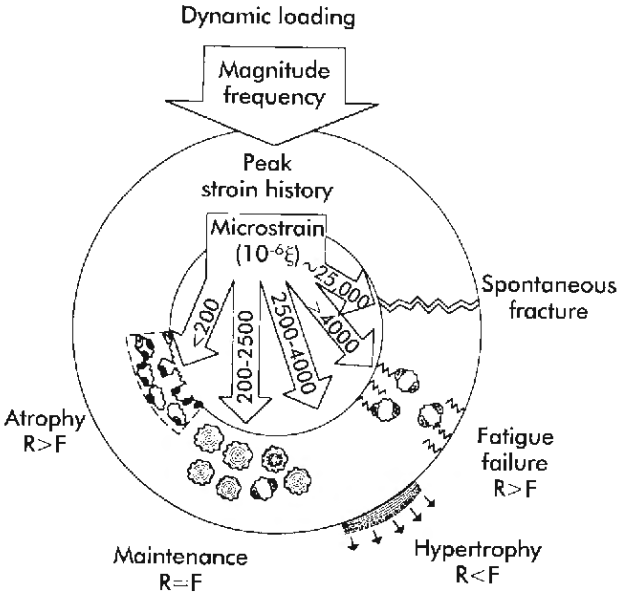


Figure 26-43 The mechanostat concept of Frost as defined by Martin and Burr. Bone formation *(F)* and resorption *(R)* are the modeling phenomena that change the shape and/or form of a bone. The peak strain history determines whether atrophy, maintenance, hypertrophy, or fatigue failure occurs. Note that the normal physiologic range of loading (maintenance $R = F$) is only at less than 10% of maximal bone strength (spontaneous fracture). Fatigue damage can accumulate rapidly at greater than 4000 με.

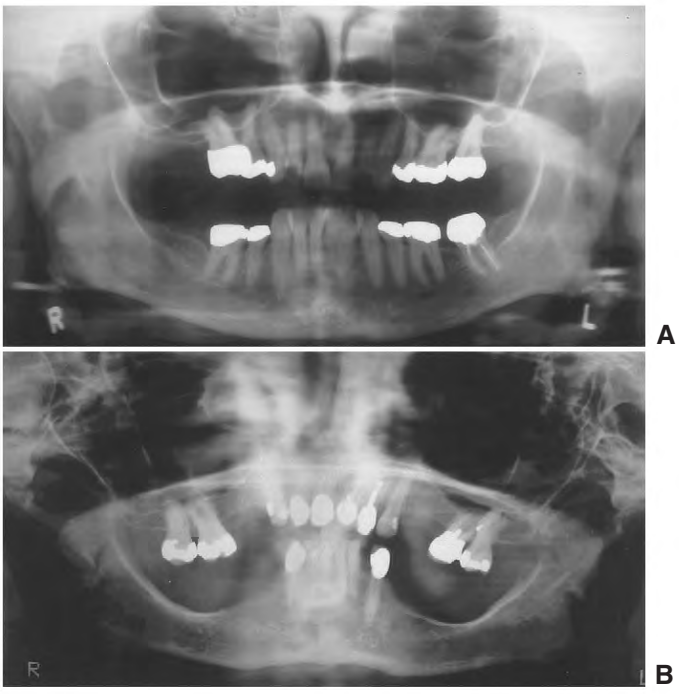

Figure 26-44 Two postmenopausal females with systemic osteopenia present widely varying patterns of lower posterior bone loss. **A,** Alveolar bone in the buccal segments is well preserved by functional loading of natural teeth. **B,** Severe resorption of the alveolar process and basilar mandible has occurred in the absence of adequate functional loading. *(From Roberts WE: Fundamental principles of bone physiology, metabolism and loading. WWW.HIGHDENT.IR

occlusal prematurities is a particular concern in treating periodontally compromised teeth.

SUTURES

The facial sutures are important mediators of skeletal adaptation to craniofacial growth and biomechanical therapy. Expansion of the midpalatal suture often is a key objective in dentofacial orthopedic treatment. Although the potential for sutural expansion has been appreciated since the middle of the nineteenth century, Andrew Haas[84] introduced the modern clinical concepts of rapid palatal expansion in the last half of the twentieth century. Despite the long history of this important clinical procedure, little was known of the cell kinetics of osteogenesis and the bone remodeling response associated with it. Sutures and the PDL were widely assumed to have similar mechanisms of osseous adaptation.

Chang et al.[85,86] compared the osteogenic reaction in the expanded midpalatal suture with orthodontically induced osteogenesis in the PDL of adjacent incisors (Figures 26-46 to 26-49). The widened PDL resulted in direct osteogenic induction of new bone, whereas the adjacent expanded suture experienced hemorrhage, necrosis, and a wound healing response. Vascular invasion of the blood clot in the expanded suture was a prerequisite for new bone formation. Chang et al.[85] also defined the angiogenic capillary budding process associated with the propagation of perivascular osteogenic cells (Figure 26-50). After its vascularity had been reestablished, the expanded midpalatal suture and adjacent widened PDL produced new osteoblasts by the same mechanism. Pericytes, the osteogenic cells that are perivascular to the venules (Figure 26-51), are the cells

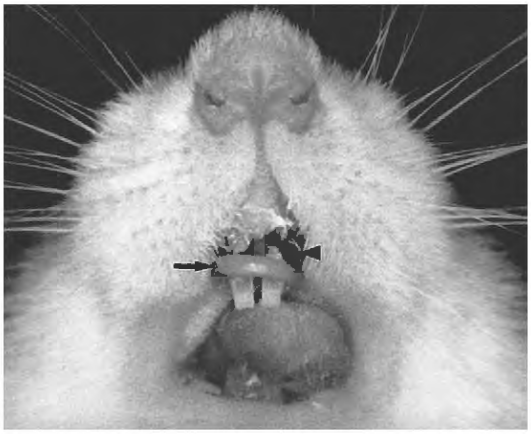

Figure 26-46 An expansion appliance is placed on the maxillary incisors of a rat. A 1-mm-diameter elastomeric ring *(arrowhead)* was fitted into the left incisor; a 2-mm-diameter elastomeric ring *(arrow)* encircled both incisors, 2 mm from cutting edges. The 2-mm ring constricts the incisors while the interproximal elastic elicits a parallel separation of the interpremaxillary suture. *(From Chang HN, Garetto LP, Potter RH et al: Angiogenesis and osteogenesis in an orthopedically expanded suture,* Am J Orthod Dentofacial Orthop *3:382-390, 1997.)*

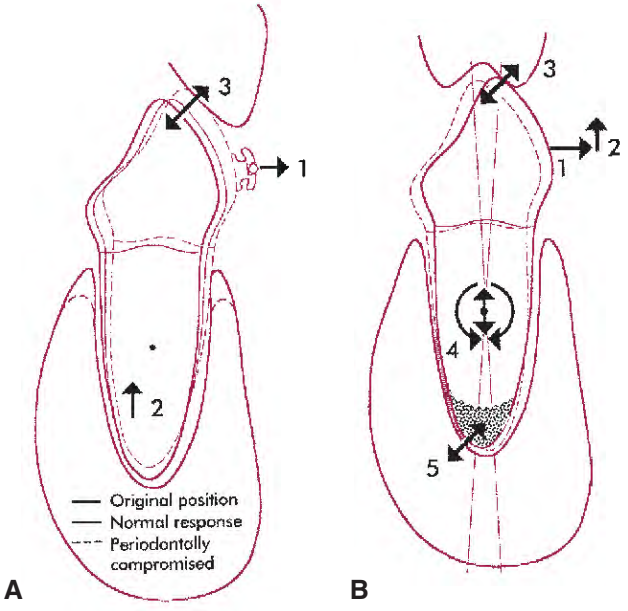

Figure 26-45 **A,** A moderate load in the buccal direction *(1)* results in tipping displacement of the crown. In the absence of vertical constraint, a normal healthy tooth would be expected to extrude slightly because of the inclined plane effect of the root engaging the tapered alveolus *(2)*. As a result of diminished bone support and destruction of restraining collagen fibers at the alveolar crest, a periodontally compromised tooth may tip and extrude considerably more. Depending on the occlusion, this displacement may cause an occlusal prematurity *(3)*. **B,** Orthodontic tipping *(1)* with an extrusive component *(2)* may produce an occlusal prematurity *(3)* and mobility *(4)*. An individual tooth in chronic occlusal trauma is expected to fatigue the root apex continuously. This combination of physical failure in a catabolic environment may lead to progressive root resorption *(5)*.

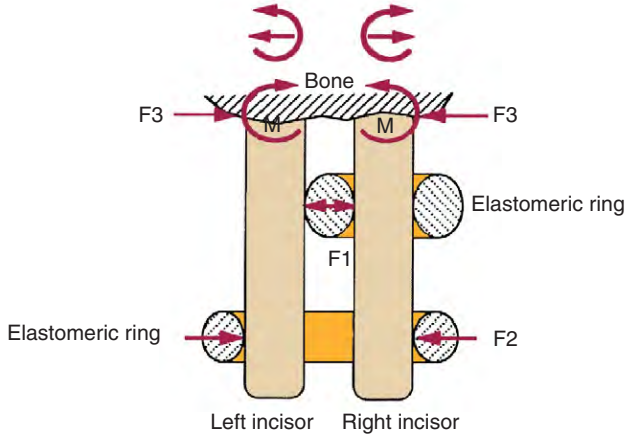

Figure 26-47 Forces *(F)* and moments *(M)* on a tooth. F1 and F2 were produced by inner and outer elastomeric rings, respectively. This illustration of the device demonstrates the formation of a couple thatresulted in parallel separation of the interpremaxillary suture. As measured in a pilot study using a Dontrix tension gauge, the outer elastomeric ring exerted about 200 g of initial separation force (F2), of which 90 g remained at the end of day 3. This force level (90 g) is suitable for premaxillary expansion in rats. *(From Chang HN, Garetto LP, Potter RH et al: Angiogenesis and osteogenesis in an orthopedically expanded suture,* Am J Orthod Dentofacial Orthop *3:382-390, 1997.)*

of origin for preosteoblasts.[85,86] The role of perivascular cells in the origin of PDL osteoblasts first was reported in 1987.[87] Over the past decade a number of investigators have reported the same mechanism for the production of osteoblasts throughout the body. Doherty et al.[88] recently reviewed the literature and provided evidence that vascular pericytes express osteogenic potential in vivo and in vitro. What is now clear is that perivascular osteogenesis is not a mechanism unique to the PDL and sutures, but rather, is the source of osteoblasts all over the body under a variety of osteogenic conditions. Parr et al.[89] used an innovative endosseous implant mechanism (see Figure 26-17) to expand the nasal bones in young adult rabbits with forces from 1 to 3 N. Injection of multiple fluorochrome bone labels documented the bone modeling and remodeling reactions that occurred not only adjacent to the suture but also throughout the nasal bones. Expansion of a suture results in a regional adaptation of adjacent bones similar to the postoperative regional acceleratory phenomenon that is characteristic of bone wound healing.[24] Parr et al.[89] described the bone formation rate and mineral apposition rate for new bone formed in the suture (Figures 26-52 to 26-54). Sutural expansion, relative to load decay, is shown for repeatedly reactivated 1- to 3-N loads (Figure 26-55). Osseointegrated implants were excellent abutments for sutural expansion mediated by loads as large as 3 N.

Overall, expanded sutures are less efficient at initiating osteogenesis because of postactivation necrosis. However, after a wound healing response has occurred to reestablish sutural vitality, the vascularly mediated origin of osteoblasts is the same as for the PDL and other skeletal sites. Expansion of a suture results in a regional

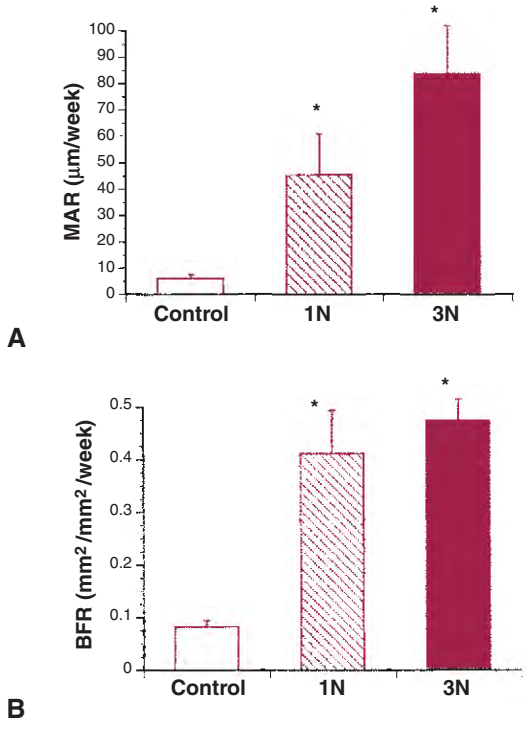

Figure 26-54 **A,** Mineral apposition rate (MAR). **B,** The bone formation rate (BFR) was calculated at the suture during the final 6 weeks of loading for three loading groups (mean ± SEM; an asterisk [*] indicates significant difference from the control at $p<0.05$). *(From Parr JA, Garetto LP, Wohlford ME et al: Sutural expansion using rigidly integrated endosseous implants: an experimental study in rabbits,* Angle Orthod *67:283-290, 1987.)*

acceleration of bone adaptive activity, which allows for extensive adaptation of the affected bones to new biomechanical conditions. These results indicate that sutural expansion within physiologic limits is a clinically viable means of repositioning the bones of the craniofacial complex to improve esthetics and function. With respect to fundamental bone physiology, sutural expansion is similar to surgically mediated distraction osteogenesis.

Using sequential labels of ^{3}H-thymidine and bromodeoxyuridine in rabbits, Sim[90] demonstrated that the osteoblast histogenesis sequence for evolving secondary osteons was a perivascular process (Figure 26-56) similar to that previously demonstrated for the PDL[91] and the intermaxillary suture.[85,86] The Sim data confirmed the hypothesis that the perivascular connective tissue cells proliferate and migrate along the surface of the invading capillaries or venules. Figure 26-57 is a three-dimensional perspective of a remodeling foci (cutting/filling cone) in cortical bone, which demonstrates that perivascular cells,

WWW.HIGHDENT.IR

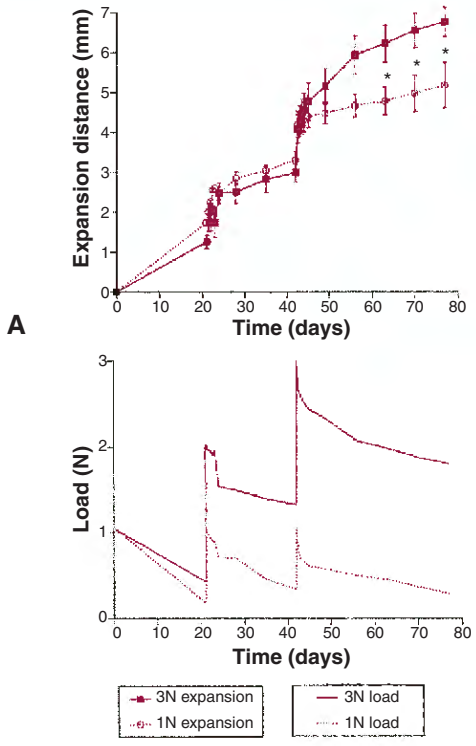

Figure 26-55 **A,** Sutural expansion measured as an increase in the distance between implants. The slope of this curve is the rate of sutural expansion. Three N is significantly greater than 1 N at these time points $p<0.05$. **B,** Load on the suture as a function of time. Load was calculated using the formula $F = kx$, where k is the spring constant and x is the distance between implants. As sutural expansion occurs, force decays. Loads were placed at day 0 and adjusted at days 21 and 42. *(From Parr JA, Garetto LP, Wohlford ME et al: Sutural expansion using rigidly integrated endosseous implants: an experimental study in rabbits,* Angle Orthod *67:283-290, 1987.)*

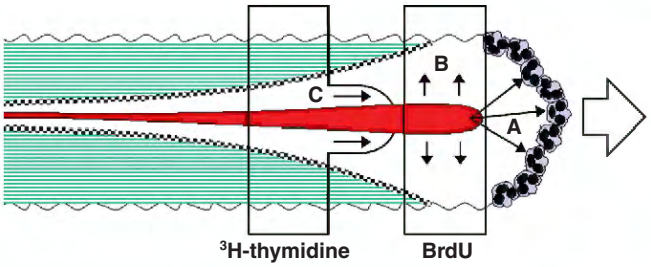

Figure 26-56 A cutting/filling cone in rabbit cortical bone shows the intravascular origin of osteoclasts *(A)*. The perivascular proliferation and migration away for the perivascular surface *(B)* is demonstrated by bromodeoxyuridine (BrdU) labeling and nuclear volume morphometry. A sequence of ^{3}H-thymidine labels from 2 to 72 hours before sacrifice and nuclear morphometric analysis revealed migration of proliferating perivascular cells in the direction of vascular invasion *(C)*. These data demonstrate the perivascular origin of osteoblasts in evolving secondary osteons. *(From Sim Y:* Cell kinetics of osteoblast histogenesis in evolving rabbit secondary haversian systems using a double labeling technique with ^{3}H-thymidine, and bromodeoxyuridine *[doctoral thesis], Indianapolis, 1995, Indiana University School of Dentistry.)*

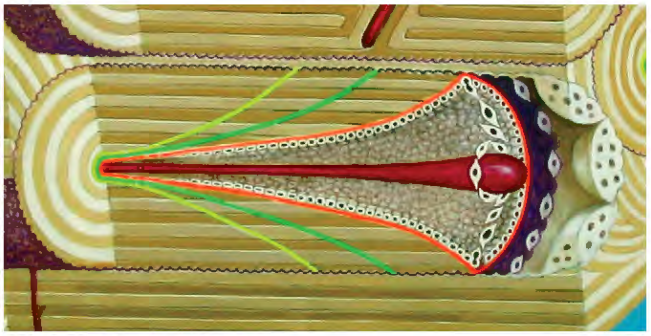

Figure 26-57 An evolving secondary osteon, moving to the right, shows a head of multinucleated osteoclasts *(right)*, followed by a layer of mononuclear cells secreting cement substance *(blue)* to cover the scalloped resorption arrest line. The perivascular osteogenic cells proliferate and differentiate to osteoblasts, which form the new secondary osteon. Three sequential colored bone labels (*yellow, green and orange*) allow the calculation of the velocity of the cutting/filling cone through cortical bone.

near the head of the proliferating blood vessel, are the source of osteoblasts for the filling cone. Confirmation of a perivascular origin of osteoblasts in PDL, sutures, and cortical bone remodeling foci strongly suggests that all osteoblasts, at least in the peripheral skeleton, are derived from perivascular precursors. These data suggest that less differentiated osteogenic cells grow along the surface of bone-related blood vessels (capillaries and venules) as they invade blood clots or other connective tissue spaces in preparation for osteogenesis. From a clinical perspective, the perivascular origin of osteoblasts confirms an important surgical principle: preservation of the blood supply is essential for optimal healing of bone.

IMPLANT-ANCHORED ORTHODONTICS

A major problem in orthodontics and facial orthopedics is anchorage control.[30] Undesirable movement of the anchorage units is a common problem that limits the therapeutic range of biomechanics.[92] An important application of the basic principles of bone physiology is the use of rigid endosseous implants for orthodontic and orthopedic anchorage. Animal studies[25] and clinical trials of custom orthodontic devices[34] have established that rigidly integrated implants do not move in response to conventional orthodontic and orthopedic forces. These devices are opening new horizons in the management of asymmetry, mutilated dentition, severe malocclusion, and craniofacial deformity.[93]

A preclinical study in dogs tested the anchorage potential of two prosthetic-type titanium implants: (1) a prototype of an endosseous device with a cervical post, asymmetric threads, and an acid-etched surface; and (2) a commercially available implant with symmetric threads (Figure 26-58). Based on label incidence (Figure 26-59, *A*) and the relative number of new osteons in microradiographs (see Figure 26-59, *B*), the rate of bone remodeling near the implant was higher

WWW.HIGHDENT.IR

A B

Figure 26-58 **A,** Two titanium implants of different design were placed in the partly edentulous mandible of young adult dogs. **B,** After 2 months of unloaded healing, a 3-N compressive load was applied between the implants for 4 months. Increased periosteal apposition (*) was noted between the implants of some dogs. None of the rigidly integrated fixtures was loosened by the continuous load superimposed on function. *(From Roberts WE, Helm FR, Marshall KJ et al: Rigid endosseous implants for orthodontic and orthopedic anchorage,* Angle Orthod *59:247-256, 1989.)*

compared with the basilar mandible only a few millimeters away.[94] Compared with titanium implants with a smooth surface, the degree of remodeling at the interface is greater for threaded implants placed in a tapped bone preparation.[30] This may be related to the increased resistance of threaded implants to torsional loads over time.[95]

Direct bone apposition at the endosseous interface results in rigid fixation (osseointegration).[96] From an anchorage perspective, a rigid endosseous implant is the functional equivalent of an ankylosed tooth. Complete bony encapsulation is not necessary for an implant to serve as a rigid anchorage unit. The crucial feature is indefinite maintenance of rigidity despite continuous orthodontic loads. Over time, orthodontically loaded implants achieve a greater fraction of direct osseous interface.[34,95] From an orthodontic and orthopedic perspective, titanium implants can resist substantial continuous loads (1 to 3 N superimposed on function) indefinitely. Histologic analysis with multiple fluorochrome labels and microradiography confirm that rigidly integrated implants do not move relative to adjacent bone (see Figure 26-59).[25] By definition, maintaining a fixed relationship with supporting bone is true osseous anchorage. Endosseous (osseointegrated) implants are well suited to many demanding orthodontic applications.[30,34]

Routine use of rigid implants for prosthetic or orthodontic applications requires that fixtures be placed between or near the roots of teeth. Inadvertent impingement on the PDL and the root of an adjacent tooth still may provide an acceptable result (Figure 26-60). Cementum repair occurs where the root is cut, the PDL reorganizes, and the implant surface is integrated rigidly with osseous tissue. No evidence exists of ankylosis of the tooth.[25]

Retromolar Implant Anchorage

The isolated loss of a lower first molar with a retained third molar is a common problem. Rather than extract the third molar and replace the first molar with a three-unit bridge, mesial translation of second and third molars to close the edentulous spaces often is preferable (Figure 26-61). The first case with long-term follow-up has been published.[34] Because of the increasing incidence of progressive bone loss and fatigue fracture associated with single-tooth implants in lower first and second molar areas, the orthodontic option for mesially translating the molars to close the space is increasing in popularity.

External Abutment Mechanism

An anchorage wire that is secured to a retromolar implant can be used to intrude and protract mandibular second and third molars to close an atrophic first molar extraction site (see Figure 26-61, *B*).[16] The tipping and extrusion of residual lower molars limits potential orthodontic repositioning. Rigid retromolar implants offer a unique capability for intrusion and alignment. Figure 26-62 demonstrates the mechanics for achieving three-dimensional control to intrude the third molar to the plane of occlusion and translate both teeth mesially. Cephalometric tracings (Figure 26-63) document the more than 10 mm of mesial translation and its stability. Panoramic radiographs show the initial alignment (Figure 26-64, *A*) and the final space closure (see Figure 26-64, *B*). Clinical details are published.[34]

Histologic analysis of implants recovered after completion of treatment has revealed important information about the continuous remodeling process that maintains the rigid integration and anchorage value of the endosseous device. Two intravital bone labels, administered within 2 weeks of implant recovery, have

WWW.HIGHDENT.IR

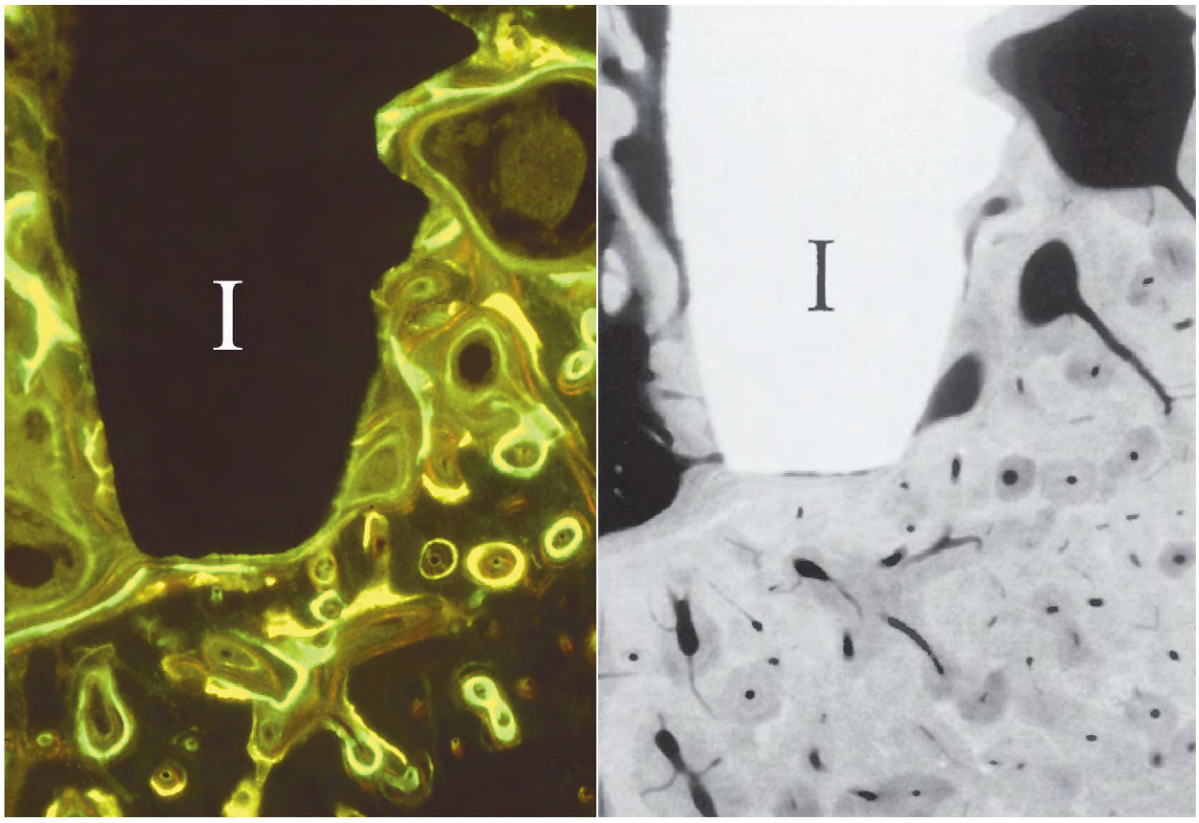

Figure 26-59 **A,** Multiple fluorochrome labels in bone adjacent to an implant *(I)* show a high rate of remodeling at the bone-implant surface. **B,** Microradiographic image of the same section shows direct bone contact on the surface of the implant. *(From Roberts WE, Garotto LP, Katona TR: Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In Carlson DS, Goldstein SA, editors:* Bone biodynamics in orthodontic and orthopedic treatment, *Ann Arbor, Mich, 1992, University of Michigan Press.)*

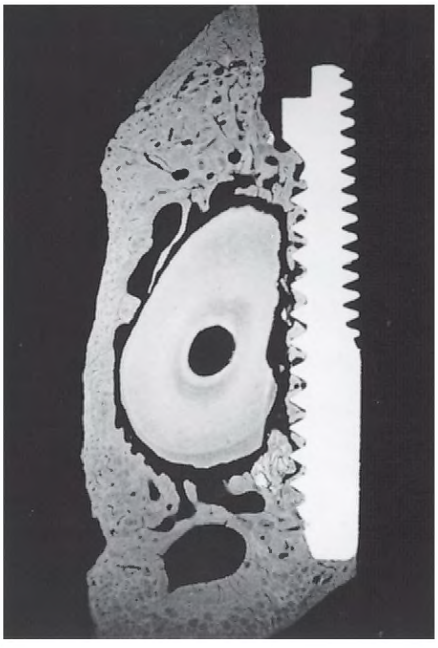

Figure 26-60 An endosseous implant inadvertently impinged on the root of a canine. The implant successfully integrated with bone and served as a rigid anchor for orthopedic loading. *(From Roberts WE et al: Rigid endosseous implants for orthodontic and orthopedic anchorage,* Angle Orthod *59:247, 1989.)*

shown a continuing high rate of bone remodeling (more than 500% per year) within 1 mm of the implant surface (see Figure 26-64, *C, D*). This biological mechanism apparently is the means by which rigid osseous integration is maintained indefinitely.[8,34] If no fracture is present at the implant interface or in its supporting bone, rigid implants are not moved by orthodontic loads.[6,25,34] Well-integrated endosseous implants remain rigid despite continued remodeling of the bone supporting them because only a portion of the osseous resorbed interface is turned over at any given time.[34] Figure 26-65 shows the mechanics for mesial translation of molars to close an edentulous space when a premolar is congenitally missing. Rigid endosseous implants show great promise for considerably extending the therapeutic possibilities of orthodontics and dento-facial orthopedics.

Internal Abutment Mechanism

The 0.019 × 0.025-inch titanium-molybdenum alloy anchorage wire (Ormco Corp., Orange, Calif.) is secured to the endosseous implant when the implant is placed (Figure 26-66). A 7 to 10 × 3.75-mm Brånemark implant (Nobel Biocare, Gothenburg, Sweden) is placed in the

WWW.HIGHDENT.IR

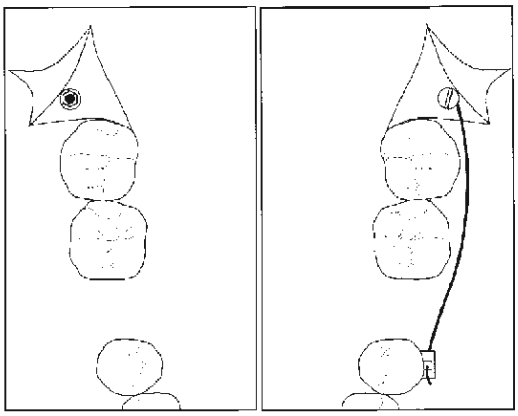

Figure 26-66 The drawing on the left shows the soft tissue flap design for placing a retromolar anchorage implant distal to a mandibular right third molar. The drawing on the right illustrates the attachment of the 0.019 × 0.025-inch titanium-molybdenum alloy wire to the implant with a standard cover screw. Note that the free end of the passive anchorage wire is inserted into the vertical slot of a bracket bonded to the buccal surface of a mandibular left second premolar. *(From Epker BN, Stella JP, Fish LC:* Dentofacial deformities: integrated orthodontic and surgical correction*, ed 2, vol 4, St Louis, 1999, Mosby.)*

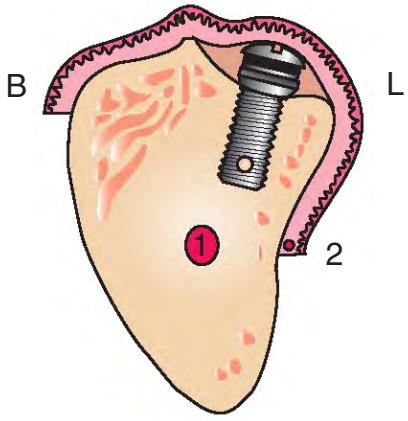

Figure 26-67 A cross section of the mandible distal to the third molar shows that the retromolar implant is inclined buccally *(B)*. Using the shelf of bone on the lingual *(L)*, the 7- to 10-mm implant is oriented toward the inferior alveolar nerve *(1)* and away from the lingual nerve *(2)*. *(Redrawn from Epker BN, Stella JP, Fish LC:* Dentofacial deformities: integrated orthodontic and surgical correction*, ed 2, vol 4, St Louis, 1999, Mosby.)*

retromolar area 3 to 5 mm buccal and distal to the terminal molar. The end of the anchorage wire is bent into a circle and firmly attached to the implant with a standard healing cap (Figures 26-67 and 26-68). This "internal abutment" approach offers a number of advantages over the original external abutment method as follows:

- Minimal surgery: no postoperative uncovering is required.
- Less expense: only one surgical procedure is needed, and no transmucosal abutment is required.
- Better hygiene: wire exiting in the depth of the buccal fold requires little or no periodontalmaintenance.
- Immediate loading: no healing period is necessary.
- More versatile intrusive force: control of the intrusive load on the mandibular molars is easier.

Nineteen years of experience with the internal abutment mechanism (Figure 26-69) has established its utility as an implant anchorage mechanism for managing edentulous spaces in the mandibular buccal segments.[97-100]

Indirect anchorage with a retromolar implant is proving to be useful for closing missing second premolar spaces in growing children. However, an increased tendency for soft tissue irritation exists if the anchorage wire is positioned in the depth of the mucobuccal fold (Figure 26-70, *A*). When the wire is repositioned to just under the brackets of the molars (see Figure 26-70, *B*), soft tissue irritation ceased to be a problem and the second molar space was closed in about 10 months.

Figure 26-68 A schematic drawing of the implant anchorage mechanism shows an internal abutment (i.e., the titanium-molybdenum alloy anchorage wire) attached to the endosseous base with the cover screw (healing cap). The anchorage wire passes through the mucosa in the depth of the buccal fold on the buccal aspect of the terminal molar. Extrusion of the molars during axial alignment and space closure is controlled by the intrusive force *(arrow)* generated by ligating the molar bracket to the anchorage wire with a steel ligature. Sagittal anchorage for mesial movement of the molars is achieved by inserting the passive anchorage wire into the vertical tube of a bracket anterior to the extraction site (*). To achieve unidirectional space closure, the "keyhole" vertical loop is activated by pulling the arch wire at the distal of the terminal molar and bending it down. *(Redrawn from Epker BN, Stella JP, Fish LC:* Dentofacial deformities: integrated orthodontic and surgical correction*, ed 2, vol 4, St Louis, 1999, Mosby.)*

Mini-Implants for Orthodontic Anchorage

Kanomi[101] introduced a series of miniscrews as miniature implants for orthodontic anchorage. Although some of the nonintegrated titanium screws served as adequate anchorage units, some loosened and failed during treatment. A new series of osseointegrated mini-implants was developed and tested in animals.[43] Deguchi et al.[102] found that 97% of 96 implants placed in eight dogs successfully integrated and 100% of the implants that achieved osseointegration were successful

WWW.HIGHDENT.IR

Figure 26-69 **A,** A mock-up demonstrates retromolar implant anchorage. Orthodontic mechanics are designed to align mandibular second and third molars and close the edentulous spaces by translating the molars mesially. The left retromolar implant shows the relationship of the fixture to supporting bone (surgical view). The right implant is covered with wax to simulate the closure of soft tissue over the implant with the titanium-molybdenum alloy anchorage wire attached. **B,** Mechanics are shown for mesial root movement of the second molar into the first molar extraction site. Note that the mesial arm on the root spring is immediately adjacent to the first premolar bracket to prevent the second molar from moving distally as it is positioned upright. To prevent space from opening mesial to the first premolar, a steel ligature ("rope tie") connects the first premolar to the canine. A steel ligature connecting the bracket of the second molar to the titanium-molybdenum alloy anchorage wire controls molar extrusion. **C,** Similar mechanics as shown in **B** are used for simultaneous alignment of both molars. A rectangular arch wire segment connects the two molars. Extrusion is controlled by tying the second molar to the anchorage wire with a steel ligature.

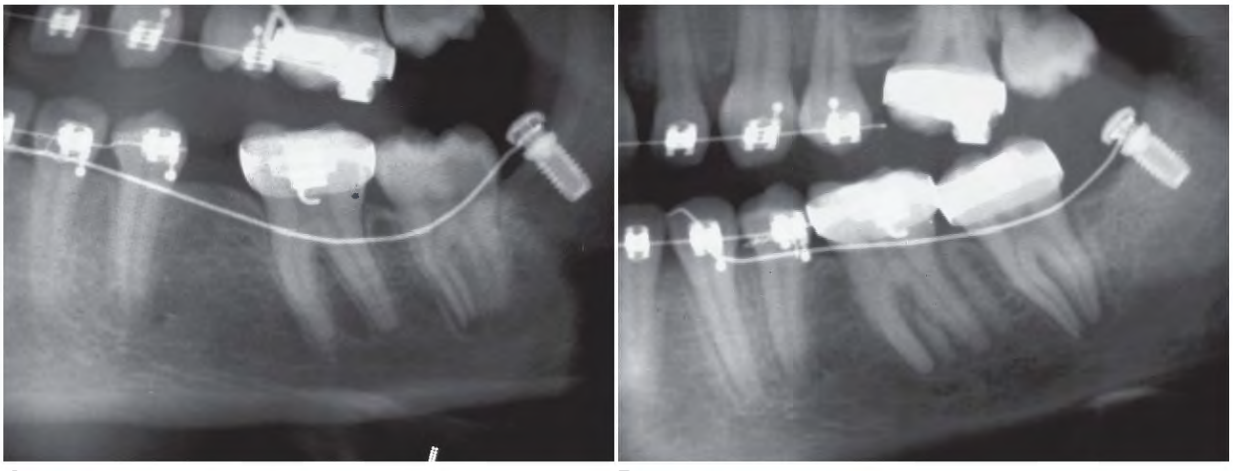

Figure 26-70 **A,** A postoperative panoramic radiograph reveals a retromolar implant to be used for indirect anchorage to close the space caused by a missing second premolar in an 11-year-old girl. Note that the anchorage wire is positioned too far apically. **B,** A panoramic radiograph shows the rapid space closure associated with mesial movement of the molars. Note the anchorage wire has been repositioned just under the molar brackets to lessen soft tissue irritation.

WWW.HIGHDENT.IR

as anchorage units. Clinical use of these simple devices have produced some impressive results. Figure 26-71 documents the treatment of a 15-year-old girl with a gummy smile and bimaxillary protrusion. Four first premolars were extracted and the maxillary anterior segment was intruded with mini-implant anchorage (see Figure 26-71, *A*, *B*). Comparison of frontal smile photographs pretreatment (see Figure 26-71, *C*) and posttreatment (see Figure 26-71, *D*) demonstrate the effective anchorage of the mini-implants. Figure 26-71, *E* is a cephalometric superimposition that demonstrates intrusion of the maxillary anterior segment and a horizontal vector of mandibular growth. Clearly, miniscrews are effective osseous anchorage for some types of malocclusion.

SUMMARY

Bone physiologic, metabolic, and cell kinetic concepts have important clinical applications in all phases of stomatognathic reconstruction: implant surgery, orthodontics, prosthodontics, and long-term functional loading. The application of fundamental concepts is limited only by the knowledge and imagination of the clinician. Modern clinical practice is characterized by a continual evolution of methods based on fundamental and applied research.

Chapter 27

Dental Implant Surfaces: A Review

Adriano Piattelli, Carl E. Misch, Ana Emília Farias Pontes,
Giovanna Iezzi, Antonio Scarano, Marco Degidi

The implant design and surface condition influences the dynamics of osteointegration. The following four distinct phases occur in the development of the bone-implant interface:

1. Surgical integration
2. Healing dynamics
3. Early loading period
4. Mature loading period

The overall implant design and the surface condition affect these four processes, often as independent features (Table 27-1). The surgical process of implant dentistry requires initial fixation and lack of relative movement during the initial phases of the development of the implant-bone interface. The implant design is of primary importance to accomplish this initial step; however, the surface condition of the implant may also be a contributing factor. For example, rougher surfaces will aid the implant to have more friction and fixation during insertion of the implant. When the overall design of the implant is a cylinder and/or the bone quality is poor, the surface roughness of the implant will improve the surgical fixation of the implant.

The initial healing period of an implant (which is not immediately loaded) is the phase of the osteointegration process that is primarily affected by the surface condition of the implant. As a general rule, roughened surfaces increase the bone-implant contact (BIC) percent during the initial bone-healing process. As a consequence, this chapter mainly addresses the contribution of the surface condition of an implant to the healing phase of integration.

Steigenga et al.[1] compared three thread shapes with endosteal implants of similar width, length, thread number, thread depth, and surface condition. The V-shaped and reversed buttress thread had similar BIC and reverse torque values. The square threaded implants had higher BIC and higher reverse torque values. Therefore thread shape may also influence the implant-bone interface during the healing period of an implant, but it is a secondary factor.

The surface condition alone may also decrease the biological width, which causes marginal bone loss when the implant extends through the mucosal tissues. Hermann et al.[2] inserted a combination of smooth- and rough-surface implants with smooth collars of 1.5 mm below the bone and other implants with the rough surface placed at the bone crest. Within 1 month the implants with smooth collars lost 1.5 mm of bone, even though the implants received no occlusal load. The implants with a roughened surface to the crest of bone and no occlusal load maintained the bone for the 6 months of the study. Therefore roughened surfaces improve the initial BIC during initial healing and decrease the marginal bone loss when the implant extends through the soft tissue, before occlusal load.

The early loading period of an implant has considerations from an implant body design and the surface condition of the implant, and both criteria are similar in importance. Stress equals force divided by the area over which it is applied and is directly related to the strain observed in the bone. Therefore BIC will directly relate to the amount of strain at the bone-implant interface. When the strain conditions are within the physiologic zone of bone, the bone-implant interface may maintain a lamellar bone organization, which is organized and mineralized and is best to resist occlusal loads to the interface. The roughened surface of an implant that improves unloaded healing may also help bear the initial occlusal load to an implant interface. For example, hydroxyapatite (HA)-coated cylinder implants reported a high BIC after healing. This implant design also reported high survival rates during the 3 initial years of loading.

The implant design also may affect the early loading period of an implant. For example, smooth-surface cylinder implants do not respond favorably to occlusal load. On the other hand, smooth-surface threaded implants have early loading success, especially in good bone types.

The mature loading period of an implant begins to occur after 3 to 5 years and continues throughout the

WWW.HIGHDENT.IR

Table 27-1 Studies That Evaluated the Role of Implant Design and Surface Condition on the Bone-Implant Interface

PHASES	IMPLANT SURFACE VERSUS DESIGN	AUTHORS	FINDINGS	EXPERIMENTAL DESIGN
1. Surgical integration	Surface condition	Shalabi et al.*	Removal torque values higher for roughed surface (76.6 N-cm) versus machined surface (50.2 N-cm)	Implants with etched or machined surfaces were evaluated after surgical insertion into the femoral condyle of goats
	Implant design	O'Sullivan et al.†	In tibia, resonance frequency values at placement were higher for 1-degree tapered implants (8131 Hz) compared with control (7782 Hz)	Experimental implants (1- or 2-degree taped) were compared with standard Brånemark implants, which were used as control; implants were evaluated after surgical insertion into the tibiae and femurs of rabbits
2. Healing dynamics	Thread shape	Steigenga et al.‡	Square-threaded implants had higher BIC value (74.37%) compared with V-shape (65.46%) and reverse buttress–threaded (63.05%) ones	Implants were placed in the tibiae of rabbits and evaluated after a 12-week healing period
	Surface condition	Hermann et al.§	No significant changes concerning bone loss were detected around implants with the rough surface placed at the bone crest; however, implant inserted with the smooth collars of 1.5 mm below the crest resulted in bone loss (1.7 mm in the first month) to the level of the rough/smooth implant interface	Implants were placed in the mandibles of dogs and evaluated at a monthly interval until sacrifice at 6 months; six combinations of smooth- and rough-surface implants were used in the study; however, data from only two groups are presented
3. Early loading period	Surface condition	Degidi et al.‖	Immediately loaded implants, despite the surface condition, presented high BIC values (average 80.6%)	Immediately loaded implants (two HA-coated and one with a sandblasted surface) were retrieved from two patients and evaluated after a 6-month loading period
	Implant design	Degidi et al.¶	Vertical bone loss was more pronounced for cylindric implants; overall BIC approximately 60% to 65%	Eleven implants submitted to immediate loading were retrieved from patients after a loading period between 10 and 11 months
4. Mature loading period	Implant design	Jeffcoat et al.#	HA cylindric implants had the highest success rate 5 years after restoration (99.0%), followed by HA threaded implants (97.9%)	Implants (threaded and cylindrical HA-coated implants, as well as threaded titanium implants) were inserted between the mental foramina of 120 edentulous patients; prostheses were attached no sooner than 3 months after implant placement; patients were observed for 60 months

WWW.HIGHDENT.IR

life span of the implant interface. In general, the surface condition of the implant is least important during this time frame. For example, roughened surfaces on cylinders often lose bone after 5 years of occlusal load. The roughened surface on a cylinder can withstand the initial loads, but fatigue factors of the bone interface begin to break down over continued cycles, similar to shin splints in long-distance runners. The higher the bone turnover rates are because of high strain conditions, the more likely the bone microstrain condition is found to be in the pathologic overload range—and the bone is lost. On the other hand, the implant design is the major feature of an implant body during the mature loading period and is primarily responsible for the bone turnover rates adjacent to the implant. Therefore the implant design becomes most important in the mature loading period.

Before the advent of osteointegration, the use of implant-supported prostheses often resulted in the formation of a fibrous structure around the implants, resulting in mobility and subsequent loss of the implant. The observation that bone can grow over titanium structures started a new pathway in the study of the intraosseous anchorage for dental prostheses.[3] As a result, long-term implant success rates are reported to be as high as 90% to 100%.[4]

Once an implant is inserted in a bone site, a cascade of biological events is initiated. Initially, osteoconduction occurs, which implies the recruitment and migration of osteogenic cells to the implant surface. Secondly, new bone formation takes place, which results in the formation of a mineralized interfacial matrix, followed by a bone-remodeling process. This phenomenon may influenced by the microtopography of the surface.[5]

However, it is important to emphasize that the surface condition of an implant is not the only requirement to ensure long-lasting implant anchorage. The implant material, status of the bone, surgical technique, surface quality, implant design, and implant-loading conditions all relate to the long-term success of a direct bone-implant interface.[6]

The percentage of BIC may be used to evaluate the stability of an implant, and values higher than 50% appear to be satisfactory for stable prosthetic results.[7] Moreover, torque removal force has been used to describe the anchorage of an implant, in such a way that the higher the value, the greater the biomechanical strength of the bone-implant interface.[8] These values are influenced by factors such as the healing period, the loading protocol, and the experimental methodology of the study. It also appears that results obtained in studies performed in humans are more reliable than the findings obtained in studies performed in animals or in vitro. However, it is more prudent to perform some analyses using an animal model (e.g., histologic or torque removal evaluations of successful implants), and in vitro studies are also important to clarify the biological response of cells in contact with different surfaces.

Scientific studies frequently compare the values of one-dimensional parameters to describe the roughness of a surface, based on the evaluation of its peaks and valleys. For example, it is common to use only parameters representative of the height: the arithmetic mean height deviation from a mean plane (also called R_a, if accessed with bidimensional evaluation, or S_a, if accessed with three-dimensional evaluation).[9] Each surface should be described by the combination of parameters representative of height and space. To simplify the description and comparison of surfaces found on an implant body, both the values of R_a and S_a are addressed in this chapter.

TITANIUM

The "osseointegration" phenomenon was firstly described by Brånemark et al.,[3] and is defined as the "direct contact between living bone and a functionally loaded implant surface without interposed soft tissue at the light microscope level."[10]

Titanium is a metal that presents low weight, high strength/weight ratio, low modulus of elasticity, excellent corrosion resistance, excellent biocompatibility, and easy shaping and finishing.[11] Because of these properties, it is the material most widely used in the manufacture of dental implants, in the commercially pure titanium (cpTi) form or as an alloy. The most frequently used alloy (titanium-6 aluminum-4 vanadium [Ti6Al4V]) is composed of 90% titanium, 6% aluminum (decreases the specific weight and improves the elastic modulus), and 4% vanadium (decreases thermal conductivity and increases the hardness).[12]

Lincks et al.[13] observed in cell cultures that the osteoblast-like cells responded in a differential manner on plates of cpTi and Ti6Al4V surfaces and speculated that the mosaicism of the alloy components would result in a more complex surface chemistry. Moreover, the authors theorized that ions released from these surfaces would have a negative effect on cell adhesion and could impair normal bone formation.[14,15] In addition, they speculated cpTi surfaces were more likely to optimize the osteoblastic differentiation[16] and to attach more strongly to bone than to the alloy.[17] A study was performed inserting implants in the tibiae of rabbits; results were observed at 1, 6, and 12 months. The removal torque of unloaded implants was not statistically different at 1 month, but at 6 months (29 N-cm and 23 N-cm, respectively, in cpTi and alloy) and 12 months (38 N-cm and 35 N-cm, respectively, in cpTi and alloy) the cpTi implants were significantly more stable. BIC values were not statistically different between

WWW.HIGHDENT.IR

the materials, but the authors emphasized a tendency of cpTi implants to have higher values as compared with the alloys implants.[18]

However, not all studies suggest cpTi improved the BIC. In a report on baboons, cpTi and Ti6Al4V dental implants were inserted in the mandible and maxilla of baboons and analyzed 3 and 6 months after implant placement. BIC values significantly increased over time in cpTi (39.1% to 56.2%) and Ti6Al4V sites (40.0% to 55.2%), but differences at 6 months were not considered statistically significant.[19] The primary use of Ti6Al4V in the industry relate to the mechanical advantages over cpTI. The alloy is as much as four times stronger than grade 1 cpTi and 2.4 times stronger than grade 3 titanium. Because the BIC and reverse torque valves are similar before loading, the alloy is often used to decrease the complications of component and/or implant body fracture or wearing of antirotational features of the abutment, which increase the risk of screw loosening.

An interesting aspect of titanium implants (cpTi or Ti6Al4V) is that immediately after its exposure to the air, an oxide layer is formed over the surface (about 2 to 5 nm thickness). This layer is the material that is in contact with the body tissues,[20,21] playing an important role in corrosion resistance, biocompatibility, and osseointegration; however, the mechanisms are not completely understood.[22-24] This most likely is the reason cpTi and Ti6Al4V have similar BIC values. The titanium oxide layer is mainly composed of titanium dioxide (TiO_2),[25] and the crystalline structure—the thickness and stability of this layer—varies according to the surfaces of the implant.[26-28]

TURNED SURFACES

The turned surfaces were the most commonly used surfaces in the past; they were submitted only to a decontamination process after the turning process. These surfaces are also called *machined* or *smooth*, but microscopic observation reveals the presence of a slight roughness because of the grooves and ridges produced during the turning process. For this reason, the use of the term *smooth* should be avoided.[12] One of the main characteristics of the turned surfaces is that it is possible to observe a distance osteogenesis (Figure 27-1).

Modifications were proposed to change the characteristics of the surface from turned to roughened, to improve the stabilization of the implant, and to increase the surface area.[18,29,30] Moreover, it was observed that the morphology of the surface plays a role in the cellular behavior.[31,32] The interaction of the surface with the culturing media and serum seems to directly affect the attachment of osteoblasts and their subsequent proliferation and differentiation,[33,34] as well as to influence the production of local cell regulators such as transforming growth factor β (TGF-β) and prostaglandin E_2 (PGE_2).[35,36,37,38]

On the preparation of modified surfaces, additive methods (e.g., plasma spraying, HA coating) or subtractive methods (e.g., sandblasting, acid etching) have been used; the optimal type of surface is still to be defined. In one study the ideal roughness for a turned surface, which ideally would result in a stronger bone response, was suggested to be 0.9 to 1.3 µm in average.[39] However, another study showed that in the 4.0-µm range, osteoblastic proliferation was reduced but not blocked, phenotypic differentiation was enhanced, and cells on smoother surfaces presented a loss of a differentiated osteoblastic phenotype.[13] In fact, the roughness average values seem to be useful only as a reference, and other factors, such as wettability and free energy,[38] have been studied to clarify their influences on bone formation, together with the average roughness.

SANDBLASTED SURFACES

Sandblasting the metal core with gritting agents creates these modified surfaces. This process is influenced by the number and the speed of the rotations to which the implant is submitted, as well as by the pressure and the size of the particles used.[12,40] The blasting procedure is performed with the aim of increasing the irregularity of the surface of the implant, using agents such as aluminum oxide (Al_2O_3, also called *alumina*) (Figures 27-2 and 27-3) and TiO_2. The analyses of different implant surfaces revealed that sandblasted samples showed the largest variability in surface appearance. Researchers have suggested that this characteristic may be explained by an inappropriate refreshing cycle of the used particles because they can break after use; these fragments may be reused, instead of being discarded after a single run.[41] In Table 27-2, comparative studies in which sandblasted implants were evaluated are presented.

Sandblasting has been shown in some studies to allow the adhesion, proliferation, and differentiation

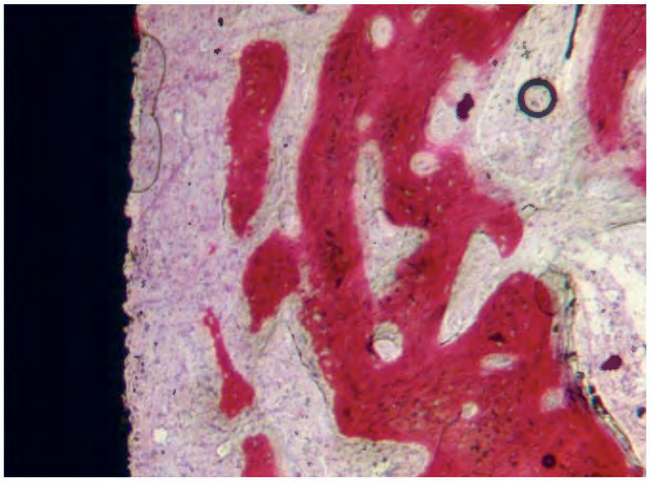

Figure 27-1 Machined surface. Distance osteogenesis. Newly formed bone is growing toward the implant surface. (Acid fuchsin-toluidine blue; ×40.)

of osteoblasts.[33,42] On the other hand, fibroblasts were found to adhere with more difficulty to this surface; this could limit the soft tissue proliferation and potentially benefit bone formation.[43,44]

Studies have compared the BIC of turned titanium and sandblasted surfaces with Al_2O_3 particles. Implants were inserted in the femoral knee joints of rabbits, and the blasted sites presented BIC values statistically higher than the turned surface sites.[45] In another study in rabbits, turned implants (S_a = 0.96 µm) were compared with implants blasted with Al_2O_3 particles of different sizes, to obtain surfaces with different roughnesses. Mean roughness values (S_a) of 1.2 µm, 1.43 µm, and 2.2 µm were observed respectively, with particles of 25 µm, 75 µm, and 250 µm. After 12 weeks, all blasted surfaces (BIC values ranging from 31% to 47%) demonstrated more bone in contact with the implant surface compared with turned surfaces (BIC values ranging from 18% to 23%). Additionally, a higher percentage of bone was found in close contact with the implant surfaces in the sites in which 75-µm particles were used.[46]

Blasting procedures leave residual particles on the surface of the implant, and this could modify the bone-healing process. Some authors believe that the presence of Al_2O_3 particles remaining may be beneficial to osseointegration, catalyzing this process,[47] whereas other researchers believe that aluminum ions may impair bone formation by a possible competitive action to calcium.[44,48-50] A study was developed with the aim of describing the effects of residual Al_2O_3 particles on the implant surface on the integration of titanium surfaces. Dental implants were sandblasted (Al_2O_3 100- to 120-µm particles) or sandblasted and decontaminated (ASTM Committee F [ASTM F] 86-68 decontamination process in an ultrasonic bath), and inserted in rabbits. After 4 weeks, no statistically significant differences were observed between the groups based on the following analyses: BIC value, quantification of multinucleated cells or osteoclasts in contact with the implant surface, quantification of multinucleated cells or osteoclasts 3 mm from the implant surface. The authors suggested these histological results did not provide evidence to support the hypothesis that residual Al_2O_3 particles on the implant surface could affect the osseointegration of titanium dental implants.[51]

Alternatives to blasting with Al_2O_3 particles have also been tested. Blasting a surface with TiO_2 particles was proposed to promote a modification on the implant by using a component of the oxide layer naturally formed around titanium implants. In a rabbit comparison study, between surfaces blasted with Al_2O_3 25-µm particles (R_a = 0.84 µm) or TiO_2 25-µm particles (R_a = 0.96 µm), implants were inserted in the tibia. After 12 weeks, no statistically different values, concerning torque removal (26.5 N-cm and 24.9 N-cm, respectively, in Al_2O_3 and TiO_2 sites) or BIC values (49.2% and 47.6%, respectively, in Al_2O_3 and TiO_2 sites), were observed between these surfaces blasted with the same size of particles.[40]

Dental implants with TiO_2-blasted surface (25-µm particles) (R_a = 0.88 µm) have also been compared with turned implants (R_a = 0.39 µm) in the tibiae of rabbits. Twelve weeks after the insertion, TiO_2-blasted implants showed a statistically significant greater removal torque force (35.4 N-cm) than turned implants (29.2 N-cm). However, BIC values were not significantly different between the implants but were generally higher in the blasted group (40.9% and 34.5%, respectively).[39] In another animal model, a comparison between TiO_2-blasted and turned surfaces was performed by placing dental implants in fresh extraction sockets in dogs. After a 12-week healing period (no prosthetic rehabilitation was performed), no significant differences were observed between the surfaces concerning BIC (69% for both groups); blasted implants, however, showed higher remo-

val torque values (150 N-cm) compared with turned sites (60 N-cm).[52]

In a comparison study between TiO_2-blasted (25-µm particles) (S_a = 1.43 µm) and turned surfaces (S_a = 1.47 µm) in humans, microimplants were inserted in 27 patients and retrieved after a mean healing time of 6.3 months in the maxillae and 3.9 months in the mandible. The analysis of the results revealed a significantly higher BIC for the blasted implants than turned groups (37% and 9%, respectively).[53] However, these findings may not necessarily modify a clinical outcome. For example, in a clinical study, implants with TiO_2-blasted (S_a values of approximately 1.5 µm) and turned (S_a values of approximately 0.7 µm) surfaces were placed in the edentulous ridges of 18 patients. Prosthetic rehabilitation was performed, and after 2-year follow-up, no statistically significant differences between groups were found in the cumulative success rate (100% and 97.7%, respectively) or in marginal bone loss (–0.2 mm and 0.0 mm, respectively).[54]

Modifications on zirconium oxide (ZrO_2) surfaces have also been proposed to improve the bone-implant interface.[55] Implants with modified surfaces were investigated in monkeys. ZrO_2 implants (Al_2O_3 sandblasting with 50-µm particles) were compared with titanium (Al_2O_3 sandblasting with 50-µm particles; followed by hydrogen peroxide [H_2O_2] and hydrofluoric acid [HF] etching). Nine months after implant placement, metallic prostheses were installed, and 5 months later, BIC values corresponded to 67.4% for ZrO_2 and 72.9% for the titanium implants. However, differences were not statistically significant.[56]

WWW.HIGHDENT.IR

PLASMA-SPRAYED SURFACES

The use of implants with plasma-sprayed surfaces has been reported in orthopedics studies since the 1970s.[57] Later it was observed that, around dental implants, bone was formed without an intervening layer of connective tissue.[58] Plasma-sprayed implants are prepared by spraying molten metal on the titanium base, which results in a surface with irregularly sized and shaped valleys, pores, and crevices,[59] increasing the microscopic surface area by 6 to 10 times.[12] This topography may improve the fixation of implants by the growth of bone into the coating, forming a mechanical interlock.[60]

SURFACE COATING

Titanium Plasma Spray

The titanium plasma spray (TPS) surface has been reported to increase the surface area of the bone-implant interface and acts similarly to a three-dimensional surface, which may stimulate adhesion osteogenesis (Figures 27-4 and 27-5). The surface area increase has been reported to be as great as 600%. Although tremendous increase in total surface area occurs at the microscopic level, the actual load-bearing capability of the coating increases the functional area by 25% to 30%, which is still substantial. Porous surfaces in the range of TPS (150 to 400 µm) also increase the tensile strength of the bone-implant interface, resist shear forces, and improve load transfer. The increased surface roughness may also improve the initial fixation of the implant, especially in softer bone. Some evidence indicates that the interface may form faster, but no consensus exists regarding whether that may shorten clinical healing times.

A comparison of the biological response of plasma-sprayed (R_a = 7.345 µm) and turned surfaces (R_a = 0.350 µm) was performed in baboons. Six months after the implantation (no prosthetic rehabilitation was performed), no statistically significant differences could be observed between groups concerning the BIC percentage (55.9% and 56.2%, respectively, in plasma-sprayed and turned surfaces).[61] Plasma-sprayed implants were used in studies in rabbits,[62] monkeys,[63,64] and humans,[65-68] even under immediate placement (i.e., implants placed in fresh extraction sites) and immediate-loading conditions.[69] In Table 27-3, comparative studies in which plasma-sprayed implants were evaluated are presented.

Plasma-sprayed surfaces obtained with more reactive materials have been proposed to accelerate and enhance the bone ingrowth into pores of the implant surface. An alkali modification was proposed after plasma spraying, using sodium hydroxide solutions at 40° C for 24 hours. The oxide layer in modified surfaces (R_a = 18.2 µm) measured about 150 nm, whereas in plasma-sprayed sites (R_a = 17.6 µm) it measured less than 20 nm. Modified and nonmodified plasma-sprayed implants were placed in the femurs of dogs and analyzed 1, 2, and 3 months after insertion. After the first month, values of the push-out test (2.6 MPa for modified implants, which is about 1.5 times of that of the nonmodified implants) and of BIC (60.5% for alkali-modified implants and 20.2% for nonmodified implants) were significantly higher statistically in modified sites. No differences were observed after the second and third month (values were not presented). The authors suggested that the alkali modification may be beneficial to reduce clinical healing times and thus to improve implant success rates.[60]

One disadvantage of using the plasma-sprayed implants is the detachment of titanium after implant insertion. Franchi et al.[70] investigated the detachment of particles around plasma-sprayed, sandblasted, and

acid-etched (Al_2O_3 with 100-µm particles or ZrO_2 with 120-µm particles) and turned implants. Fourteen days after placement in femoral and tibial diaphyses of sheep, titanium debris was observed only in the plasma-sprayed samples. In another investigation in which the tissues around plasma-sprayed and HA-coated implants were evaluated, the presence of granules of titanium was found only around the plasma-sprayed surfaces.[71,72] This phenomenon could be related to the friction between the implant surface and the host bone cavity during implant placement, but its implications are not clear.

Acid-Etched Surfaces

Acid-etching a titanium base was proposed to modify the implant surface without leaving the residues found after the sandblasting procedure, to avoid the nonuniform treatment of the surface, and to control the loss of metallic substance from the body of the implant (Figures 27-6 and 27-7).[12] This is performed using baths of hydrochloric acid (HCl), sulfuric acid (H_2SO_4), HF, and nitric acid (HNO_3) in different combinations. The roughness before etching, the acid mixture, the bath temperature, and the etching time all affect the acid-etching process. Table 27-4 lists the results from histologic evaluation of retrieved implants from humans.

Researchers compared etched (HCl and H_2SO_4) and turned surfaces by inserting implants in rabbit femurs.[8] The roughened surface was characterized by "an even distribution of very small (1 to 2 µm) peaks and valleys." The resistance to torque removal was evaluated 2 months after implant placement in rabbits, and it was found

to be four times greater for acid-etched implants (20.50 N-cm) compared with the turned ones (4.95 N-cm).

A dual acid–etched technique has been proposed to produce a microtextured (instead of a macrotextured) surface, which could be more predisposed to achieve desirable results.[73] This is because higher adhesion of platelet genes and higher expression of extracellular genes were observed in this dual acid–etched surface.[74,75] Dental implants were inserted in areas with poor bone quality in dogs (mandibular premolar teeth were extracted and left healing for 8 months). Four months later (no prosthetic rehabilitation was performed), BIC values were significantly higher for dual acid–etched implants (62.9%) as compared with turned sites (39.5%).[76]

Degidi et al.[77] presented the histologic analysis of two dual acid–etched implants (HCl and H_2SO_4) retrieved from humans. The implants were removed 6 months after implantation because of the positioning of the implants in contact with the inferior alveolar nerve and

resultant discomfort. These two integrated implants presented a mean BIC percentage of 61.3%, with no gaps or fibrous tissues present at the interface.

The use of dual acid–etched implants in immediate-loading procedures was histologically investigated in humans. Two implants were inserted in the mandible of a patient to immediately support a provisional fixed partial denture (FPD). Four months after occlusal loading, during the uncovering procedure of the submerged implants, those immediately loaded implants were retrieved, and histomorphometric evaluation revealed high levels of BIC, ranging from 78% to 85%.[78] These results were confirmed in an experimental study in humans in which microimplants (measuring 2 × 5 mm, with one side treated by dual acid etching and the other side left turned) were used. These implants were inserted in the posterior maxillae of 11 patients; 6 months later, the BIC values in dual acid–etched sites (72.35%) were statistically higher than in turned sites (35.32%).[79]

In a comparison among dual acid–etched (R_a = 494.16 nm), plasma-sprayed (R_a = 7.01 nm), and turned (R_a = 185.14 nm) surfaces, mean torque values were evaluated in rabbit femurs, 1, 2, and 3 months after implant placement. Values obtained at the third month were 27.40 N-cm, 59.23 N-cm, and 6.73 N-cm, respectively. Moreover, at the earliest time point, the stability of dual acid-etched implants was comparable to that of plasma-sprayed implants, whereas the stability of the turned implants was comparatively lower.[73]

Cho and Park[80] tested different acid concentrations in implants placed in the tibiae of rabbits. For the preparation of the dual acid–etched surfaces, the first bath was performed using HF in different concentration (12%, 24%, or 48%), and the second bath was performed with 70% HCl and H_2SO_4. Turned surfaces were used as the control. Twelve weeks after implant placement, the removal torque required for dual acid–etched implants (34.3 N-cm, 34.7 N-cm, and 38.7 N-cm respectively) was statistically higher than that for the turned implants (15.2 N-cm). The authors concluded that less correlation exists between removal torque and the difference in HF volume percent and that rough acid-etched implants achieved greater resistance to reverse torque removal than machined implants.

Sandblasted and Acid-Etched Surfaces

In the 1990s the study of a modified surface resultant from blasting (to produce a macrotexture) followed by acid etching (to produce a final microtexture) showed promising results. The resultant surface was constituted by uniformly scattered gaps and holes, and it appeared to be slightly less rough than the plasma-sprayed surface, which presented a deeply irregular texture that provided a less favorable environment for cell spreading (Figures 27-8 to 27-11).[81] In Table 27-5, comparative studies in which acid-etched implants were evaluated are presented; Table 27-6 lists the results from histologic evaluation of retrieved implants from humans.

A comparison study between sandblasted and acid-etched surfaces (R_a = 2.0 µm) and acid-etched surfaces (R_a = 1.3 µm) was performed in miniature pigs. Up to 3 months, implants with sandblasted and acid-etched surfaces presented significantly high torque removal values (186.8 N-cm), which were 75% to 125% higher than those observed in acid-etched sites (95.7 N-cm).[82] In a dog model, Abrahamsson et al.[83] evaluated the pattern of bone formation in blasted and acid-etched (S_a = 2.29 µm) and turned (S_a = 0.35 µm) surfaces. BIC values were significantly greater in sandblasted and acid-etched sites than in turned surfaces 1, 2, 4, 6, 8, and 12 weeks after implant placement. Most of the data were presented as a graphic, without corresponding numerical values; however, in the twelfth week the BIC

WWW.HIGHDENT.IR

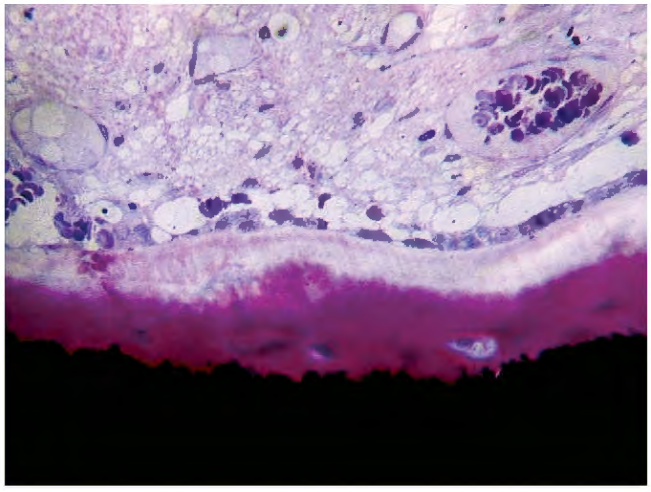

Figure 27-10 Sandblasted and acid-etched surface. At higher magnification it is possible to see that bone is in close contact with the implant surface with no intervening gaps. A rim of osteoblasts is depositing osteoid matrix. (Acid fuchsin-toluidine blue; ×200.)

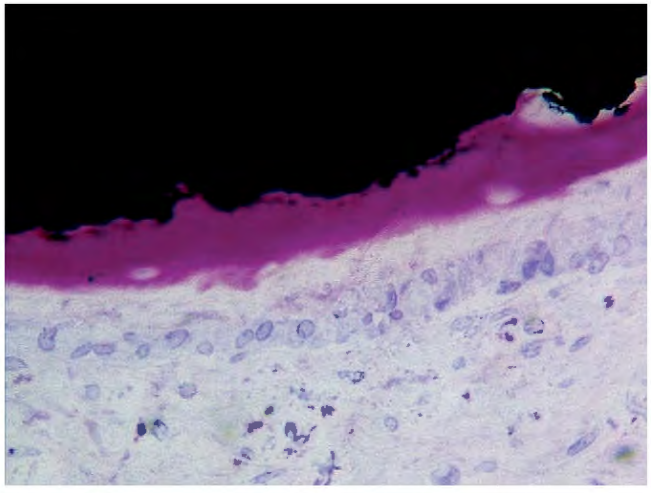

Figure 27-11 Sandblasted and acid-etched surface. Bone has grown inside the irregularities of the implant surface. (Acid fuchsin-toluidine blue; ×200.)

was approximately 60% in sandblasted and acid-etched implants and approximately 40% in turned implants. The authors concluded that the rate and degree of osseointegration is superior in sandblasted and acid-etched implants.

Sandblasted and acid-etched implants tend to promote greater osseous contact at earlier time points compared with plasma-sprayed, coated implants. This conclusion was derived from a dog study in which the test surface was prepared by blasting with 250- to 500-µm corundum particles, and the acid etching was done with HCl and H_2SO_4. Histologic analyses were performed 3 months after implant placement (3 months of healing), 3 months after loading (6 months of healing), and 12 months after loading (15 months of healing). Sandblasted and acid-etched implants had a significantly higher percentage of BIC than did the plasma-sprayed implants after 3 months of healing (72.33% and 52.15%, respectively). Differences were not observed after 6 months of healing on sandblasted and acid-etched and plasma-sprayed implants (68.21% and 78.18%, respectively). After 12 months of loading, BIC values were significantly higher in sandblasted and acid-etched than in plasma-sprayed sites (71.68% and 58.88%, respectively).[84] Sandblasted and acid-etched surfaces also present better osteoconductive properties and a higher capability to induce cell proliferation than plasma-sprayed surfaces.[71,81,85]

In the maxillae of miniature pigs, the removal torque values were evaluated in sandblasted and acid-etched (sandblasted with 0.25- to 0.50-µm particles, and acid-etched with HCl and H_2SO_4) (R_a = 2.0 µm), plasma-sprayed (R_a = 3.1 µm), and turned (R_a = 0.15 µm) surfaces, after 4, 8, and 12 weeks of healing. The values in sandblasted and acid-etched (values ranged between 1.31 and 1.43 N-cm) and plasma-sprayed (values ranged between 1.14 and 1.54 N-cm) implants were significantly higher statistically than turned implants (values ranged between 0.15 and 0.26 N-cm). Values between sandblasted and acid-etched and plasma-sprayed sites were not statistically significant.[86]

The analysis of sandblasted and acid-etched implants in humans was performed in studies by analyzing retrieved implants from patients. In a case report, an implant was inserted in the palatal bone of the maxilla of a patient as anchorage for orthodontic treatment, and 6 months later the implant was retrieved; the BIC was 76.6%.[85] In another case report, an implant was removed after 40 months of function, for a fracture of the abutment screw, and a 75.4% BIC value was observed.[87]

Some authors suggest that, in cases of healthy patients with sufficient bone volume and of patients with good bone quality (Classes I to III), sandblasted and acid-etched implants can be restored after approximately 6 weeks of healing, with a high predictability of success.[88] Of course, it is also reported that immediate loading after implant insertion is possible, with a wide range of implants and surface conditions.

Sandblasting can be performed using different abrasive particles. For example, the surface obtained from acid etching and sandblasting with ZrO_2 particles is reported to favor a better bone deposition as compared with plasma-sprayed and turned surfaces.[89]

In another situation, the response of osteoblasts to acid-etched and sandblasted surfaces prepared with Al_2O_3 or ZrO_2 particles was compared with plasma-sprayed (R_a = 9.5 µm) and turned (R_a = 0.56 µm) surfaces. Blasting with Al_2O_3 was performed with 100-µm (R_a = 1.98 µm) and 150-µm (R_a = 1.14 µm) particles, and blasting with ZrO_2 was performed with 60-µm (R_a = 1.52 µm) and 120-µm (R_a = 1.32 µm) particles. best growth and differentiation patterns were obtained in microroughed surfaces blasted with 60-μm ZrO_2 particles, which in this study were also the cleanest surface, with no toxic contaminating residues. The authors suggested that the depth and distribution of irregularities, the cavity morphology, and the presence of contaminating elements derived from the treatment procedures seems to play an important role in cell behavior.[90]

A specific method to produce HA-blasted implants was proposed—the "resorbable blast material" (Figure 27-12). The base of titanium is submitted to blasting, followed by a passivity procedure to remove the calcium phosphate ($CaPO_4$) and, finally, cleaning. The blast media is resorbed during these processes, and a surface of pure TiO_2 is produced that is free of contaminants.[91] In a comparison performed in rabbits, 8 weeks after implantation the BIC value in the modified surface (62.3%) (R_a = 2.14 μm) was significantly higher than the 51% observed in the turned surface (R_a = 0.78 μm).[92] In a 50-month follow-up study, 1077 implants were placed in 348 patients, resulting in a 99.3% success rate in the mandible and 100% in the maxilla.[93]

Anodized Surfaces

The oxidation process has been used in dental implants to change the characteristics of the oxide layer and, consequently, to improve the biocompatibility of the surface (Figure 27-13).[27] The advantage is to modify

the surface without depositing grit particles. Anodized surfaces are prepared by applying a voltage on the titanium specimen immersed in an electrolyte. The resultant surface presents micropores of variable diameters and demonstrates lack of cytotoxicity; moreover, cell attachment and proliferation are enhanced as compared with turned surfaces.[94]

The removal torque of anodized surfaces with different oxide thicknesses (oxide thickness of approximately 200, 600, 800, or 1000 nm; S_a ranging from 0.96 to 1.03 µm) was also investigated in comparison with turned implants (oxide thickness of 17.4 nm; S_a = 0.83 µm). Six weeks after implant placement in rabbit tibiae, the values obtained (11.3, 12, and 12.9 N-cm, respectively) in anodized sites were significantly higher than those reported for the turned sites (removal torque value of 7.5 N-cm).[27] However, in rabbit tibiae, anodized, anodized and hydrothermally treated, and turned surfaced titanium implants were inserted. Six and 12 weeks after implantation, BIC values and removal torque strength were not statistically different among the groups.[95]

In humans an experiment was developed to compare anodized (S_a = 1.17 µm) and turned (S_a = 0.78 µm) surfaces. With this aim, microimplants (2.3 × 5 mm) were inserted in a suitable edentulous area in maxilla or mandible of 20 patients. Each patient had an oxidized and a turned implant inserted, and mean healing time

WWW.HIGHDENT.IR

was 6.6 months. BIC values were statistically higher in oxidized (34%) than in turned (13%) implants. The authors suggested that these results may be explained by the thicker oxide layer, increased surface roughness, different surface morphology in terms of porosity, or change in crystal structure.[96]

A comparison of the response of osteoblasts was evaluated using anodized (Nobel Biocare TiUnite, R_a = 0.76 µm), blasted and acid-etched (Dentsply Friadent DPS, R_a = 2.41 µm; Dentsply Friadent Plus, R_a = 2.75 µm; Straumann SLA, R_a = 2.93 µm), plasma-sprayed (Dentsply Friadent TPS, R_a = 3.5 µm), acid-etched (3i Osseotite, R_a = 0.86 µm), and turned (Nobel Biocare Mk III, R_a = 0.81 µm) surfaces. The rate of cellular spreading was significantly increased in surfaces combining blasting and acid etching. The authors observed that differentiation and calcification occurred on surfaces of both rough and smooth microstructure, and they speculated that a rough surface of porous microstructure may enhance the rate of cell spreading.[59] In Table 27-7, studies in which anodized implants were evaluated are presented.

HYDROXYAPATITE

Hydroxyapatite Coatings

Hydroxyapatite coatings have a similar roughness and increase in functional surface area as TPS (Figures 27-14, 27-15, and 27-16). A direct bone bond shown with HA coating and the strength of the HA-to-bone interface is greater than titanium to bone and even greater than TPS to bone. In addition, accelerated interfacial bone formation and maturation have been observed in dogs.[97] An initial implant-to-bone interface contract is essential for a predicable interface to form.[98] The space or "gap" between the implant and bone may affect the percentage of bone contact after healing. Gap healing may be enhanced by the HA coating.[99,100] The corrosion rate of metal is also reduced, which is more significant for cobalt chrome alloys.[102]

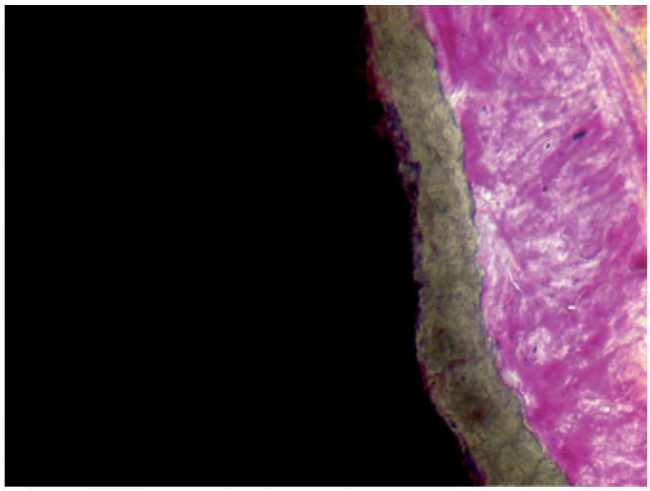

Figure 27-15 Hydroxyapatite (HA)-coated implant. A very tight connection is present between bone and HA coating with no intervening gaps at the interface. (Acid fuchsin-toluidine blue; ×100.)

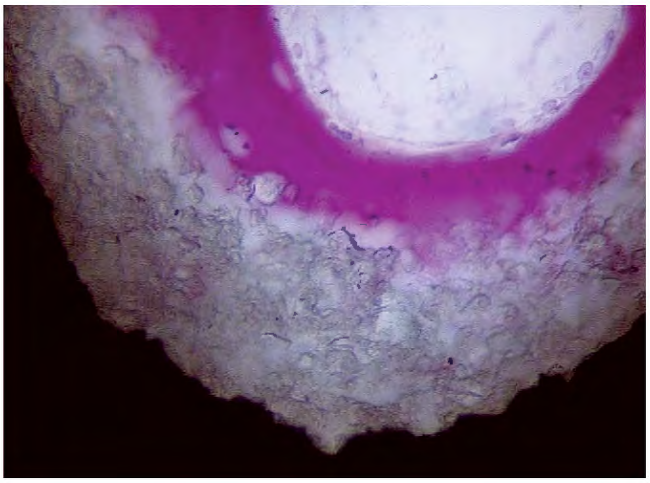

Figure 27-16 Hydroxyapatite (HA)-coated implant. At higher magnification it is possible to observe that bone is in close contact with the HA coating. (Acid fuchsin-toluidine blue; ×200.)

The clinical advantages of TPS or HA coatings may be summarized as the following:

1. Increased surface area
2. Increased roughness for initial stability
3. Stronger bone-implant interface

Additional advantages of HA over TPS include the following:

1. Faster-healing bone interface
2. Increased gap healing between bone and HA
3. Stronger interface than TPS
4. Less corrosion of metal

Disadvantages of Coatings

Although coatings on implant bodies have benefits, several disadvantages exist. The coating may flake, crack, or scale on insertion, especially when being inserted into dense bone. In addition, the increased surface roughness increases the risk of bacterial contamination when present above the bone. HA may not only increase plaque retention when exposed but also may act as a nidus for bacteria, and bacterial endotoxins may be more adherent because of the surface charge and characteristics.

Although a faster bone interface may develop,[30] it may be an unnecessary risk to reduce the healing time of the loaded implant interface. Coatings also increase the cost of the implant body, compared with uncoated implants. Therefore the disadvantages of coatings include the following:

1. Flaking, cracking, or scaling on insertion
2. Increased plaque retention when above bone
3. Increased bacteria and nidus for infection
4. Complication of treatment of failing implants
5. Increased cost

The HA or TPS coating should not be the only system of load transfer to the bone. This is especially important when bone loss occurs, and the coating must be removed for repair of the implant. However, a coating may enhance an implant body design.

As a consequence, the decision to use a coating may be based more on the bone density than nearly any other factor. Type 1 (D1) and type 2 (D2) bone have the greatest strength and bone contact. In addition, increased risk of material flaking from the implant occurs during insertion. The risk of implant failure as a result of implant design is reduced, as is the incidence of crestal bone loss. Rather than using a coating, D1 and D2 implants benefit from a roughened surface, sound biomechanical design, and a minimum implant length of 10 to 11 mm. Type 3 (D3) bone is approximately 50% weaker than D2 bone. As a result, the advantages of TPS outweigh its disadvantage. The increased initial fixation, increased bone contact, and greater strength of the interface all support its use. Care is taken to reduce crestal bone loss through sound design so that the TPS does not become exposed and the increased plaque retention is not a concern. Type 4 (D4) bone has proven to be the one most at risk. Therefore the benefits of HA are most required in the type of bone. Although it may have the greatest risk relative to bacteria, the benefits of gap healing, faster bone mineralization, and increased bone contact all favor HA. Higher success rates have been reported when HA-coated implants have been used in soft bone. The HA should be added to an implant body with the most macroscopic load-bearing surface area. To minimize crestal bone loss, larger diameter and an increased number of implants are also suggested in this very weak bone.

Synthetic HA is a ceramic material that was introduced as a surface modifier in the 1980s.[97,98] In nature

WWW.HIGHDENT.IR

this material is a component of bone; for this reason it can provide reliable, early, and strong fixation by chemical bonding with bone[99] on the so-called biointegration level.[100] HA surfaces have been used in dental implants to improve the bone-implant anchorage, and it was demonstrated that osteoblasts respond to this contact with immediate changes in gene expression associated with osteoblast adhesion, proliferation, extracellular matrix synthesis, and differentiation.[101]

Histological evidence of the clinical success of HA coating has been reported. Two dental implants, fractured because of an accident, were retrieved from a patient after an 18-month period of loading. Dense bone was found in close relation to the surface of the implants, and the interspaces of each thread were filled with mineralized bone. BIC values were 87.5% and 97.4%, and the authors reported that the connection between the HA coating and the metal was uniformly tight and constant (30 and 50 µm).[102] High survival rates for HA-coated implants have been reported in studies with 3, 8, and 12 years of follow-up.[103-105] Specifically in the 12-year follow-up study, 120 patients (156 titanium and 232 HA-coated implants) were evaluated. The survival rate of HA-coated implants was 93.2%, which was statistically higher than titanium implants (89%).[105]

Histological postmortem analyses of two implants removed 10 years after loading revealed 70.74% and 86.23% BIC values. Interestingly, HA-coating disappearance had occurred in 23.5% and 22.0% of the implant perimeter; however, in these areas bone was in direct apposition to the titanium surface.[106] Other authors also observed this phenomenon of resorption and degradability of HA coating when in contact with the biological environment.[107] For example, Buser et al.[71] demonstrated that this resorption can be followed by bone apposition, resulting in high BIC values.

In humans, in a postmortem evaluation, five titanium implants (85 months of loading) and two HA-coated implants (38 months of loading) were analyzed. Differences were observed concerning the arrangement and pattern of bone contact between the surfaces: HA coating was separated from the maxillary implants in some areas and was free within surrounding connective tissue or surrounded by invaginating sulcular epithelium.[108] Furthermore, in a case report by Piattelli et al.,[109] localized chronic suppurative bone infection was observed as a sequela of peri-implantitis in an HA-coated implant. The patient presented poor hygiene and signs of overloading caused by an imperfect prosthetic treatment plan. The authors observed that bacteria, which penetrated into the marrow spaces and destroyed the mineralized matrix of the bone, filled most of the surrounding bone. Despite the fact that the implant was clinically stable, the histologic analysis showed that the coating was almost completely detached from the titanium surface. Notwithstanding, this resorption must be higher with the presence of periodontal pathogens, which was demonstrated when experimental peri-implantitis was induced in dogs.[110,111] Thus the instability of the coating-substrate interface, the unstable duration of coating, and the lack of long-term observation provided a basis for some authors to question the clinical reliability of this material as a surface modifier.[112,113]

The contrasting results observed in the literature related to a HA surface in an implant body can be attributed to the quality of the different HA coatings, which include factors such as chemical composition and physical and mechanical properties. Different methods can be used to achieve HA coating: dip coating and sintering, electrophoretic deposition, immersion coating, hot isostatic pressing, solution deposition, sputter coating, and thermal spraying techniques (including plasma spraying, which is the method most frequently used).[114] Each of these processes leads to a difference in composition, physical and mechanical properties, thickness, and adhesion to the metal to which it the coating is applied.

HA plasma spraying was created to combine the chemical-bonding properties of HA and the bone-implant mechanical interlock achieved with the plasma-spraying technique. A comparison study between HA plasma-sprayed, plasma-sprayed, and turned cylindrical implants was performed in dogs 12 weeks after implantation (before loading) and 1 year after loading. After both time periods, significantly higher BIC values were observed for HA implants (77.8% and 88.9%, respectively) when compared with plasma-sprayed (58.6% and 64.9%, respectively) and turned (71.2% and 67.1%, respectively) implants. However, this result was not reflected in the pullout strength, in which plasma-sprayed and HA implants exhibited similar values. The authors attributed this phenomenon to the weak coating-substrate interfacial strength.[115]

HA plasma spraying can present problems, including variation in bond strength at the coating-metal interface, nonuniformity in coating density, and structural and chemical alterations of the coatings as a result of the process.[116] To solve the problems regarding the quality of coating, different techniques have been proposed, such as heat treatment[117] or the technique of ion beam–assisted deposition (IBAD).[118,119]

In a comparison of HA-coated implants using the IBAD process (R_a = 1.04 µm), implants blasted with Al_2O_3 particles (50 µm) (R_a = 1.13 µm), and turned surfaces (R_a = 1.13 µm), dental implants were inserted in the tibiae of rabbits. Twelve weeks later, BIC values were significantly higher in IBAD surfaces (62.5%) than in blasted (54.2%) and machined (38.2%) surfaces. The removal torque values of IBAD (48.5 N-cm) and blasted (47.3 N-cm) surfaces were statistically higher than machined (32.3 N-cm) surfaces. The authors mentioned that advantages of the HA-deposited implants in the early healing phase could be apparent, and the separation or fracture of the coating layer could be prevented. However, the control of resorption needs

WWW.HIGHDENT.IR

to be further investigated.[118] The best form of HA of HA coatings to obtain more favorable results using this technology is under evaluation.[120]

ZIRCONIA

Zirconia (ZrO_2) is a ceramic material used in implantology because of its biocompatibility, esthetics (because its color is similar to the teeth), and mechanical properties, which are better than alumina.[121] Implants produced with ZrO_2 are biocompatible, bioinert, and radiopaque, and they present a high resistance to corrosion, flexion, and fracture.[122-127]

This material is reported to present a contact with bone and soft tissue similar to that observed in titanium implants,[56,128] and it can be used to produce a entire implant or as a coating. The interface is composed by a proteoglycan layer, which is thicker than titanium (ranging from 300 to 500 Å and 200 to 400 Å, respectively).[129,130] However, the amount of bone formed 1 and 6 months after implant placement (in rabbits) did not differ in titanium and zirconium implants.[130]

Bone response to ZrO_2 implants was evaluated in a rabbit study. Four weeks after implantation, the BIC value was 68.4%, and the authors reported an absence of epithelial down growth, foreign bone reaction, gaps, or fibrous tissue between bone and implant.[55] The stability of osseointegration around ZrO_2 implants was also evaluated under different loading protocols in a monkey model. Dental implants were inserted, and 3 months later, prostheses were installed (single freestanding implant support, connected freestanding implant support, and a combination of implant and tooth support). Peri-implant tissues were observed by clinical, histologic, and histomorphometric examination 12 and 24 months after loading, and statistically significant differences were observed among groups (BIC values ranged from 66% to 81%).[131]

In humans, Kohal and Klaus[132] presented a case report in which a ZrO_2 implant was immediately inserted in substitution to a central incisor extracted because of a longitudinal fracture. After a 6-month healing period, a ZrO_2 abutment was cemented and the extracted tooth was modified and served as provisional restoration. One month later, a ZrO_2 single-crown framework was cemented onto the implant. The results obtained with ZrO_2 implants seem promising, and further studies are necessary to clarify the biological response of ZrO_2 implants, especially after longer time periods.

SUMMARY

An enormous quantity of studies is being published to investigate the viability of modified surfaces. Some results are promising; for example, the use of titanium nitride (TiN) surface, nanostructured surfaces, surfaces modified by laser, and the improvement of ceramic materials.[55,133] Nanostructured surfaces, with typical features in the range of 1 to 100 nm, may affect the early events of tissue interaction of the surface with the environment.[134,135] An in vitro study demonstrated that this modification of the surface supported a significantly larger extension of the fibrin clot formation when compared with two control surfaces.[136] In dogs it was shown that a higher percentage of new bone was formed on this type of surface compared with plasma-sprayed and turned surfaces.[137] Finally, in retrieved human implants, observed BIC values varying from 55% to 96%, 6 to 8 weeks after implantation of nanostructured implants, were observed.[138]

Covering titanium implants with TiN was proposed to obtain a surface less susceptible to the release of ions. This is possibly the result of a "physical vapor deposition" that produces a thin TiN layer (about 1 µm), which has a similar histological response to titanium. This layer is responsible for an increase in the corrosion resistance, reduces the bacterial adhesion, and confers a golden aspect to the implant, which can be useful in esthetic zones because the color of these implants is more easily covered by the peri-implant soft tissues.[139-144]

Laser ablation is a technique that can be used to produce a surface with predetermined reproducible characteristics. Implants were modified to produce a controlled, micron-sized surface, with topographical features on the flanks of the threads. These implants demonstrated a significantly greater BIC and greater peak removal torque values compared with a turned surface (BIC values of 40% and 32%, respectively).[145,146] Further studies are necessary to evaluate the responses to this treatment.

$CaPO_4$ coating is also being widely studied because of its chemical bonding property, similar to HA, which seems to result in an improvement in bone response during the healing phase.[147] Biphasic $CaPO_4$ and tricalcium phosphate (TCP) have been studied to evaluate their use in implant coating[148-150]; however, the optimal coating is not yet reported.[151,152]

It is important for the clinician using implants on patients that many studies investigating the biological responses to different surface topographies are performed under in vitro conditions. Although this kind of study is consistently important to clarify the mechanism of interaction between a surface and specific type of cells, the clinical relevance of these results is believed to be low, and the development of long-term clinical evaluations is fundamental. Ideally, those experiments should be designed in humans as randomized controlled trials (e.g., if each hemiarch of one patient is randomly designed to allocate an implant of a specific surface).[153] Different implant topographies seem to influence the outcome of dental implants, but the magnitude and clinical relevance of this influence are

WWW.HIGHDENT.IR

still being investigated. Based on randomized controlled trials available in current literature, Esposito et al.[154] concluded no evidence shows that any particular type of dental implant has superior long-term success. However, the authors report that those findings were based on "a few studies, often at high risk of bias, with few participants and relatively short follow-up periods" and suggest that "more randomized controlled trials should be conducted, with follow-up of at least 5 years including a sufficient number of patients to detect a true difference if any exists." Thus clinicians should consider that, even if several new surface treatments have been proposed, only long-term results can be helpful to evaluate the real biological response of each given surface on the market.

Chapter 28

Bone Response to Mechanical Loads

Girish Ramaswamy, Martha Warren Bidez, Carl E. Misch

In an effort to optimize the interaction between bone and dental or skeletal implants, many researchers have focused their attention on the implant-tissue interface.[1-19] The importance of the events that take place at the interfacial "zone" between an implant and the host tissue cannot be overstated. This complex interaction involves not only biomaterial and biocompatibility issues but also the alteration of the mechanical environment that occurs when placement of an implant disturbs the normal physiological distribution of forces, fluids, and cell communication. The purpose of this chapter is to describe the current state of understanding regarding the biological and biomechanical response of bone to mechanical loads, with particular emphasis on the dental implant–bone interface.

BIOLOGICAL RESPONSE

The implant-tissue interface is an extremely dynamic region of interaction. This interface completely changes character as it goes from its genesis (placement of the implant into the prepared bony site) to its maturity (healed condition). The biomechanical environment plays an immediate role in the quality and compositional outcome of the new interface. For example, extensive research shows that if the implant is stable in the bone at the time of placement, then the interface is more likely to result in osteointegration.[15,20] Relative movement (or micromotion) between the implant and the bone at the time of placement is more likely to favor the development of a fibro-osseous interface.[11,18] The healing stage of the interface, however, is only the beginning of its dynamic nature. Functional loading of the implant brings additional biomechanical influences that greatly affect the composition of this junction.

A topic of intense research for many years is the transduction of loading-induced strain at the interface into a signal that can direct the interfacial tissues to respond or remodel. It has been proven that bone responds to both hormonal and biomechanical (functional loading) regulation. These two regulating mechanisms are often in opposition to each other. Research has shown that even in instances in which a large demand exists for calcium (the primary objective for hormonal regulation), functional loading can compete and maintain bone mass.[21] Researchers have theorized that the actual strain (see Chapter 23) that is perceived by the bone tissue initiates a chain of events that results in a biological response. For tissue strain to influence bone adaptation at the bone-implant interface, it must elicit some sort of a chemical or biological response in a strain-sensitive population. The current hypothesis is that bone cells in conjunction with the extracellular matrix comprise the strain-sensitive population and that each plays a vital role in the mediation of the interface. Based on this rationale, the objective of a good implant design would be to establish and maintain a strain environment within the host bone tissue and at the interface that favors osteointegration of the implant.

MECHANOTRANSDUCTION

Mechanotransduction is a multistep process that includes (1) mechanocoupling (transduction of mechanical forces into signals sensed by sensor cells), (2) biochemical coupling (conversion of mechanical signal into a biochemical signal to elicit a cellular response such as gene activation), (3) transfer of a signal from sensor to effector cells, and (4) the effector cell response.[22] Recent studies have led to the current consensus that osteocytes embedded within lacunae in bone matrix act as mechanosensors and help translate mechanical loads into biochemical signals.[23-25] Osteocytes are the most abundant cells and inhabit an extensive lacunocanalicular network that enables them to communicate with other osteocytes, as well as with periosteal and endosteal osteoblasts.[24-26] Furthermore, osteocytes have higher sensitivity to mechanical stimulation than osteoblasts.[27-29]

The strains experienced at the tissue level in vivo during normal activities (0.04% to 0.3%) are much less than the strain levels (1% to 10%) required to elicit a cellular response.[30,31] Initially, shear stress caused by

WWW.HIGHDENT.IR

fluid flow in the canalicular spaces was believed to be the primary driver of biochemical coupling in bone, with strain being the dominant stimulus.[23,32] Later, You et al.[33] proposed a model for the amplification of physiologically induced strains to levels that would initiate intracellular biochemical responses. The model suggested that drag forces on the transverse tethering fibers[34,35] during fluid flow through the pericellular space (filled with matrix between osteocyte cell membrane and canalicular wall) will produce a tensile stress, which will in turn create a hoop strain in the intracellular actin cytoskeleton that is two orders of magnitude higher than the strains at the whole-bone level. This model was further modified using updated ultrastructural data on the cytoskeleton, transverse tethering fibers, and their structural rigidity.[36] Cowin[37] compared and reviewed the two models by focusing on the relationship between the bone microstructure and the mechanism by which osteocytes sense the fluid flow as the result of mechanical loading. Possible mechanoreceptors, mechanisms by which osteocytes sense mechanical stimuli, and intracellular signaling pathways are discussed in several research groups.[38-40] Regulation of osteoblastic activity by osteocytes has been proposed to occur through gap junctions,[41-44] with the stimulation of gap junctions mediated by prostaglandin E_2 (PGE_2).[45-49]

Loading of bone decreases osteocyte apoptosis, whereas disuse and supraphysiological strains increases it followed by haversian remodeling.[50-52] Bone disuse, even for short durations, may rapidly induce a hypoxic state of stress in osteocytes, which when extended may lead to apoptosis. This hypoxia can be reversed by short-term physiological loading, which suggests that mechanical loading at such magnitudes plays a key role in osteocyte viability.[53] This may adversely affect bone strength independent of bone loss.[54] Hypoxic osteocytes may also mediate disuse-induced bone resorption by increasing osteopontin expression.[55]

Biomechanically Based Bone-Remodeling Theories

Biomechanically based bone-remodeling theories largely fostered the desire to optimize the effects of strain at the bone-implant interface to encourage osteointegration. In 1887, Meier[56] described the systematic structure of trabecular bone in the femoral head. In 1892, Wolff[57] described these events as a law of nature and stated that the trabecular bone will place or displace itself in relationship to the functional pressures. In 1895, Roux[58] suggested that the tissue changes to loading were a result of a cellular-regulation process. Frost[59] proposed the theory of the mechanostat. He postulated that bone mass is a direct result of the mechanical use of the skeleton. This agrees with Wolff's law[57] that essentially states, "form follows function." Frost established a mechanical-adaptation chart relating trivial loading, physiological loading, overloading, and pathologic loading zones to ranges of microstrain (Figure 28-1). His studies showed that strains in the range of 50 to 1500 microstrain (με) stimulated increases in cortical bone mass until the strains were reduced to the threshold range (or minimum effective strain). This process of the mechanostat would effectively switch the bone modeling *on* and *off*. This phenomenon led him to the flexure drift hypothesis in which he proposed that long bones (e.g., femur) were geometrically curved to minimize the strain distribution down the long axis of the bone.[60] Frost suggested that the curvature of the long bones canceled the bending moment caused by the eccentric pull of the muscles.

Bone may reduce strains by bone apposition or reduction, by bone formation or resorption, and by changing modulus of elasticity or stiffness by changing mineral content.[61-63] Necrosis of bone cells appears to determine the upper equilibrium level. Cell destruction can be observed when stresses exceed 6.9×10 N/mm^2, whereas a stress of 2.48×10 N/mm^2 will cause an increase in bone growth.[64]

Turner et al. [23] and Turner[65] summarized the rules governing bone adaptation as (1) dynamic (not static) loading drives bone adaptation; (2) short-term loading has an anabolic effect, whereas increased duration degrades bone adaptation; and (3) abnormal strains evoke bone adaptation, whereas bone becomes accustomed to routine strains and remodeling ceases.

Dynamic loading has consistently been found to have more osteogenic potential than static loading.[66] Dynamic axial loading for short durations, which produced strains within the physiological range that were added to normal activity, led to adaptive straightening of growing rat

ulnae. Reduced and increased periosteal bone formation were observed at moderate and higher peak strains, respectively.[67] Similar studies observed adaptive osteogenic response to be proportional to the strain rate and local surface strain.[68-69]

Contrary to the previously stated anabolic responses by rat ulna, both static and dynamic axial loading have been found to cause a reduction in longitudinal bone growth.[70,71] Growing male rats[70] receiving 10-minute bouts of static loading at 17 N, static loading at 8.5 N, or dynamic loading at 17 N exhibited shorter bone growth than the controls. The suppression was mainly visible in the hypertrophic zone and was proportional to the load magnitude. A later study[71] investigated the growth plate biology after the application of three different compressive loads (4 N, 8.5 N, and 17 N) for 10 min/day for 8 days on rat ulnae. The longitudinal mineralization rate was completely suppressed and never recovered in the 17-N rats, whereas other groups showed significant suppression that recovered within 1 week after loading. From their results, the authors suggested that even low-magnitude compressive loads suppress growth rate (Figure 28-2), which supported Hert's proposal[72] and deviates from Frost's chondral growth force response curve.[73]

Studies show that adaptive osteogenic response attains saturation after the initial few cycles during continuous cyclic loading, despite further increases in magnitude of load and cycle number.[74] Dynamic loading in short bouts (i.e., with rest periods inserted between loading) have been found to induce an increase in the number and activity of osteoblasts[75,76] and enhance osteogenesis in normal and aged skeletons[76-79] during normal activities such as walking. This consequently improves the biomechanical integrity of the bone despite only slight increments in bone mineral density and content.[80] Rest-

Figure 28-3 Summary of recent studies on anabolic effects of rest insertions between mechanical loading cycles. *(Adapted from Gross TS, Poliachik SL, Ausk BJ et al: Why rest stimulates bone formation: a hypothesis based on complex adaptive phenomenon,* Exerc Sport Sci Rev *32:9-13, 2004.)*

inserted loading decreased the threshold for lamellar bone formation,[81] reduced the number of cycles required to stimulate bone formation, and promoted an increased osteogenic response at any load magnitude (Figure 28-3).[82] Recently, Gross et al.[82] hypothesized that rest periods between each cycle in cyclic loading enhances fluid flow through the canalicular network, thereby extending the communication range of osteocytes by improving transport of signaling molecules between them. Furthermore, rest-inserted loading may also turn on synchronized activity among osteocytes.

Osteogenic response has been found to vary with respect to anatomical site and even at different regions within the same bone. Axial compressive dynamic loading of adult female rat ulnae led to greater periosteal lamellar bone formation distally and lower bone formation proximally when compared with middiaphysis. Strain thresholds and periosteal lamellar bone formation correlated with the peak strains experienced in rat ulnae being higher distally than proximally with intermediate values at the diaphysis.[83] Results from a previous study showed that treadmill exercise increased cancellous bone at the distal tibia more markedly than the proximal tibia, whereas vertebra showed no change.[84] A more recent study in mice revealed that the metaphyseal region in

WWW.HIGHDENT.IR

the distal femur showed an increased osteogenic response as compared with the cortical bone at the middiaphysis.[85] Loading of the knee increased bone formation and mineral apposition on the medial side of the tibial diaphysis compared with the lateral and posterior sides.[86]

Small increases in such mechanical signals to which bones are exposed during regular activities such as standing produce a local, rather than systemic, adaptive anabolic response in cancellous bone without any effect on cortical bone.[87,88] Anabolic effects on trabecular bone were attributed to an increase in bone mineral content and trabecular number, whereas decreases in trabecular spacing indicated the creation of new trabeculae and thickening of existing ones. In addition, researchers observed the adaptation of trabecular bone from rod shaped to plate shaped, primarily in the weight-bearing direction, consequently exhibiting increased strength and stiffness when measured longitudinally.[89] Short bursts of such stimuli inhibit bone resorption by reducing osteoclastic activity and concurrently increase bone formation, maintaining the bone matrix properties.[90] This anabolic response is not controlled by matrix strain magnitude but by applied frequency.[91] Controlled compressive load producing a peak pressure of 1 MPa was applied for 10, 25, or 50 cycles/day at a frequency of 0.5 Hz for 1 month on the distal femoral condyles of rabbits. The loaded limbs showed increased bone volume fraction, trabecular thickness, mean intercept length, and mineral apposition rate when compared with unloaded contralateral limbs.[92] Such low-magnitude, high-frequency mechanical signals (whole-body vibrations) have high potential in the treatment of osteoporosis.[93]

Mechanical stimulation has also been used to accelerate bone formation during fracture and trauma. In vivo dynamic axial compression loading of low magnitude after a short delay increased the strength of fracture callus, whereas immediate loading and shear movement inhibited and delayed the healing process.[94,95] Alternate axial compression and distraction, called *dynamization*, was found to be more effective than either technique applied alone; this combination stimulated callus at both central (influenced by distraction) and peripheral (influenced by compression) regions in a closed transverse fracture in rat tibiae.[96]

Indicators of the Biological Response

The characterization of the biological responses resulting from cellular deformation is equally as diverse as the deformation methodologies. These include changes in the concentration of intracellular mediators and cellular proliferation.

Changes in Concentration of Intracellular Mediators

Numerous investigators have reported fluctuation in the concentrations of intracellular second-messenger molecules.[97-112] In general, cell surface receptors relay information by activating a chain of events that alters the concentration of one or more small intracellular-signaling molecules often referred to as *second messengers* or *intracellular mediators*. In turn, these messenger molecules pass the signal on by altering the behavior of selected cellular proteins. Some of the most widely used intracellular mediators are cyclic AMP (cAMP), Ca^{2+}, and cyclic GMP (cGMP).[113] PGE_2 and prostacyclin are paracrines that are released by osteoblasts in response to mechanical strain.[97,104-108] They are essential for bone formation by mechanical loading[114-119] and are also increased by fluid shear stress[120-125] in a dose-dependent manner. The anabolic effect of mechanical stimulation in vivo has been shown to be greatly depressed by the addition of indomethacin, a chemical that blocks the production of these prostaglandins (PGs).[109] Increase in messenger ribonucleic acid (mRNA) of c-fos and insulin-like growth factor 1 (IGF-1) in osteocytes immediately after mechanical stimulation led to the study involving compressive dynamic loading of the eighth caudal vertebrae in rats. When indomethacin and N^G-monomethyl-L-arginine (L-NMMA), inhibitors of PG and nitric oxide (NO), respectively, were administered individually, c-fos (a marker for mechanical responsiveness in osteocytes) was suppressed partially, whereas combined administration resulted in drastic suppression.[126] This suggested that PG might be produced by NO-dependent and NO-independent mechanisms. Rats injected with NO donors showed increased osteogenic response only when loaded, which suggested that NO requires other molecules such as PG induced by mechanical loading for bone.[117] Human bone cells from osteoporotic patients subjected to pulsating fluid flow showed reduced long-term release of PGE_2, suggesting that long-term adaptive response of these bone cells to mechanical stimuli may have been affected.[127]

Harrell and Binderman[99] observed that isolated osteoblasts, grown on a polystyrene plate that had an orthodontic jackscrew glued to its bottom, responded to continuous strain by increasing PGE_2 concentrations followed in minutes by an increase in cAMP release. Rodan et al.[100] agreed that mechanical strain affected the second-messenger cAMP and also reported changes in cGMP and calcium ions. Yeh and Rodan[97] suggested that PGs might be involved in the transduction of mechanical strain but did not apply physiological levels of strain to their samples. Fluid shear experiments by Reich and Frangos[101] and cyclic biaxial strain studies by Brighton et al.[98] have demonstrated that osteoblasts respond with an increase in cellular levels of inositol triphosphate.

Osteoblasts form bone by secreting many extracellular matrix proteins, including type I collagen, osteopontin, osteocalcin, osteonectin, biglycan, and decorin. Osteopontin was first purified from rat bone matrix and is considered to play an important role in the

WWW.HIGHDENT.IR

cascade of events required for the formation of bone matrix.[110] In vitro studies have revealed osteoblasts to be more responsive to fluid forces than mechanical strain, associating increased osteopontin expression with increases in force magnitude without any dependence on strain magnitude or rate.[128] Recently, experiments on the femoral epiphyses of rabbits have shown that cyclic loading can influence endochondral bone formation by accelerating formation of secondary ossification centers, increase expression of RUNX2 (an important transcription factor of osteoblasts) and extracellular proteins including osteopontin, type X collagen, and decorin.[129] Osteocalcin, also known as *bone Gla protein*, is widely used as a marker for bone metabolism. Studies have shown that the production of osteocalcin can be stimulated by mechanical stress both in vivo[112] and in vitro.[113] Experiments on bone marrow stromal cells have revealed that shear caused by fluid flow enhances maturation of osteoblasts by stimulating the expression of osteocalcin,[130] osteopontin, and bone sialoprotein[131] but not proliferation of stromal cells.

Parathyroid hormone (PTH) has been found to play a vital role in bone adaptation to mechanical stimuli. Rats with thyroparathyroidectomy did not show any osteogenic response caused by mechanical loading of vertebrae,[132] but the response could be restored by a single PTH injection before loading. However, the restoration did not occur when PTH was injected 3 days after mechanical stimulation. Expression of c-fos was observed only in loaded rats injected with PTH,[132] further highlighting the importance of PTH in mechanical adaptation of bone. In vitro studies on mouse osteoblasts provided further insights into the interactive effects of PTH and pulsating fluid flow on PGE_2 and NO production. Although fluid flow stimulated a twofold rise in PGE_2 and NO production, PTH induced a similar effect on PGE_2 but reduced NO production by degrading the enzyme activity of NO synthase. When applied together, the stimulatory effects of fluid flow were nullified. According to the authors, the results suggested that PTH enhances NO-independent PGE_2 production but inhibits stress-induced NO production by degrading NO synthase, in turn reducing NO-dependent PGE_2 production.[133] PTH may also regulate mechanotransduction by influencing the influx of extracellular calcium in hypotonic osteocytes.[134]

Changes in Cellular Proliferation

As previously discussed, the response of osteoblast-like cells to mechanical strain has been shown to be variable. Many studies have reported increases in cell proliferation,[98,102,135-137] total protein production, and DNA synthesis[135,136,138,139] in response to mechanical strain. A review by Burger and Veldhuijzen[31] suggested that at high magnitudes of strain, osteoblasts proliferate and decrease their production of osteoblast phenotypic markers, such as alkaline phosphatase and bone matrix proteins. At lower magnitudes of strain, osteoblasts exhibit a more differentiated state, with an increase in alkaline phosphatase and matrix protein production and a decrease in proliferation. Strains of physiological magnitude (1000 με) applied by cyclic dynamic stretching on human osteoblast cultures increased cell proliferation and osteoblast activities related to matrix production but decreased alkaline phosphatase and osteocalcin release.[140-142] Frequency and cycle number affect proliferation of bone cells and expression of various osteoblast genes in a different manner.[143,144] Applying uniaxial strain at a constant frequency, the cell number increased up to 1800 cycles. At a constant cycle rate, frequency variation produced only slight differences. Frequencies of 1 Hz and 300 cycles were optimum, having the maximum positive effect of cell proliferation.[144]

In addition to experiments correlating increased proliferation with increased or altered strain levels, several investigators have focused their attention on the timing of the proliferative response. Studies conducted by Lanyon[145] have shown that cellular metabolism is activated within the first few minutes of loading. Raab-Cullen et al.[146] investigated the pattern of gene expression in the tibial periosteum shortly after in vivo controlled external load application. They documented that mRNA expression was altered within 2 hours after loading and that the pattern of specific mRNA expression first reflected proliferation and subsequently differentiation. Cyclic equibiaxial stretching[147] of 7-day osteoblast cultures increased apoptosis independent of the strain range (0.4% to 2.5%), whereas more mature cell culture (2 weeks) increased proliferation. This study revealed the importance of the differentiation stage of osteoblasts in their response to mechanical stimulation.

Chondrogenesis at the periosteum of long bones possesses both osteogenic and chondrogenic potential and holds clinical significance in the repair of articular cartilage and in fracture healing.[148-151] Dynamic fluid pressure was found to increase proliferation of periosteal chondrocytes from immature rabbits in vitro.[152] The possible chondrogenic effects stimulated by continuous passive motion of joints after periosteal arthroplasty via dynamic fluid pressure were investigated using periosteal explants suspended in agarose gel. Low-level pressure application increased chondrogenesis and type II collagen in a dose-dependent manner, whereas high-pressure completely inhibited these activities.[153]

Changes in Cellular Morphology and Organization

Ives et al.,[154] using human and bovine endothelial cells, found that the cells responded differently to various types of strain. The cells oriented themselves parallel to the direction of shear strain induced by fluid flow but perpendicular to the axis of mechanical deformation on a cyclically stretched polyurethane membrane. Investigations by Buckley et al.,[136] using osteoblast-like cells stimulated by cyclic mechanical strain, also resulted

WWW.HIGHDENT.IR

in the alignment of the cells perpendicular to the strain vector. This perpendicular alignment was noted at 4 hours after loading and was significant by 12 hours. They suggested that the preferred orientation might have resulted from a mechanical effect on the osteoblast, wherein cell attachments were broken in the maximum strain direction, leaving only those attachments already present in the least strained conformation. A second hypothesis suggested that the cells may have resolved their focal contacts and migrated in an attempt to minimize the strain to which they were subjected.

Another study involving osteoblast-like cells was reported by Carvalho et al.[155] They investigated cytoskeletal organization in mechanically strained alveolar bone cells isolated from the alveolar processes of Sprague-Dawley rats. The earliest change in cytoskeletal organization was noted at 30 minutes after the initiation of strain. They observed that the cells oriented themselves perpendicular to the long axis of the applied mechanical strain.

In vitro studies on osteoblastic and osteocytic cell lines subjected to unidirectional and oscillatory fluid shear stresses showed that stress fibers formed and aligned in osteoblasts within 1 hour of unidirectional stress but were delayed in the latter type of stress. Osteocytes show alignment for unidirectional stress and dendritic morphology for oscillatory stress only after 24 hours.[156]

Altered Expression and Reorganization of Osteoblast Integrins

Although changes in the distribution of the cytoskeleton in mechanically strained cells have been reported, the exact mechanism for the initial detection and transduction of mechanical force into a biological signal has yet to be determined. One possible transduction pathway is the extracellular matrix integrin cytoskeletal axis.[22,155,157] To understand how the cells interact with the extracellular matrix, attention must be given to the nature of the attachment.

Integrins are the primary receptors used by animal cells to attach to the extracellular matrix,[158] and they function as transmembrane linkers that mediate bidirectional interactions between the extracellular matrix and the actin cytoskeleton. Integrins are composed of two noncovalently associated transmembrane glycoprotein subunits called α and β, both of which contribute to the binding of the matrix protein. Electron micrographs of isolated integrins suggest that the molecule has approximately the shape shown in Figure 28-3, with the globular head projecting more than 20 nm from the lipid bilayer. After the binding of a typical integrin to its ligand in the matrix, the cytoplasmic tail of the β chain binds to both talin and α-actinin and thereby initiates the assembly of a complex of intracellular attachment proteins that link the integrin to actin filaments in the cell cortex[37,158] (Figure 28-4). This process is thought to be how local

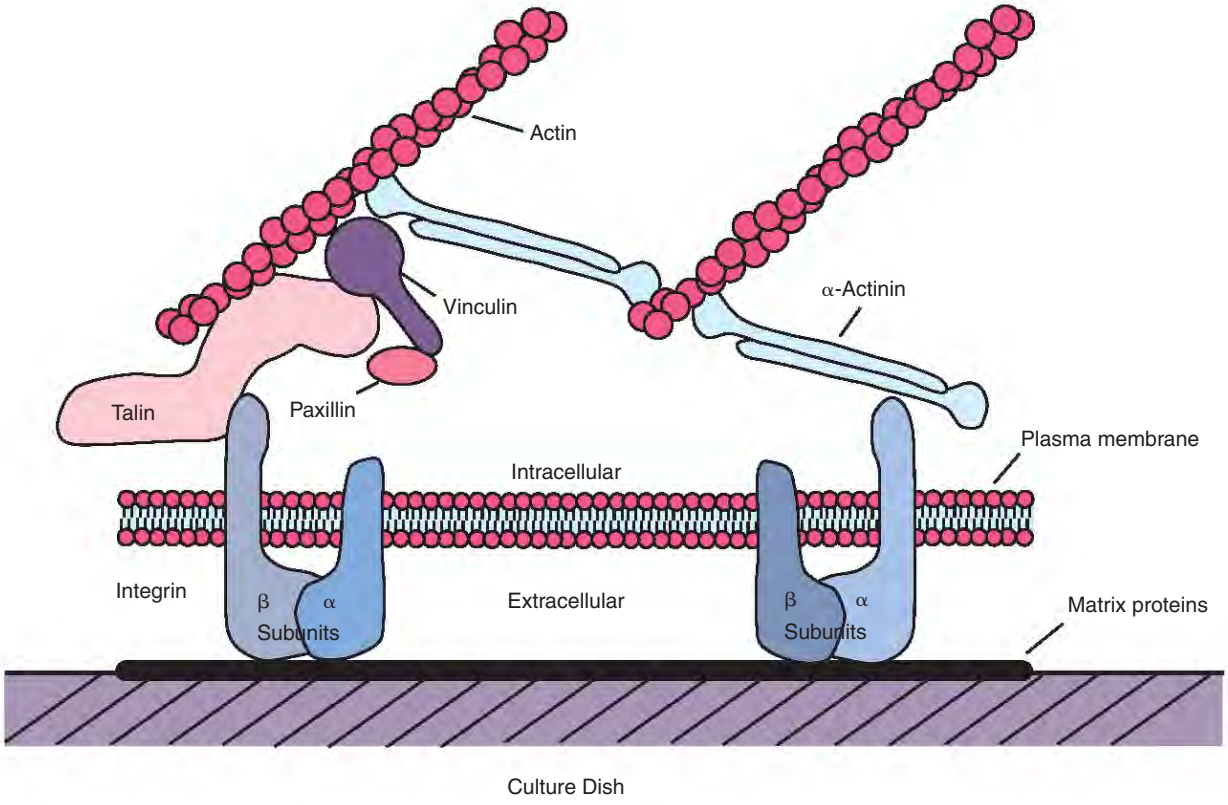

Figure 28-4 Diagram illustrating cytoskeletal components at point of attachment with extracellular matrix in vitro. *(Adapted from Duncan RL, Turner CH: Mechanotransduction and the functional response of bone to mechanical strain,* Calcif Tissue Int *57:344-358, 1995.)*

WWW.HIGHDENT.IR
انجمن دندانسازان و دندانپزشکان

contacts form between cells and the extracellular matrix. If the cytoplasmic tail of the β chain is removed or mutated using recombinant DNA techniques, then the integrins can still bind to the matrix, but the strength of the bond is decreased and the integrins no longer cluster at the focal contacts.[158]

The connection between integrins and the actin cytoskeleton is considered to be a possible pathway for sensing mechanical signals and producing a response in bone.[159-161] The interactions that integrins mediate between the extracellular matrix and the cytoskeleton play an important part in regulating the shape, orientation, and movement of the cells.[162] Schwartz and Ingber[163] suggested a direct link between mechanical strain and cellular response. Integrins of endothelial cells subjected to shear stress were shown to realign with the direction of flow, suggesting that cell adhesion is a dynamic process responding to mechanical strain.[164] Wang et al.[165] demonstrated that a physical strain applied directly to integrins using a magnetic twisting device was shown to be resisted by the cytoskeleton. Pavalko et al.[161] performed in vitro studies on MC3T3-E1 osteoblasts to analyze the role of actin and actin-membrane interactions in altering gene expression because of mechanical loading. Observations of reorganization of actin filaments into contractile stress fibers, formation of focal adhesions, and recruitment of β_1-integrins and α-actinin to focal adhesions revealed a critical role played by actin cytoskeleton in altering gene expression (upregulation of COX-2 and c-fos) in osteoblasts as a response to fluid shear stress. Increase in the number and size of stress fibers and focal adhesion complexes associated with mechanical strain indicated a combined change in both cytoskeleton and extracellular matrix favoring tighter adhesion of osteoblasts to the latter.[160] Both cell adhesion and mechanical stimulation induce expression of integrin-binding proteins—osteopontin, fibronectin, and bone sialoprotein—by osteoblasts but via different mechanisms at different time frames after stimulation. Although strain-induced (dynamics biaxial strain of 1.3% at 0.25 Hz) osteopontin expression was dependent on cytoskeletal integrity, cell adhesion was not.[166-168] These observations indicate that the extracellular matrix integrin cytoskeletal system may be part of the cascade responsible for the transduction of mechanical strain into a biological response.

Other studies have shown that several intracellular signaling pathways are activated coincident with a clustering of integrins at the focal contacts between the cells and the matrix. These clustered integrins may generate intracellular signals by initiating the assembly of a signaling complex just inside the plasma membrane, similar to that of growth factor receptors. Many cells in culture will not respond to growth factors unless the cells are attached via integrins to the extracellular matrix molecules.[158,169] Recent investigations have related the extracellular signal-regulated kinase (ERK) pathway (one of the mitogen-activated protein [MAP] kinases identified) to growth and differentiation of osteoblasts,[170] differentiation of mesenchymal stem cells toward osteogenic lineage,[171] and also mechanotransduction.[172-179] Fluid flow applying physiological strain levels on human osteoblasts rapidly induced ERK phosphorylation and clustering of $\alpha v\beta_3$ integrins in vitro,[176] whereas the mechanism behind the regulation of osteocyte apoptosis by mechanical stimulation involves and requires the activation of an integrin/cytoskeleton/Src/ERK pathway.[179] These results have led researchers to suggest that both mechanical (e.g., fluid flow, cyclic stretching) and chemical (e.g., hormones, growth factors) stimuli may act through the same intracellular signaling pathways.[176,179]

Numerous subunits have been characterized, and different combinations of α and β subunits function as receptors for a variety of extracellular proteins.[180,181] The β_1 integrin subunit is often expressed in bone cells both in vitro and in vivo.[181] Carvalho et al.[155] demonstrated that changes in the organization of the β_1 subunit were induced by the application of strain as early as 4 hours from its onset. They compared the expression of the β_1 integrin subunit mRNA from strained cultures with unstrained controls.

CHANGES IN GENE EXPRESSION

To characterize the biological response of osteoblast-like cells to external mechanical loading, many researchers are investigating strain-induced alterations in patterns of osteoblast gene expression. Several authors have reported that the initial response to strain is a rapid increase in c-fos mRNA expression, indicative of increased proliferation, paired with a rapid decline in levels of mRNA encoding bone matrix proteins, such as type I collagen, osteopontin, and osteocalcin.[146,182] A "rebound" effect or reversal of this trend is usually seen with time as the proliferation tapers off, accompanied by an increase in expression of the matrix proteins.[146,182-184]

The term *matrix proteins* refers to both collagenous and noncollagenous proteins. Type I collagen is the most abundant protein in the organic matrix of bone. This molecule is composed of one α_2 and two α_1 chains. These three chains are initially assembled into a triple helical structure within the cell and are subsequently bundled into fibrils once secreted from the cell. These extracellular fibrils are arranged in a specific, repeating orientation that produces the typical banded appearance common to type I collagen. Intermolecular cross-links stabilize this pattern and produce a porous, repeating, three-dimensional structure.[21] Active osteogenesis involves the expression of genes that result in the production of collagen type I protein.[184] This trait makes the type I collagen molecule a valuable indicator of differentiated osteoblastic activity. Cyclic pressure increases mRNA

WWW.HIGHDENT.IR

expression for type 1 collagen and accumulation of calcium by improving osteoblast function without affecting the cell number.[185] Cyclic stretching of rat calvarial osteoblasts increased collagen production at lower strains (500 με) and inhibited production at higher strain levels (1500 με).[186]

In the last 20 years, noncollagenous proteins have received increased attention. Researchers have suggested that these minor components of organic bone matrix may play a role in regulating bone function, expression, and turnover.

Osteocalcin (bone Gla protein) is a noncollagenous protein that binds calcium and has been isolated from bone, dentin, and other mineralized tissues. It is specifically synthesized by differentiated osteoblasts and, like type I collagen, is an ideal marker for osteoblast phenotypic expression.[187]

Another noncollagenous protein that is generating great interest is osteopontin. This bone sialoprotein is synthesized by primary osteoblasts and has been shown to play a role in cell attachment and spreading. Osteopontin contains a binding sequence that appears to be recognized by an integrin cell surface receptor related to the vitronectin receptor.[187]

Both osteocalcin and osteopontin are regulated by a number of hormones and growth factors. The most common promoter of osteocalcin and osteopontin expression and secretion is 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$), which directly influences the genes of both proteins. This is possible because the genes for both osteopontin and osteocalcin contain regions that recognize vitamin D.[183] A study by Harter et al.[183] analyzed the expression and production of bone matrix proteins in human osteoblast-like osteosarcoma cells in response to 1 to 4 days of chronic, intermittent, mechanical strain. Northern analysis for type I collagen detected an increase in collagen message after 48 hours of strain. Immunofluorescent labeling of type I collagen indicated that secretion was also enhanced. In the absence of vitamin D, osteopontin message levels were increased severalfold by the application of mechanical load. This increase in osteopontin expression was doubled when the cells were subjected to mechanical load in the presence of vitamin D.

Osteocalcin secretion was also increased with cyclic strain. Osteocalcin levels were not detectable in vitamin D–untreated control cells; however, after 4 days of induced load, significant levels of osteocalcin were observed in the medium. With vitamin D present, osteocalcin levels were four times higher in the medium of strained cells compared with unstrained controls. This study demonstrates that mechanical strain of osteoblast-like cells is sufficient to increase the transcription and secretion of matrix proteins via mechanotransduction without hormonal induction.[183] Osteoblasts in mechanically loaded mouse periodontium showed increased expressions of osteocalcin, type I collagen, and alkaline phosphatase.[188] The first two were more responsive and were found to be stimulated within a short time after loading. The authors suggested that mechanical stimulation drives rapid differentiation of committed osteoblast precursors to produce an anabolic skeletal adaptation.[189] Weight loading of chicks at the prepubertal stage led to development of shorter bones with narrower growth plates but with increased mineralization and vascular penetration. Increased osteopontin and matrix metalloproteinases (MMP9 and MMP13) led to the speculation by the authors that MMPs allowed greater penetration of blood vessels carrying osteoblasts and osteoclasts, whereas osteopontin increased osteoclast numbers, thereby increasing resorption at the growth plate region.[190]

Disruption of genes can alter the normal bone formation response to mechanical stimulation as observed in mice lacking thrombospondin 2[191] that showed contrasting behavior as compared with wild-type mice with increase in endocortical bone formation despite higher strains at the periosteal surface.

Frost[59] has reported that the mechanism for the biomechanical response of osteoblasts is not discrete. Osteoblastic products such as interleukin-1 (IL-1) can stimulate osteoblasts. He groups these cells as basic multicellular units (BMUs). These BMUs are most prevalent on periosteal and endosteal surfaces, and the periosteal BMUs are most sensitive to biomechanical stimuli.

Limitations of Previous Studies

Although these cell culture studies generate promise for the quantitative delineation of the mechanically induced cellular response of bone, the enthusiasm for all of these studies must be tempered in light of the experimental models that were used. Virtually all of these models used some form of polyurethane membrane, collagen ribbon, or silastic plate as the substrate on which the cells were grown and mechanically stimulated. Given the complex host-biomaterial interactions within the human body, the cellular response of isolated bone cells on polyurethane membranes or collagen ribbons may be significantly different from bone cells in intimate contact with a contemporary implant biomaterial, such as titanium or titanium alloy. Investigations are in progress to confirm the effects of mechanical strain on the cells of the bone-implant interface in an experimental system that allows growth of osteoblastic-like cells on the surface of an actual implant material.[192]

Additional limitations can be found in the methodologies mentioned previously. In many of the experiments, the imposed strains were not quantified. Some of the other studies that did report strain magnitudes used levels of strain that were either supraphysiological (>7000 με)[22] or subphysiological (<1500 με)[22] in nature.

The experimental techniques that have been discussed so far, such as strain gauges being applied to living bone, organ cultures, and cell culture, can provide illuminating data, but all the techniques have drawbacks and sources of error. Strain gauges are technique sensitive and are difficult to use with biological tissues because of moisture, heat, irregularity of surface, and sometimes poor access to the application site. Their application to animal models can introduce further complications caused by the unpredictability of the behavior of the animal. Movements and loads artificially created when the animal is anesthetized may not give accurate data concerning physiological loads, but the animal may pull wires loose when it is awake.

Organ culture analysis may retain some of the spatial accuracy needed to test strain in the matrix; however, perfusion is necessary to maintain the organ tissue, and not much working time exists before the organ culture dies. Isolated cell culture models can give very useful information related to the release of certain biological mediators in response to the cells' environment. However, again, organization has been lost, and this departure from the in vivo situation must be kept in mind when the results of such experiments are analyzed.

All of these experimental techniques are very valuable despite their individual drawbacks. When they are used in combination and their limitations are understood, helpful insight can be obtained and used to further understand functional loading and its biological ramifications.

BIOMECHANICAL RESPONSE

A compelling argument has been presented for strain-induced biological response of bone to mechanical load. The question remains: What controls the magnitude of strain imparted to the dental implant–bone interface?

Strain has been generically defined (see Chapter 21) in relation to deformation and applied stress. The discussion of strain must be necessarily extended for biological structures. The mechanical properties of the trabecular and cortical bone found within the oral environment exhibit a high degree of variation as a function of load direction, rate, and duration. In addition, the structural density of the bone has a significant influence on its stiffness (modulus of elasticity) and ultimate strength. As such, the mechanical strain exhibited in bone is ultimately a function of the bone density.

Dependence on Direction of Loading

The degree to which the mechanical properties of cortical bone are dependent on its structure is referred to as *anisotropy*. This concept is illustrated in Figure 28-5, which illustrates how a material may exhibit directionally dependent mechanical properties (e.g., modulus of elasticity). A material is said to be *orthotropic* if it exhibits different properties in all three directions and *isotropic* if the properties are the same in all three directions. *Transversely isotropic* describes a material in which two of the three directions exhibit the same mechanical properties.

Reilly and Burstein[193] and Yoon and Katz[194] have reported bone to be transversely isotropic (referring to Figure 28-5, E_1 and E_2 are the same). Knets and Malmeister[195] and Ashman et al.[196] have described bone as *orthotropic* (i.e., $E_1 = E_2 = E_3$). The mandible has been reported as transversely isotropic, with the stiffest direction oriented around the arch of the mandible[197] (see Figure 28-5). These authors suggest that cortical bone of the mandible functions as a long bone that has been molded into a curved-beam geometry. The stiffest direction (around the arch) thus corresponds to the long axis of the tibia or femur.

Early studies on the mandibular and supraorbital bone reported elastic constants of cortical bone in all three orthogonal directions at both locations to be different, suggesting the anisotropy of craniofacial bone. Comparing properties from both locations, mandibular bone along a longitudinal direction was stiffer than bone from a supraorbital region, which may be the result of a difference in function.[198] Cancellous bone in human mandible exhibited transverse isotropy by compression tests and symmetry along inferosuperior directions. Elastic modulus was greatest in the mesiodistal direction (907 MPa), lowest in the inferosuperior direction (114 MPa), and intermediate in the buccolingual direction (511 MPa).[199] Finite element (FE) analysis of mandibular bone around implants indicated an increase in stresses and strains because of anisotropy. A compressive and shear anisotropy of 3% and 1% in cortical bone and 40% and 38% for cancellous bone, respectively, increased stresses by 20% to 30% in the cortical crest. Although tensile and radial-hoop shear stress increased by threefold to fourfold in the cancellous bone along

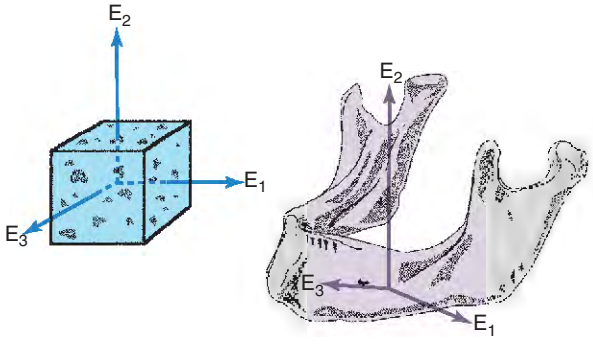

Figure 28-5 Cortical bone of the human mandible has been reported as transversely isotropic, with the stiffest direction oriented around the arch of the mandible (E_3). *(From Ashman RB, Van Buskirk WC: The elastic properties of a human mandible,* Adv Dent Res *1:64-67, 1987.)*

WWW.HIGHDENT.IR

the lingual side, anisotropy decreased radial-vertical interface shear stress by 40% on the buccal side near the apex in cancellous bone.[200]

Such data raise interesting questions regarding the primary loads that the mandible experiences: occlusal loads or flexural loads imposed during opening and closing of the mouth. Clinical experience has qualitatively revealed that the actual mandible has more compact bone at the inferior border, less compact bone on the superior aspect, and greater quality of trabecular bone, especially between the mental foraminae. In addition, the presence of teeth and/or implants significantly increases the trabecular bone amount and density within the residual alveolar bone. Several models have analyzed stress distributions around implants and supporting bone in mandible as an effect of differences in load directions.[201,202] Experiments and models have suggested that off-axial loads produced during occlusal loading produce higher strains in the cervical region and cause significant concern regarding crestal bone loss, cervical tooth loss, and failure of osseointegration.[203-205] Off-axial loads also induce adaptive bone remodeling around oral implants as shown by experimental and FE analysis in dog mandibles.[206,207] The experimental study revealed a significant remodeling difference between axial and nonaxial loading. Although axial loads produced a uniform and mild remodeling response that decreased from the coronal aspect to the apex of the implant, nonaxial loads induced more dynamic remodeling in the surrounding cortical bone and more severely in trabecular bone.[206] The FE analysis (incorporating vertical and horizontal loads and a moment) attributed this difference in response to the horizontal component of the stress experienced by the loads. Horizontal compressive stresses were found to induce more intense remodeling as compared with tensile stresses in the same direction. In addition, stress distributions revealed that stresses decreased from periosteum to endosteum in the cortical bone and then increased along trabecular bone toward the apex of the implant.[207]

Nanoindentation is a new method used to measure the material properties (hardness and indentation modulus) of bone at a microstructural level.[208-210] Cortical bone shows elastic anisotropy at a lamellar level as shown by nanoindentation experiments on human tibial cortical bone.[211] Indentation experiments in 12 different directions in three principal planes for osteonal and interstitial lamellae revealed variation in indentation modulus along different directions in each plane.[211]

At small strains, trabecular bone elicits a nonlinear response that varies with respect to the anatomical site and type of loading. The nonlinearity measured by the reduction in tangent modulus was found to differ based on mode of loading (tension or compression) and was positively correlated with density in tension. Yield strains are higher in compression than tension for trabecular

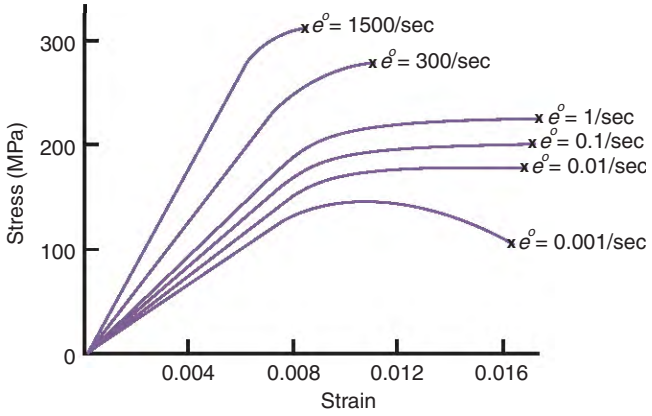

Figure 28-6 Strain rate dependence of bone. *(From McElhaney JH: Dynamic response of bone and muscle tissue,* J Appl Physiol *21:1231, 1966. Used by permission.)*

bone[212,213] in long bones. Microdamage is reported to occur before apparent yield in trabecular bone. Yield is said to occur at 88 to 121 MPa in compression and 35 to 43 MPa in tension at local principal strains of 0.46% to 0.63% for the former and 0.18% to 0.24% in the latter.[213] Comparison of apparent and tissue level yield strains in trabecular bone from femoral neck specimens by FE models revealed that apparent and tissue level yield strains were equivalent in tension but not in compression, and the equivalence was attributed to the highly oriented structure.[214] In compression, yield strains at tissue level were found to be 17% higher than at apparent level. This could lead to residual strains, local tissue yielding, and damage accumulation, degrading the apparent mechanical properties of trabecular bone.[215] Increase in compressive or shear strain could increase the number of microcracks but not the mean length. Any change in the mode of loading can cause cracks to propagate beyond microstructural barriers.[216]

Dependence on Rate of Loading

A material is said to be *viscoelastic* if its mechanical behavior is dependent on the rate of load application. McElhaney[217] investigated the strain rate dependence of bone (graphically illustrated in Figure 28-6). A significant difference can be noted in both ultimate tensile strength and modulus of elasticity over a wide range of strain rates, with bone acting both stiffer and stronger at higher strain rates. Restated, bone fails at a higher load but with less allowable elongation (deformation) at higher as compared with lower strain rates. Thus bone behaves in a more brittle fashion at higher strain rates. Bovine cortical bone has been found to be three to four times more brittle under dynamic load than under a quasistatic load. This brittleness was attributed to a possible shear stress on the fibers in the bone at a high-velocity loading.[218] A similar idea of a change in failure mode because of increasing brittleness at higher strain rates was observed in a study on a galloping horse.[219]

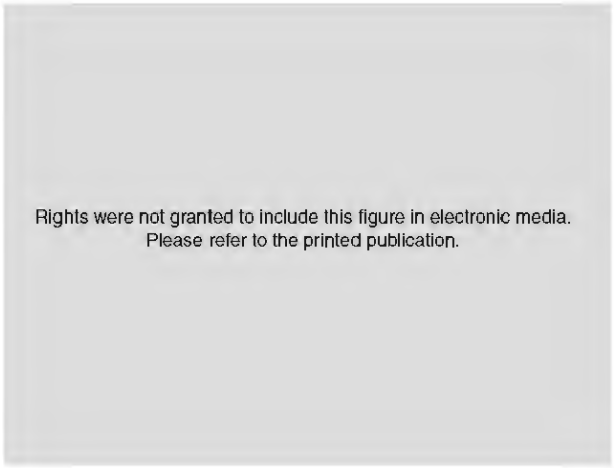

Figure 28-7 Creep curve for adult human cortical bone at constant stress of 60 MPa. *(From Carter DR, Caler WE: Cycle dependent and time dependent bone fracture with repeated loading,* J Biomech Eng *105:166, 1983. Used by permission.)*

Variations in properties such as stiffness, strength, and ultimate strain of human trabecular bone from proximal tibiae[220] and vertebrae[221] were explained using linear and power function relations to strain rate. When compared with compression, strain rate was found to have a higher effect on the change in trabecular bone properties in shear.[222]

Carter and Hayes[223] have reported both strength and elastic modulus of human bone to be proportional to strain rate raised to the 0.06th power. Strain rate to which bone is normally exposed varies from 0.001 sec^{-1} for slow walking to 0.01 sec^{-1} for higher levels of activity. Although closure speeds of the human mouth have been reported by one author,[224] no data are available regarding human mandibular or maxillary bone strain rates in vivo.

At a microstructural level, modulus measured by nanoindentation of human cortical bone (osteons and interstitial bone tissue) was found to increase with increase in loading rates.[225] The difference in modulus at different loading rates was observed to be higher that than predicted by early uniaxial tensile and compression studies at the continuum level.[220,226] However, a previous study investigating the viscoelasticity of cortical bone found modulus to be a function of strain rate raised to the 0.06th power,[227] which compared well with the early macroscopic studies.[226] Similarly, an increase in mechanical properties with increasing strain rates was found in cortical bone from lateral and medial aspects of human femur.[228]

Dependence on Duration of Loading

Carter and Caler[229] have described bone damage or fracture caused by mechanical stress as the sum of both the damage caused by creep or time-dependent loading and cyclic or fatigue loading and the relative interaction of these two types of damage.

Creep refers to the phenomenon whereby a material continues to exhibit increasing deformation as a function of time when subjected to a constant load. Carter and Caler[230] have reported the creep-fracture curve for adult human bone at a constant stress of 60 MPa (Figure 28-7). Over approximately 6 hours, a threefold increase in strain was observed. Such data raise the question of whether resorption and/or failure in the dental bruxer or "clencher" patient may be partially (or wholly) the result of an accumulation of creep damage.

Mixed results have been reported of the effects of creep on fatigue damage of trabecular bone. Although Moore et al.[231] concluded that creep does not contribute to fatigue failure in bovine trabecular bone except for possible effects on low-density osteoporotic bone, recent study on cadaveric vertebrae revealed that trabecular bone does not fully recover from residual strains[232] (time for complete recovery is twentyfold greater than duration of applied loads) caused by creep (static or cyclic loading) and may lead to nontraumatic fractures. Both static and cyclic loading led to similar residual strains of the order of magnitude of initially applied elastic strain. [232]

Fatigue strength of a material refers to an ultimate strength below which the material may be repetitively subjected for an infinite number of cycles without failure. Carter et al.[233,234] have investigated the fatigue properties of human cortical bone. Fatigue failure has been reported for in vivo bone at relatively low cycles (10^4 to 10^8 cycles).[235-237] Given the high magnitude of cycles encountered in oral function, the relatively low in vivo fatigue life reported in bone (i.e., accumulated fatigue damage) is likely accommodated in vivo through the normal process of bone remodeling.

Excessive cyclic loading of bones is known to cause microcrack growth and increase fracture risk.[238,239] Fatigue failure of cortical and trabecular bone has been characterized by a continuous reduction in modulus, with increasing number of cycles with a drastic drop closer to failure and increasing plastic strain. [229,230,240-242] Cortical bone has been observed to behave in an increasingly nonlinear form, with the cyclic energy dissipation increasing with number of cycles in both tensile and compressive cyclic loading.[240,243-245] Thresholds levels of 2500 με and 4000 με in compression were noticed, below which bone exhibited viscoelastic behavior and above which a microdamage accumulation started.[240] Resistance to fracture is a combination of resistance against initiation and propagation of cracks. Discontinuities in osteons and other features such as haversian canals or Volkmann's canals have been suggested to act as microstructural barriers and slow or stop the propagation of cracks.[245,246-252] Osteonal lamellae in cortical bone are hypothesized to play a key role in preventing propagation of smaller cracks, whereas they may be areas of weakness in cases of

WWW.HIGHDENT.IR

longer cracks.[253,254] Cortical bone typically exhibits cyclic softening during cyclic loading, which refers to the nonelastic strain amplitude greater than zero after the initial few cycles, along with a simultaneous rise in stress amplitudes (Figure 28-8). Because of viscoelastic behavior and crack formation, this value stabilizes after the initial few cycles but undergoes a drastic increase before the final failure owing to macroscopic crack growth.[245]

Models relating modulus reduction to microcrack growth have also been proposed.[255-257] Tests have supported a strain-based failure criterion in bovine trabecular bone, with maximum strain attained during the cyclic loading being a better indicator of normalized modulus and linearly related to secant modulus and residual strain.[258] A threshold of –0.5% was observed to attain plasticity in strain, change mechanical properties, and begin the accumulation of microdamage in cyclic and uniaxial compression loading.[259,260]

Rats subjected to external loads by orthodontic tooth movement at different times of the day were found to exhibit increased bone formation on the side experiencing tension and increase in osteoclast formation on the compression side during light periods than dark periods. Inhibition of proliferation and differentiation of chondrocytes by mandibular retractive force was also higher in light periods. Based on these results, the authors suggested that bones and cartilage are more metabolically active during rest periods than during activity; furthermore, orthodontic treatment by force application during rest periods may be more effective than when subjects are active.[261-263]

Dependence on Species and Anatomical Location

Large variations have been noted in experimental measurements of elastic modulus and ultimate compressive strength of trabecular bone. The strength of human mandibular trabecular bone[264] is lower than the proximal femoral trabecular bone reported in previous studies.[265] In the proximal part of the femur, the thickness of the cortical bone wall gradually reduces from the shaft to the metaphyseal region. At the femoral head, the cortical bone represents only a thin shell. Three sets of lamellae arrangement of cancellous bone can be observed in this region, and the cancellous network shows a sheet and strut architecture lined up along the compression and tension lamellae. The trabecular bone in this region is thus the primary structure to dissipate and transfer loads.

Trabecular architecture being either "rodlike" or "platelike"—depending on the anatomical site—could be responsible for the intersite differences.[266] Although vertebrae have the former architecture, femoral neck and proximal tibiae have the latter.[267] Experimental data suggest that rodlike structure is more susceptible to large

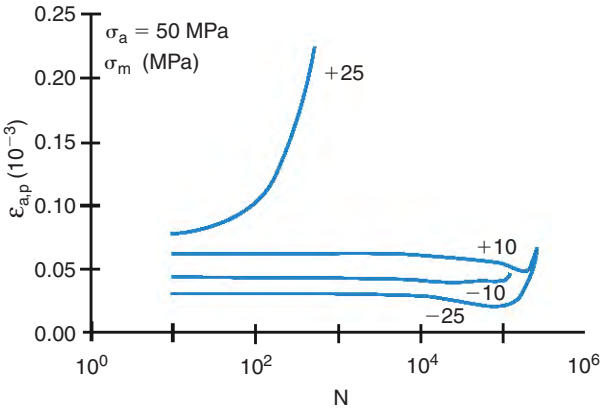

Figure 28-8 Increase in nonelastic strain amplitude with increase in mean stress and cycle number. *(Adapted from Fleck C, Eifler D: Deformation behaviour and damage accumulation of cortical bone specimens from the equine tibia under cyclic loading,* J Biomech *36: 179-189, 2003.)*

deformations by bending and rotation of trabeculae than platelike structures. A comparative study of compressive and tensile yield strains in trabecular bone from vertebra, the proximal tibia, the femoral neck, and the femoral greater trochanter revealed that compressive and tensile yield strains were higher at the femoral neck and vertebra, respectively, whereas yield strains within an anatomical site were found to vary less[266,268] despite huge variations in elastic modulus and yield stress.[266,269-271] Volume fraction (density) and architecture had very little effect in the variations of apparent-level yield strains, which was predominantly influenced by tissue yield strains.[213]

Nonlinearity of trabecular bone, measured as percent reductions in tangent modulus at 0.2% and 0.4% strains, was found to differ at four different sites—vertebra, proximal tibia, and proximal femora from human and bovine proximal tibia. The percent reductions were found to be higher in tension than compression at all sites at 0.4% strain and only in bovine proximal tibiae at 0.2% strain.[272] Occasional overloading of trabecular bone (up to 3% strain) degrades its mechanical properties and increases the risk of fracture.[273] This damage behavior may apply to lumbar and lower thoracic vertebral bodies that are predominantly occupied by trabecular bone and play an important role in causing vertebral fractures.[274] A study of different sites showed femoral neck to possess the highest resistance to fracture initiation for both tension and shear loading in a comparison among femoral neck, femoral shafts, and tibial shafts, whereas femoral shaft possessed the least.[275]

In the edentulous mandible, trabecular bone is continuous with the inner surface of the cortical shell. In the dentate mandible, trabecular bone is surrounded by a thick cortical shell and dense alveolar bone under the teeth. Finite element models of the human mandible[276,277] have shown that cortical bone plays a major role in the dissipation of occlusal loads. Thus load patterns on trabecular bone and microstructure

WWW.HIGHDENT.IR

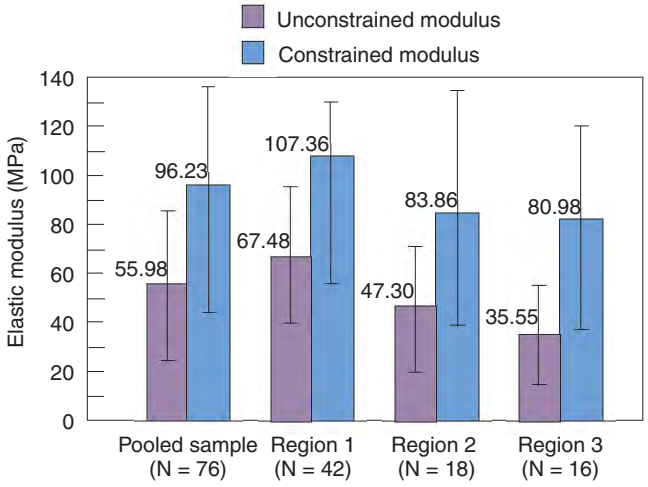

Figure 28-9 Ultimate compressive strength of human mandibular trabecular bone.

of trabecular bone may contribute to differences in the mechanical behavior of the mandible as compared with other anatomical regions. Given that implants do not routinely engage apical cortical bone, attention to trabecular bone mechanical properties is paramount.

Mechanical loads in the mandible are different from those typically experienced by long bones. In the long bones, such as the femur and tibia, loads are primarily axial. In contrast, muscle loads in the mandible may be large and include dorsoventral shear, twisting about the long axis of the mandible, and transverse, increasing in magnitude from posterior to anterior in the mandible.[278] The regional differences observed in the mechanical properties within the human mandible likely reflect the difference in load carried by the different regions of the mandible. With muscle attachments located posteriorly on the mandible, the anterior mandible experiences a large moment load, even in the absence of occlusal loads, caused by the buccolingual flexure of the mandible. Thus significantly higher densities are to be expected in the anterior as compared with posterior mandible. Study on the material properties of human dentate mandible and maxilla revealed regional and directional variations in the properties in both anatomical sites.[279,280] In mandible,[279] direction of maximum stiffness varied at different regions being parallel to occlusal plane at the corpus to vertical orientation at the ramus. Among the corpus, symphysis, and ramus—although symphysis had the thicker cortex, lesser density, anisotropicity, and stiffness—the ramus showed the opposite properties; the material properties of the corpus were between the two others. Such regional variations left questions about relationships between the material properties and mandibular function as suggested by the authors. Edentulation produces a change in all these material properties in the mandible.[281] In the maxilla,[280] alveolar regions were thicker, less dense, and less stiff, whereas cortical bone from the body of the maxilla was thinner, denser, and stiffer. Elastic properties, specifically principal stiffness direction, were more variable in the maxilla than the mandible. Stress and strain distributions along different orientations and between working and balancing sides of the mandible to gain a better understanding of its function augmented the previous studies. The results from the balancing side suggested bending and twisting of the mandible during mastication and transducer biting, whereas the working side was found to undergo torsion. Lingual aspect was stiffer than the buccal side.[282]

Although twofold to threefold higher bite (occlusal) forces are present in the posterior as compared with the anterior mandible, both apparent density and ultimate compressive strength of trabecular bone are lowest in the posterior mandible.[283] These data suggest that the large, multiple-root structure of molar teeth serves to dissipate such posterior occlusal loads as opposed to concomitantly higher ultimate strengths in the bone itself. Current clinical practice routinely places the same-size dental implant diameter and geometry in the posterior and anterior mandible. This practice appears contraindicated given the inherent strength variations within human mandibular bone.

Dependence on Side Constraint

The biomechanical response of trabecular bone in the mandible is highly dependent on the presence or absence of cortical plates as a "side constraint." Qu[264] showed a 65% higher stiffness (elastic modulus) for trabecular bone of the mandible when constrained by cortical plates as compared with unconstrained test values (Figure 28-9). In these tests, fluid was allowed to escape circumferentially so that stiffness trends were lower compared with additional hydrostatic stiffening effects afforded by a constraining test mode. These results are supported by the work of Linde and Hvid,[284] who reported a 19% greater stiffness of trabecular bone specimens (from the proximal tibia) tested when constrained by the surrounding trabecular bone compared with comparable unconstrained tests.

Dental implant patients exhibit variation in the integrity of the buccal and lingual cortical plates. In some instances, one or both plates are completely absent. Treatment planning for such patients should incorporate consideration of the significantly compromised mechanical stiffness (and likely, strength) of the trabecular bone in such anatomical sites.

Dependence on Structural Density

Trabecular bone is a porous, structurally anisotropic, inhomogeneous material. A 25-year literature base documents the work of numerous investigators,[285-296] who have reported in vitro data used in the development of mathematical relationships between elastic modulus and structural density, as well as ultimate strength and

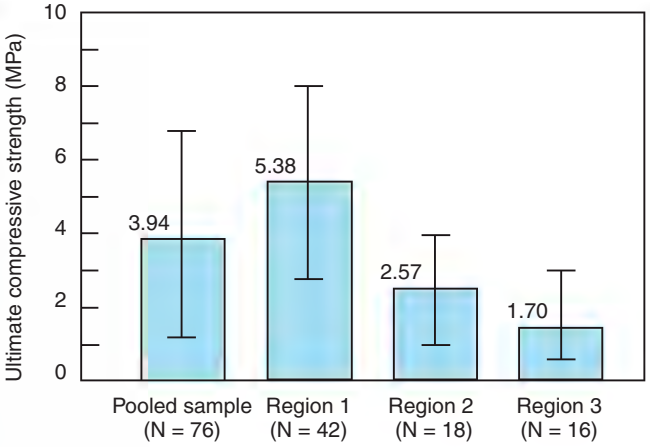

Figure 28-10 Elastic modulus for constrained and unconstrained test conditions in human mandibular trabecular bone.

structural density. Vertebral trabecular bone was found to be highly anisotropic and stiffer in the superoinferior direction,[297] suggesting that trabecular bone should not be considered transversely isotropic. The anisotropy was found to increase with decrease in apparent density to maintain stiffness in the load-bearing direction as suggested by the authors. In addition, structural Young's modulus in all three directions was found to have good correlations explained by power-law models with apparent density. Compressive yield strains of human vertebral trabecular bone depend on apparent density, whereas tensile yield strains do not.[298-300] Buckling of individual trabeculae dominates as the on-axis compressive failure mode at lower densities, whereas axial yielding takes over as the major failure mode at higher densities.[298]

Qu[264] specifically reported on the mechanical properties of mandibular trabecular bone. The study design used cylindric trabecular bone specimens (5 mm in diameter and 5 mm high) from the human mandible. These tests were mechanically tested in compression in the occlusal-apical direction and were performed at a constant strain rate of 0.01 sec^{-1} under both nondestructive and destructive testing conditions. In the nondestructive tests, the trabecular bone specimens were constrained by cortical plates in the buccal and lingual directions and by trabecular bone in the mesial and distal directions. Before the destructive test, the cylindric specimens were measured and weighed to determine the apparent (structural) density.

Regional differences were noted in the human mandibular trabecular bone elastic modulus and ultimate compressive strength, exhibiting up to 47% to 68% higher mean values in the anterior (region 1) compared with the posterior region of the mandible (Table 28-1). No differences were observed in elastic modulus and ultimate compressive strength in the region between the premolars and molars (regions 2 and 3) (Figure 28-10). The compressive strength was correlated at a high level of significance ($r = 0.88$, $p < 0.0001$) with the trabecular apparent density for a best-fit cubic relationship.

Based on clinical experience with varying densities of available trabecular bone, Misch[285] defined two types of trabecular bone in his clinical classification scheme for the mandible and maxilla: (1) *coarse* (Division 2 [D2]) in the anterior mandible and (2) *fine* trabecular bone in the posterior mandible (Division 3 [D3]). Qu[264] found a significant difference between apparent density in region 1 (anterior mandible) and in regions 2 and 3 (posterior mandible). No significant difference was noted between region 2 and region 3. The results of the study by Qu thus provide quantitative validation of Misch's classification scheme for trabecular bone in the oral environment.

Chapter 29

Density of Bone: Effect on Surgical Approach and Healing

Carl E. Misch

The density of available bone in an edentulous site has a primary influence on treatment planning, implant design, surgical approach, healing time, and initial progressive bone loading during prosthetic reconstruction.[1,2] A direct bone-implant interface has been demonstrated with a variety of endosteal implant designs and materials. Three requirements necessary for initial rigid fixation—atraumatic bone preparation,[3] close approximation of living bone to the biocompatible implant surface,[4] and absence of movement at the interface during healing[5]—are all closely dependent on the bone density at the implant site. The quality of the recipient bone directly influences the amount of trauma generated during osteotomy preparation. This in turn provokes a cascade of reactions at the bone-implant interface that affect the quality of the load-bearing surface.

Once the implant is initially integrated with the bone, the bone-loading process from occlusal forces becomes a critical factor in long-term implant survival. The bone density under load is directly related to the bone strength and is therefore a critical parameter for long-term survival.[6,7] The occlusal stresses applied through the implant to the bone must remain within the physiologic to mild overload zone; otherwise, pathologic overload with associated bone loss and microfracture, and implant mobility may occur. The treatment planning and scientific rationale of strength, modulus of elasticity, bone-implant contact percent, and stress transfer difference related to bone density has been addressed in a previous chapter. This chapter addresses the modifications of the surgical and healing aspects related to each bone density in the oral environment.

LITERATURE REVIEW

Lekholm and Zarb[8] listed four bone qualities found in the anterior regions of the jawbone: quality 1 comprises homogeneous compact bone; quality 2, a thick layer of compact bone surrounding a core of dense trabecular bone; quality 3, a thin layer of cortical bone surrounding dense trabecular bone of favorable strength; and quality 4, a thin layer of cortical bone surrounding a core of low-density trabecular bone. Irrespective of the different bone qualities, all bone was treated with the same implant design and standard surgical and prosthetic protocols.

Following the proposed protocols of Brånemark et al., it was found that implant survival in initial surgical success was related to the quality of bone.[4] A higher surgical failure was observed in softer bone types, especially in the maxilla. For example, Engquist[9] reported the surgical loss of 38 of 191 implants in the maxilla in D4 bone (20% loss), compared with 8 of 148 mandibular implants (5% loss) before stage II surgery. Jaffin and Berman reported an overall 8.3% surgical and initial healing loss in 444 maxillary implants with softer bone.[10] Friberg et al. reported a 4.8% implant failure at stage II uncovery for 732 maxillary posterior implants, which was greater than mandibular failure.[11] Quirynen et al. also reported a 4.1% implant loss at stage II uncovery out of 269 implants in the maxilla.[12] Fugazzotto et al. reported 22 failures out of 34 implants placed in quality 4 bone.[13] Hutton et al. identified poor bone quantity and quality 4 as the highest risk of implant failure in a study of 510 implants with an overall failure rate in the maxilla nine times greater than in the mandible.[14] Sullivan et al. indicated a 6.4% stage II failure rate in the maxilla (12/188) and a 3.2% failure in the mandible (7/216).[15] Snauwaert et al. reported more frequent early failures in poor density maxillae.[16] Herrmann et al. correlated failure factors such as poor bone quality and volume.[17] A number of reports in the literature demonstrated the greatest risk of surgical failure was observed in the softest bone type (D4), especially when found in the maxilla.

On the other extreme, a large clinical study from 33 U.S. Department of Veterans Affairs (VA) hospitals by the Dental Implant Clinical Research Group (DICRG) states quality 1 bone had the highest surgical failure rate

WWW.HIGHDENT.IR

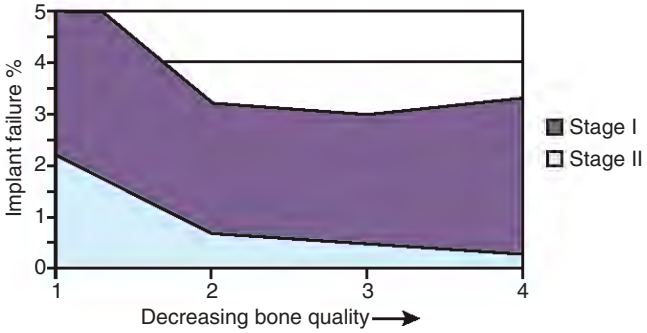

Figure 29-1 The Dental Implant Research Group represents 33 different hospitals that place dental implants. The highest surgical failure rate was quality 1 bone, followed by quality 4 bone. The fewest surgical failures were observed in quality 3 bone.

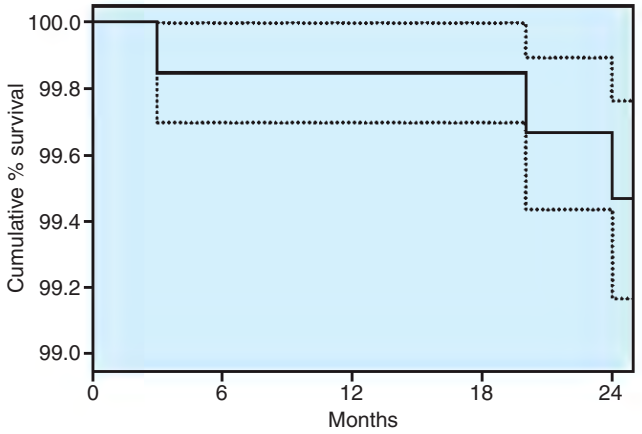

Figure 29-2 A multicenter study reported a surgical success of 99.6%, regardless of bone quality. *(Data from Misch CE, Hoar JB, Beck G et al: A bone quality based implant system: a preliminary report of stage I and stage II,* Implant Dent *7:35-42, 1998.)*

(4.3%), followed by quality 4 (3.9%), quality 2 (2.9%), and quality 3 with the fewest failures at 2.6% (Figure 29-1). The overall implant surgical failure was 3%; the maxilla had better success at stage II surgery (98.1%) than the mandible (96.4%).[18] It must be emphasized that these reports only present implant failures up to stage II uncovery. The DICRG also noted that the failure rate was twice as great for surgeons who had placed fewer than 50 implants, compared with more experienced surgeons. The literature contains many published reports that indicate an implant surgical failure range from 3.2% to 5% in the mandible and 1.9% to 20% in the maxilla, with most reports indicating the greatest failure rates in maxillary implants with soft bone. It is clear from these reports that a wide range of results may be achieved and therefore consideration should be given to methods that improve surgical survival.

Misch developed a different surgical protocol for different bone qualities in 1988. Following these specific methods, prospective and retrospective multicenter clinical studies in a wide range of office settings found surgical survival above 99%, regardless of the density type of bone, the arch (mandible versus maxilla), sex and age of the patient.[19-24] Therefore a different surgical protocol for different bone densities appears warranted.

The implant design, surgical protocol, healing, treatment plans, and progressive loading time spans are unique for each bone density type.[1,2,25] More recently the use of improved rotary instruments, implant designs, and surgical approaches for different bone qualities has been recognized as a valid recommendation. A multicenter prospective clinical study by Misch et al. of 364 consecutive implants in 104 consecutive patients found a surgical survival rate (up to abutment connection) at stage II of 100% for D1, 98.4% for D2, 99.8% for D3, and 100% for D4 implants[19] (Figure 29-2). Altering the surgical approach and implant design for each bone density can yield an overall implant surgical survival of 99.8% and a 2-year survival of 99.4%. In this chapter the surgical considerations and optimal healing time are discussed relative to each bone category, based on the literature, prospective clinical studies, and long-term experience.

BONE DENSITY CLASSIFICATIONS

Misch defined four bone density groups in all regions of the jaws that vary in both macroscopic cortical and trabecular bone types.[2] The regions of the jaws are divided into: (1) the anterior maxilla (second premolar to second premolar); (2) posterior maxilla (molar region); (3) anterior mandible (first premolar to first premolar); and (4) posterior mandible (second premolar and molars). The regions of the jaws often have similar bone densities.

In general, the anterior mandible is usually D2 bone; the posterior mandible, D3 bone; the anterior maxilla, D3 bone; and the posterior maxilla, often D4 bone. This generalization is used for the initial treatment plan. However, resorbed anterior mandibles may be D1 bone in approximately 25% of male patients and the posterior maxilla may have D3 bone after 6 months in the majority of sinus graft patients. The regional locations of the different densities of cortical bone are more consistent than the highly variable trabecular bone. Bone density may be most precisely determined before surgery by a computed tomography (CT) scan of the edentulous site (accompanied by Hounsfield values of the bone). Reformatted software allows "electronic surgery" of the CT images and relates the Hounsfield values at the implant-bone interface. It may also be grossly estimated by radiographic evaluation of tomograms. Conventional dental radiographs, such as periapical, panoramic, or lateral cephalometric images, are usually not diagnostic.

A common point at which to evaluate bone quality is during surgery. The presence and thickness of a crestal cortical plate and the density of trabecular bone are easily determined during implant osteotomy

WWW.HIGHDENT.IR

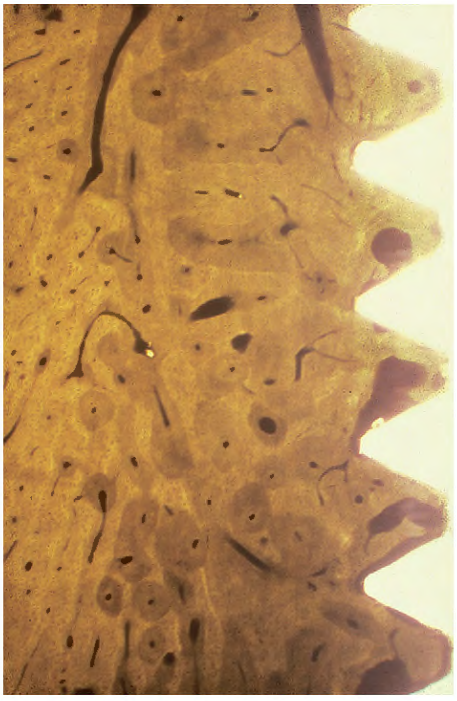

Figure 29-3 D1 bone has the highest bone-implant contact (BIC), which is usually greater than 80% after initial bone healing. Thus the strongest bone is also the bone with the greatest BIC. Both these conditions make D1 bone most suitable for occlusal loading.

preparation. The density of bone is determined by the initial bone drill, and evaluation continues until the final osteotomy preparation.

It should be emphasized that the bone density (D1 to D4) classification of Misch is slightly different from Lekholm and Zarb's bone quality types (Q1 to Q4). According to Misch et al., D3 bone has fine trabeculae and is 47% to 68% weaker than D2 trabeculae, and 20% stronger than D4 trabeculae, whereas Lekholm and Zarb stated that Q3 bone has favorable-strength trabeculae similar to Q2.[7,8] In other words, the actual strength of the trabecular bone is different for each bone density, regardless of the presence or absence of cortical bone adjacent to the implant. In addition, the Lekholm and Zarb bone quality only evaluated bone in the anterior maxilla and mandible. The Misch bone density scale also evaluated the posterior molar regions of the jaws. As a result, a primary difference between D3 and D4 bone is also the presence of cortical bone in D3, which increases its overall strength and modulus of elasticity.[6,7] The quality 4 bone of Lekholm and Zarb is similar to Misch's D3, whereas D4 bone is even weaker because little to no cortical bone is present to improve the strength or the elastic modulus of the fine trabecular bone.

Dense Cortical (D1) Bone

The very dense (oak- or maplelike) D1 bone is composed of almost all dense cortical bone. The maxilla almost never presents D1 bone. In Division A bone, approximately 4% of the anterior mandibles and 2% of the posterior mandibles have this dense bone category. In Division C–h bone of an anterior mandible, these numbers increase and may reach 25% in males, whereas weaker bone density D3 and D4 bone are less commonly encountered.

Advantages of D1 Bone

The homogeneous, dense D1 bone type presents several advantages for implant dentistry. Composed histologically of dense lamellar bone with complete haversian systems, it is highly mineralized and able to withstand great occlusal loads. The cortical lamellar bone may heal with little interim woven bone formation, ensuring excellent bone strength while healing next to the implant.[26,27] Four splinted, threaded, titanium plasma spray implants immediately loaded in the anterior mandible have yielded very predictable long-term success (above 94%), to support an overdenture.[28] Other screw-type implants inserted with a similar surgical and prosthetic approach also resulted in similar long-term survival in this bone region.[29]

D1 bone is more often found in anterior mandibles with moderate to severe resorption and greater crown/implant ratios. A threaded implant design provides greater surface area than a cylinder, especially in shorter lengths, and improves the dissipation of stresses in the crestal cortical region despite higher moments of force from the greater crown height, to sustain long-term functional stress.

The percentage of light microscopic contact of bone at the implant interface is greatest in D1 bone type and greater than 80% (Figure 29-3). In addition, this bone density exhibits greater strength than any other type.[6,7] The strongest bone also benefits from the greatest bone-implant contact (BIC). Less stresses are transmitted to the apical third of the implants than in other bone types. As a result, shorter implants can better withstand greater loads than in any other bone densities. In fact, the placement of longer implants may decrease surgical survival rates, as overheating during osteotomy preparation is a primary concern in this bone type. Greater heat is often generated at the apical portion of the osteotomy, especially when preparing dense cortical bone.[30]

Disadvantages of D1 Bone

Dense cortical bone also presents several disadvantages. The implant height is often limited to less than 12 mm in the atrophic mandible, and the crown height space is often greater than 15 mm. As a result, additional force-multiplying factors (such as cantilevers or lateral forces) are further magnified on the implant-prosthetic system. Stress-reducing factors may be incorporated in the prosthesis design to reduce these effects, not only on the bone, but also on the prosthetic components.

WWW.HIGHDENT.IR

Box 29-1 Implant Osteotomy Preparation in Dense Compact (D1) Bone

Overheating during Osteotomy

Abundant external or internal irrigation
Cooled saline irrigation
Intermittent pressure on drill
Pause every 3 to 5 seconds; keep irrigating
New drill designs, flutes, geometry
Incremental drill sequence (more drills; pass same drill more than once)

Blood Supply

Primarily from periosteum
Minimal reflection

Final Osteotomy Drill

Greater width
Greater height
Slower speed used

Bone Tap

Short of full osteotomy depth
Allows passive implant fit
Prevents internal implant-body/implant-bone interface microfracture
Removes drill remnants

Final Implant Placement at or above Bone Level

Unthread $^1/_2$ turn to relieve internal stresses

Slower Healing Rate

Lamellar bone
Fewer blood vessels
Five months to achieve mature interface

Stage II Uncovery

Three to 4 months
May often use immediate loading (when prosthesis is biomechanically stable)

D1 bone has fewer blood vessels than the other three types, and therefore it is more dependent on the periosteum for its nutrition. The cortical bone receives the outer one third of all its arterial and venous supply from the periosteum.[31,32] This bone density is almost all cortical, and the capacity of regeneration is impaired because of the poor blood circulation.[33] Therefore delicate and minimal periosteal reflection is indicated. When D1 density is present, the bone width is usually abundant. Fortunately, there are few occurrences when facial or lingual undercuts are observed with D1 bone densities, and flap reflection can be safely kept to a minimum. The precise closure of the periosteum and the overlaying tissue has been shown to help recover the blood supply and is encouraged.[34]

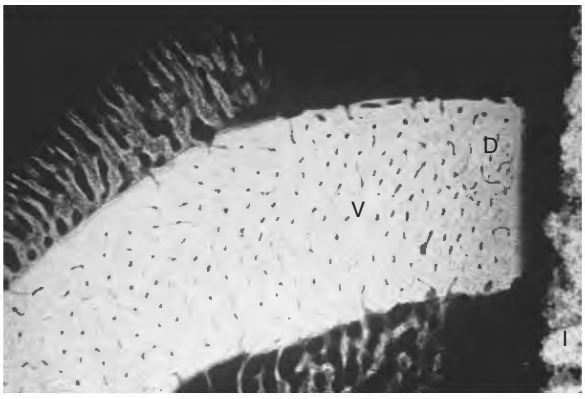

Figure 29-4 Devital zone *(D)* of bone next to the implant *(I)* is primarily created by heat generated during surgery, which radiates from the site, especially in cortical bone. Other contributing factors include lack of blood supply, pressure necrosis from implant placement, microfracture from bone tapping, and implant insertion. *V,* Vital bone.

Implant Osteotomy

The primary surgical problem of D1 bone is that the dense cortical bone is more difficult to prepare for endosteal implants than any other bone density (Box 25-1). The most common cause of implant failure in this bone quality is surgical trauma resulting from overheating the bone during the implant osteotomy procedures, because rotary drills progress with more difficulty. The zone of devitalized bone that forms around the implant is larger in this bone density and must be remodeled and replaced by vital bone for the interface to be load bearing (Figure 29-4). As a result, implant surgical failure may be greater in D1 bone than any other bone density.[2,18] Therefore the dental surgeon must strive to minimize the thermal trauma. The heat generated during an implant osteotomy is related to the presence and temperature of irrigation,[35-37] amount of bone being prepared,[38,39] drill sharpness and design,[40-43] time of preparation,[44] depth of the osteotomy,[37,30,41,45] pressure on the drill,[40] drill speed,[39,46,47] and variation in cortical thickness.[35,48]

Bone cell survival is very susceptible to heat. Eriksson has demonstrated that in rabbit, bone temperature as low as 3° C above normal (40° C) can cause bone cell necrosis.[49] Therefore a conscious effort is made to control temperature elevation every time a rotary instrument is placed in contact with bone. At least 50 mL/min of cooled irrigation, such as sterile physiologic saline, is used as a profuse irrigant and is a critical element to reduce heat.[35-37,50] Distilled water should not be used, as rapid cell death may occur in this medium.[51] Intravenous dextrose solution (D_5W) also may be used, with the clinical advantage of decreasing hand piece breakdown occurring from the effects of the salt in a saline solution, although the surgical gloves often feel sticky near the conclusion of the surgery. The irrigant also acts as a lubricant and removes bone particles from the implant osteotomy site. Without irrigation, drill temperatures

WWW.HIGHDENT.IR

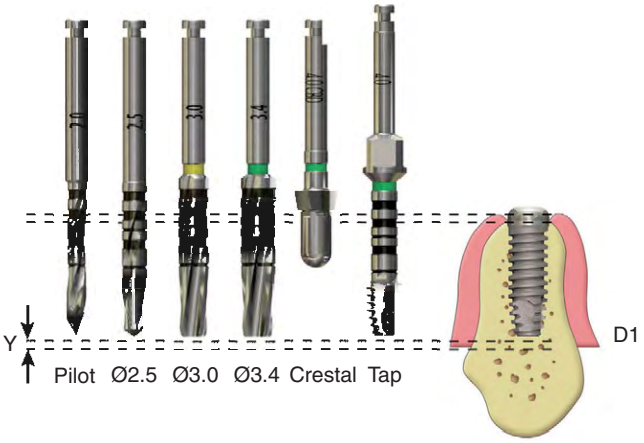

Figure 29-5 The number of steps in the preparation of the osteotomy is related to the bone density. D1 bone requires four drills, a crestal bone drill and a bone tap. D3 requires only three drills and no crestal drill or bone tap.

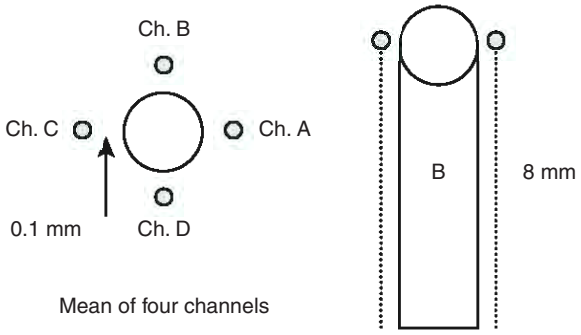

Figure 29-6 Thermocouples were positioned within 1 mm of the drill site and inserted into bone for a depth of 8 mm. The wires were connected to a computer to measure the temperature, time of preparation, and time the bone temperature was elevated.

above 100° C are reached within seconds during the osteotomy,[52] and consistent temperatures above 47° C are measured several millimeters away from the implant osteotomy. The temperatures of the irrigant can also affect the bone temperature.[36,39] Copious irrigation is suggested, especially in D1 bone.

The amount of heat produced in the bone is directly related to the amount of bone removed by each drill.[53] A 3-mm pilot drill generates greater heat than a 2-mm pilot drill.[39,54] As a result, most manufacturers suggest the first drill be 2 mm in diameter. In a similar fashion, the amount of heat generated by successive drills is also directly related to the increase in drill diameter.[52,43] A 3-mm drill after a 2-mm drill cuts 0.5 mm on each side of the drill. A 2.5-mm drill after a 2-mm drill only cuts 0.25 mm of bone on each side of the osteotomy. The smaller incremental drill size allows the surgeon to prepare the site faster, with less pressure and less heat.[42] In addition, when large increases in drill diameter are used to prepare bone, the surgeon may inadvertently change the angulation of the drill, because the larger drill is removing a greater bone volume and the tactile sense is decreased. As a result, an elliptical osteotomy

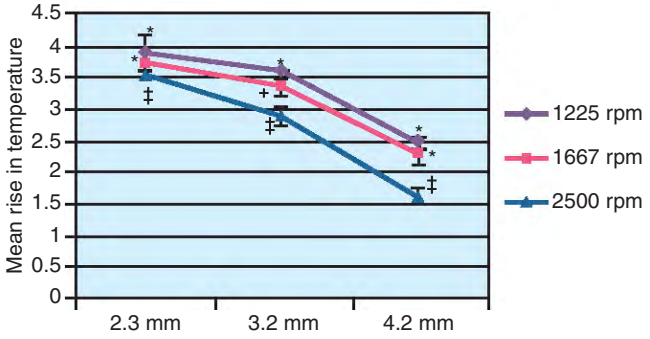

Figure 29-7 The internally cooled drill of the Paragon implant system recorded 41° C with the first drill at 1225 rpm. A rpm of 2500 reduced the bone temperature preparation for all drill diameters.

may be prepared that does not correspond accurately to the round implant diameter. The gradual increase in osteotomy size also reduces the drill shatter at the crestal opening, which can inadvertently chip away pieces of bone on the crest where complete bony contact is especially desired. The gradual increase in drill diameter also keeps each drill sharper for a longer period, which also reduces the heat generated (Figure 29-5).

In the past, the rotational speed of the drill has been suggested to be less than 2000 rpm, and several manufacturers have recommended speeds al low as 750 rpm. It has been an accepted theory that the higher the speed, the higher the bone temperature during preparation.[4] This is false; otherwise, slow-speed hand pieces would be used to prepare natural teeth. A high-speed hand piece (300,000 rpm) can remove bone over an impacted tooth or during an apicoectomy and still allow bone regeneration. Rafel prepared bone at 350,000 rpm in a human mandible and found a temperature of only 23.5° C at a distance of 3 mm from the drill periphery.[47] High-speed drills at 300,000 rpm have been used to prepare blade implant osteotomies, yet bone grew over the blade shoulder and was in direct contact with the implant.[55]

A study by Sharawy et al. compared four drill designs (two internal irrigated and two external irrigated) at speeds of 1225, 1667, and 2500 rpm.[39] Thermocouples connected to a computer to record temperature and time were placed within 1 mm of the osteotomy site in D2-type bone (Figure 29-6). All drill designs in the study recorded lower bone temperatures with the greatest rpm and, conversely, found the highest bone temperatures with the lowest rpm (Figures 29-7 and 29-8). As important, the slowest rpm resulted in bone temperatures at or above 40° C, which may be a threshold of bone-cell death. The highest rpm (2500) increased the bone temperature by 2° to 3.5° C, whereas the 1225 rpm recorded a bone temperature above 41° C. Therefore the higher speed of 2500 rpm may prepare bone at a lower temperature than 1500 rpm, especially when in dense bone.[39] The rotational speed of the drill is one of the more critical criteria to reduce bone temperatures.

WWW.HIGHDENT.IR

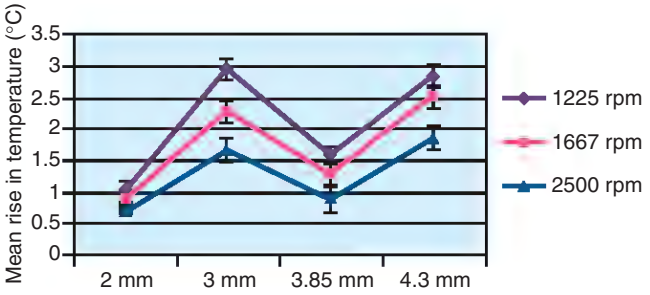

Figure 29-8 The externally cooled drills of the Brånemark implant system recorded reduced temperatures at 2500 rpm compared with slower speeds.

Eriksson reported bone cell death when a temperature of 40° C was applied for 7 minutes, or when a temperature of 47° C was applied for 1 minute.[49] In other words, time and temperature are interrelated critical factors in implant site preparation. As the temperature increases, the time the bone temperature is elevated must be reduced. In the study by Sharawy et al., the time the bone temperature remained elevated was recorded for each rpm evaluated.[39] When the drill prepared an 8 mm depth osteotomy, the temperature remained elevated for 45 to 58 seconds (Figure 29-9). The slower the rpm (1225), the longer the bone temperature remained above the baseline. Because two to three drills are used to prepare an implant site, at 1225 rpm the first drill may increase the temperature to 41° C, the second drill to 45° C, and the third drill to 49° C, when the time between each sequence is not extended more than 1 minute. Therefore, after each drill is used within an osteotomy, a 1-minute pause should be observed before the next drill. In the Sharawy et al. study, the first drill diameter recorded the longest preparation time and the highest temperature, and the longest recovery time.[39] Therefore to reduce the preparation time within the bone to a minimum in D1 bone, the surgeon should not apply constant pressure to the drill, but "bone dance" with intermittent pressure for 1 second in the D1 bone and 1 to 2 seconds out of the bone while the cooled irrigation is allowed to perfuse the site. The surgeon should also pause approximately every 5 to 10 seconds of bone preparation for 1 minute to allow the limited blood supply access to the surgical site, permit dissipation of heat, irrigate the area to reduce bone temperatures, and remove debris from the osteotomy site.

The pressure used against the bone should neither be so hard as to stall the drill, nor so light that the drill only creates heat and does not prepare the bone. Hobkirk and Rusiniak found that the average force placed on a hand piece during preparation of an osteotomy is 1.2 kg.[48] Matthews and Hirsch concluded that the force applied to the hand piece was more influential than the drill speed in temperature elevation.[40] When the pressure on the hand piece was increased appropriately, drill speeds from 345 to 2900 rpm did not affect the temperature. They found that increasing both speed and pressure allowed the drill to cut more efficiently and generated less heat. The effect of drill speed and pressure related to bone temperature was also reported by Brisman.[46] In cortical bone, speeds of 1800 rpm with a load of 1.2 kg produced the same heat as when speed increased to 2400 rpm with pressure of 2.4 kg. The greater speed and greater pressure was more efficient than low speeds. Increasing pressure alone increased heat; increasing speed alone also increased heat. Different amounts of pressure are therefore used in response to the density of the bone. Sufficient pressure should be used on the drill to proceed at least 2 mm every 5 seconds. If this is not achieved, new (sharper) or smaller-diameter drills are indicated for each site preparation. The pressure on the drills should not reduce the rpm, which makes the drill less efficient and increases heat. Hand pieces of sufficient torque should be used to prevent this complication.

Lavelle has demonstrated lower drilling temperatures in cortical bone with internally irrigated drills.[56]

Figure 29-9 The internally cooled drills of the Nobel Biocare, Steri-Os implant system demonstrate the temperature in the bone remains elevated for an extended period (up to 58 seconds) after site preparations in D2 bone. The lower the rpm, the longer the temperature remains elevated.

WWW.HIGHDENT.IR

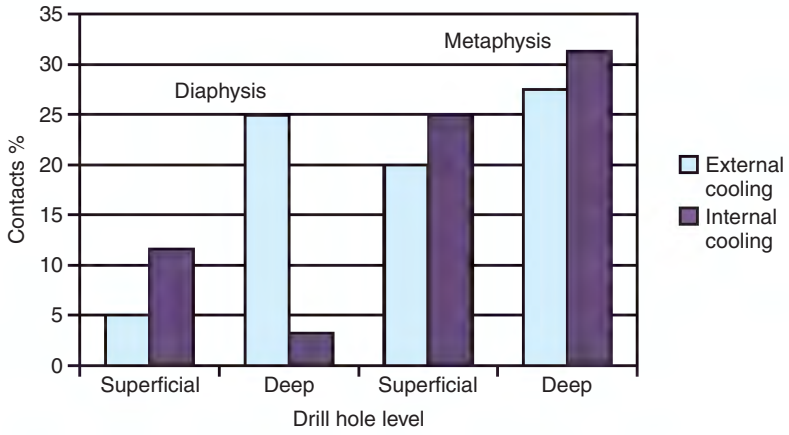

Figure 29-10 The externally irrigated drill had more bone-implant contact (BIC) after 4 weeks of healing in trabecular bone (metaphysics) and for shallow osteotomies in cortical bone (diaphysis). The internally irrigated drill had a higher BIC in deeper osteotomies of cortical bone.

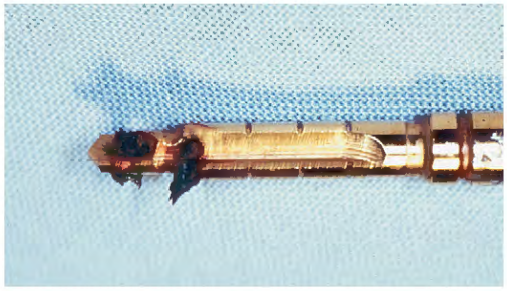

Figure 29-11 Organic debris from a previous surgery may be retained in the chamber of an internally irrigated drill.

Thus many manufacturers suggest that an internally irrigated drill be used during implant osteotomy preparation. However, the bone temperature in the study by Sharawy et al. compared two different internal irrigated drill systems (Zimmer and Nobel Biocare) with two different external irrigated systems (Nobel Biocare and BioHorizons).[39] The two external irrigated drill systems prepared the bone osteotomy at lower bone temperatures than the two internal drill systems. The difference in the bone temperatures between the four systems ranged from 1° to 3° C (depending upon the drill diameter). This study did not use the same drill design when comparing internal versus external irrigation. Therefore, the difference in bone temperature elevation may be related more to drill design than to the method of irrigation. Benington et al. tested internal and external irrigation systems on bovine bone. At a constant load of 1.7 kg, no difference was found between the two designs.[43]

Internal irrigation of drills may present several disadvantages. The portal of the internal-cooled drill that exits at the drill apex often becomes clogged once the drill is in the bone deeper than 5 mm.[57] As a result, no irrigant escapes the portal and the drilling must be repeatedly stopped to remove debris. The pressure required during drilling dense bone also may completely prevent saline from flowing out of the drill in deeper preparations, with bone debris obturating the portal of the irrigation chamber. In a histologic study by Watzek et al., the BIC percentages between internal and external irrigated drill systems in cortical and trabecular bone were compared 4 weeks after implantation. In cortical bone, the BIC was highest in internal irrigated drills when the osteotomy was deep. In trabecular bone or less deep cortical sites, the external by irrigated dills recorded greater BIC values[45] (Figure 29-10).

Complete cleaning of the internal chamber of the internal irrigated drill is virtually impossible, and the drill usually retains organic contaminants in the chamber from a previous surgery[57] (Figure 29-11). Although these organic remnants may be sterilized as the drills are autoclaved after each surgery, it seems unwise to allow organic debris to be transmitted from one patient to another. The external irrigated drill may be sterilized for a following surgery. In addition, the internally cooled drill fabrication in smaller diameters poses technical problems and may cause fracture during use in more dense bone. The externally irrigated drill is also less expensive to fabricate and can be made in smaller diameters.

The externally irrigated drill also presents disadvantages. The external irrigant may not be applied at the bone-cutting surface, but inadvertently on the shank of the drill or on the external aspects of the bone. Some external irrigated systems require a surgical assistant to spray the surgical site while the dental surgeon prepares the osteotomy. It is beneficial when the irrigation portal is attached to the head of the hand piece. The irrigation may not adequately flood the surgical site. As the depth of the osteotomy increases, the risk of the inadequate irrigation increases.[30,45] Either internal or external irrigating drilling techniques (or a combination of the two) may be used satisfactorily, with understanding

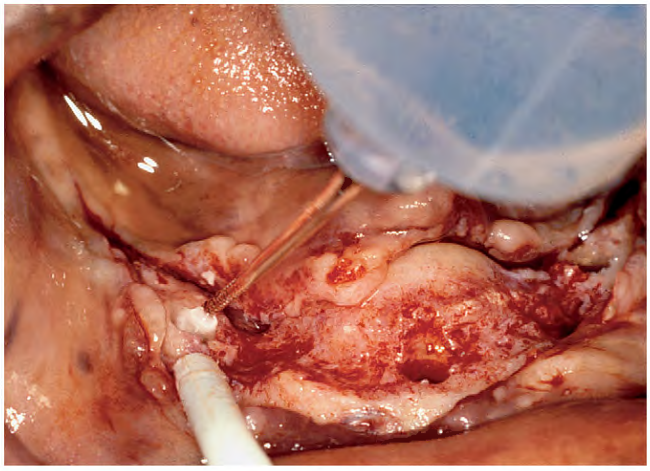

Figure 29-12 Bone chip debris should be frequently removed by irrigation in D1 bone to improve efficiency of the following drill and before implant insertion after bone tapping.

Figure 29-13 The bone debris in the drill should be evaluated. A brown or beige color indicates the temperature is too high and the bone is devital.

Figure 29-14 The bone debris in the drill should be reddish, which indicates vital bone and ideal preparation conditions.

of the limitations. Irrigation, drill design, rpm, and drill sizing are paramount to reduce heat, not whether internal or external irrigation is used.

Bone chips in the osteotomy should be frequently removed by irrigation in dense bone to maintain optimal cutting action (Figure 29-12). In addition, the bone debris should be frequently wiped off the cutting flutes of the drill with a surgical sponge. These bone shavings prevent coolant from reaching the bone and make the drill less efficient. The color of these bone shavings is important to evaluate. Any beige coloration to the bone debris indicates excessive heat is being generated and the bone debris is nonvital (Figure 29-13). A brownish color indicates the bone cell death extends several millimeters away from the implant osteotomy. The color of the bone debris should be reddish, which indicates vital bone (Figure 29-14). As a general rule, the first drill introduced into the implant osteotomy will have beige-colored bone debris. However, the last drill in the sequence should have reddish bone within the cutting flutes.

The use of new drills with a sharp cutting flute is most critical for D1 bone surgery. Bone drills become dull after repeated use. Chacon et al. evaluated three different drill systems after repeated drilling and sterilization. The bone temperature 0.5 mm from the osteotomy preparation increased every 25 uses of the system, even though light microscopic evaluation showed little wear.[42] Many manufacturers suggest the drills be reused, without attention to longevity of the cutting surface. The doctor may inadvertently use the same drills for hundreds of implant osteotomies. When the drills become dull, the doctor may not appreciate it in softer bone, but when D1 bone is prepared, the drill sharpness can become critical. Another method to improve the sharpness of the drill in D1 bone may be the use of coatings. However, not all coatings are of benefit. In a study by Ercoli et al., titanium nitride-coated drills (SteriOss and Paragon) showed greater wear and significantly lower bone removal rates than noncoated drills.[37] Diamond coatings, although expensive, may add longevity to the drill sharpness and are suggested for the initial drills used for the D1 bone osteotomy.

Reduced bone temperature is the primary method to decrease the incidence of surgical healing failure. A secondary cause of failure may be related to mechanical trauma of the bone. There are several methods to reduce mechanical trauma in D1 bone, and one of these is related to final drill size selection. In D1 bone, the final bone preparation may be sized slightly larger in both width and height, especially for a threaded implant, than the manufacturer-recommended surgical protocol. This reduces the risk of microfracture trauma between the implant threads during insertion, which may lead to fibrous tissue formation at the bone-implant interface. In addition, a final drill dimension only used in D1 bone remains sharper for this critical step. If a drill of slightly greater diameter is not available with the implant system, the implant surgeon can use the final drill size available and pass it within the osteotomy several times. This is an effective method to slightly oversize the site.

Most implant designs have a larger crest module compared with the body of the implant. This design feature ensures a bone "seal" around the top portion of the implant after it is threaded into position. The crest

WWW.HIGHDENT.IR

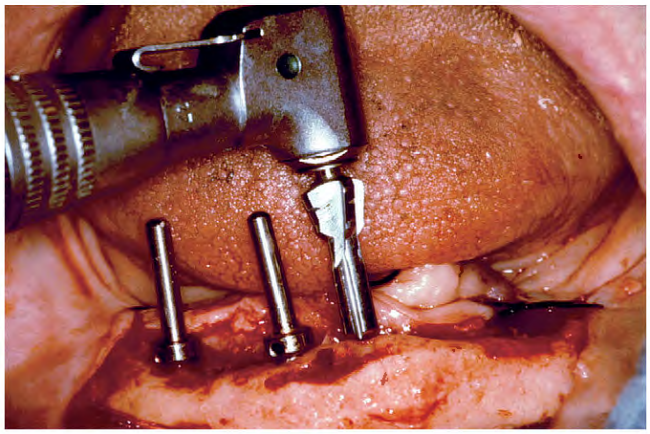

Figure 29-15 A crestal bone tap should be used in D1 bone to prepare marginal bone to receive the crest module of the implant body, which is larger in diameter than the implant body.

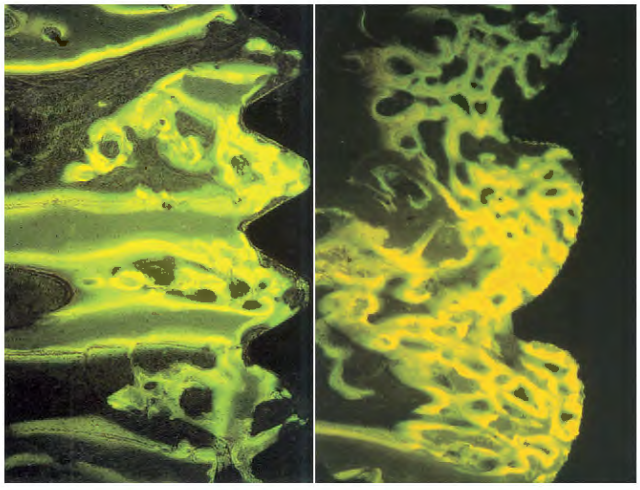

A **B**

Figure 29-16 **A,** A pretapped bone site has less woven (newly generated) bone and illustrated less trauma upon implant insertion. **B,** A self-tapping implant insertion causes greater bone trauma and exhibits massive woven regenerative bone formation as a consequence. *(From Watzek G, Danhel-Mayhauser M, Matejka M et al:* Experimental comparison of Brånemark and TPS dental implants in sheep *[abstract]. Presented at UCLA Symposium: Implants in the partially edentulous patient, Palm Springs, Calif, 1990.)*

module is usually 4.1 mm for a 3.75-mm-diameter implant. Because the final osteotomy drill of many systems is in the 3.2-mm-diameter range, the 0.9-mm difference is substantial, especially in crestal cortical bone. As a result, a crestal bone drill is used in D1 bone, which prepares the larger diameter at the top of the osteotomy (Figure 29-15). In a study by Novaes et al., the difference in crestal bone loss after an initial healing period of 3 months was 1.5 mm between using a crestal drill compared with no crestal drill.[58] The additional bone trauma from compressing a larger crest module into the osteotomy is significant and may increase surgical bone loss around the implant. Therefore a

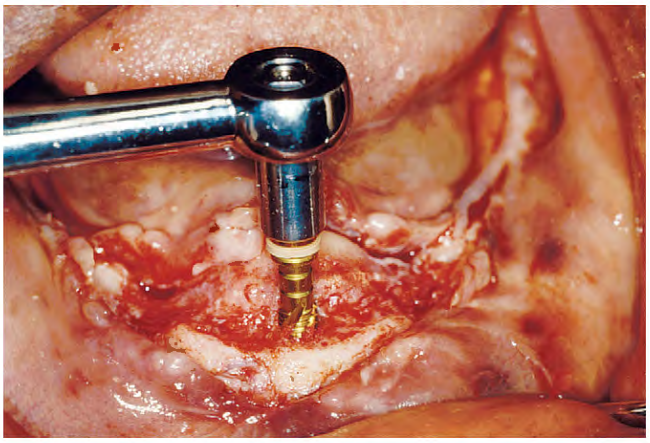

Figure 29-17 A hand wrench and bone tap should be used to prepare the threads for the implant when the bone is D1. A handpiece may stall or break down when attempting to tap the bone in this density.

crestal bone drill should be used in D1 bone as the last drilling step in the preparation of the osteotomy.

A bone tap should be used in D1 bone before insertion of a threaded implant. There are several reasons for the use of a bone tap. Because the final drill osteotomy is almost 1 mm smaller than the outer diameter of the implant, the bone tap creates the space for the thread of the implant. This device has open flutes, which permit the shaving of the bone to accumulate and be removed before placing the implant. A self-tapping implant insertion compresses the bone in the region of the threads. This is an advantage in softer bone types, but not in cortical bone. The tap reduces the mechanical trauma to the bone while the implant is inserted. The bone is also able to slightly recover from the trauma of the tap once it is removed and permits a more passive implant placement. Watzek et al. found a higher woven bone interface (a sign of bone trauma) when a self-threading implant design was used, compared with a pretapped implant site[59] (Figure 29-16, *A*, *B*). Satomi et al. found a higher BIC after initial healing with pretapped implant osteotomies compared with a self-tapping site, also indicative of less bone trauma.[60] The use of a self-tapping implant insertion technique in dense bone qualities has demonstrated a significantly higher degree of hard tissue trauma and is therefore not recommended in D1 bone.[59,60]

The bone tap should be used with a hand ratchet and irrigation (Figure 29-17). The slow-speed, high-torque hand piece is very efficient and has several advantages in D2 bone. However, D1 bone is so strong that the hand piece gears may strip, and the hand piece is more likely to require repeated repair.

The hand position of the surgeon is important in maintaining constant force and direction on the hand ratchet during the bone-tapping process. When using a ratchet, the horizontal rotation on the tap causes it to tip back and forth around the vertical axis. Therefore,

WWW.HIGHDENT.IR

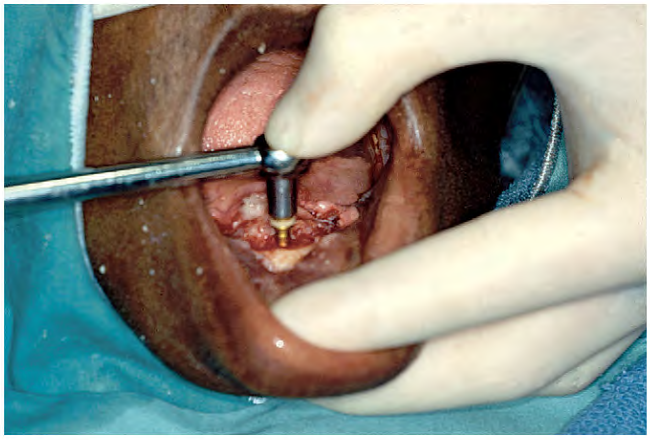

Figure 29-18 The hand position in D1 bone of an anterior mandible is demonstrated. One hand uses a thumb on the wrench with pressure in the long axis of the osteotomy; a forefinger retracts the lip; and the middle finger is placed under the chin and directs the tap in the apical direction.

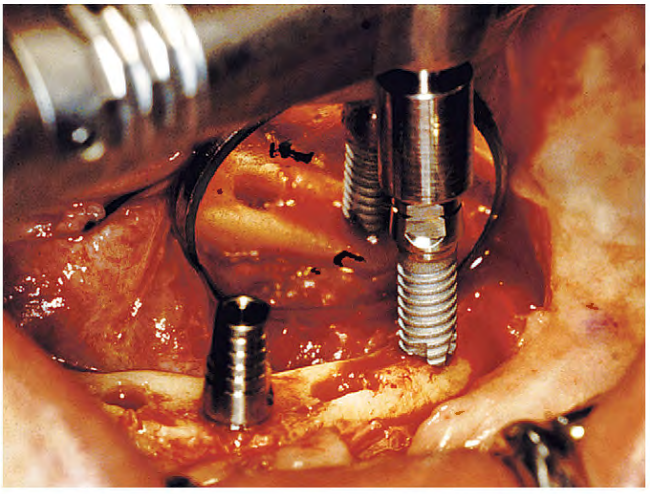

Figure 29-19 A high-torque, low-speed handpiece may thread the implant into the pretapped osteotomy at 30 rpm.

when using a ratchet, the ratchet is held while the thumb of the other hand is placed directly over the bone tap; the index finger of the same hand retracts the lip for improved access and vision; and the middle finger is placed under the mandible in the direct path of the osteotomy. The ratchet rotates the tap with one hand while the thumb and middle finger of the other hand apply constant pressure and direction to the tap, so it does not tip back and forth or strip the osteotomy site (which may happen if the tap does not continue to advance within the osteotomy each turn of the tap) (Figure 29-18).

A bone tap in D1 bone prevents the antirotational component of the implant body from being damaged during implant insertion in this dense bone type. A minor advantage to tapping may be the fact that drill remnants are more likely to be left in the implant osteotomy during preparation in dense bone or with a new drill and cutting edge.[56] The bone tap may remove these remnants and decrease the risk of long-term corrosion from dissimilar metals contacting within the bone, although no reports in the literature have indicated this to be a problem.

Once the tapping process is complete, the osteotomy is irrigated and suctioned. The implant may be inserted with a slow-speed, high-torque hand piece or a hand ratchet (Figure 29-19). The implant should not be tightened with a high torque pressure (>75 N-cm) to the full depth of the osteotomy; this causes it to "bottom out" and may set up microfractures along the implant interface (Figure 29-20). Instead, once the threaded implant is introduced into the osteotomy and in final position, it is often unthreaded one half turn to ensure that there is no residual pressure along the bone interface. This step is primarily used in D1 bone, because excessive initial strain may form at the interface of the cortical bone with even one extra rotation of the implant.[61] The

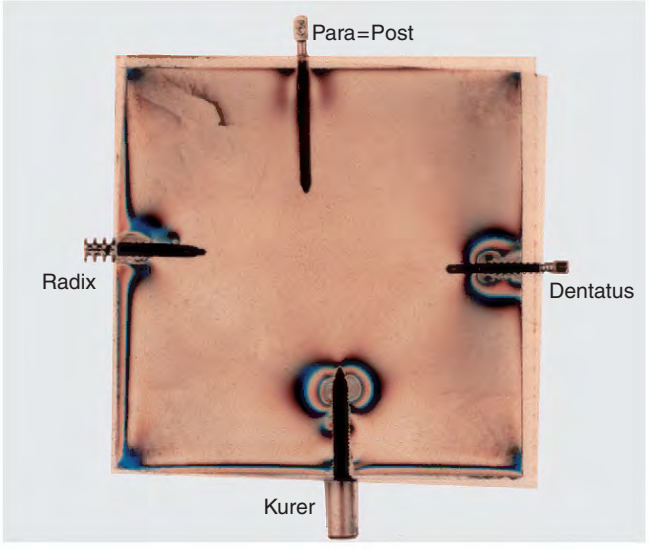

Figure 29-20 The implant should not be tightened into position, which may increase the strain to the surrounding bone. In this in vitro study, self-threading posts were placed in a dentine simulant (similar to cortical bone strength) in the 3, 6, and 9 o'clock positions. In the 12 o'clock position is a predrilled passive post insertion.

rotational stress is highest at the crestal region, which may even cause mechanical bone microfracture and marginal bone loss.[62,63]

The ideal implant length for D1 bone is 12 mm for a 4-mm-diameter implant. There is little, if any, benefit to increased implant length beyond 12 mm in D1 bone for a threaded implant body, as most all the stresses after healing are limited to the crestal half of the implant with occlusal loading. The longer implant makes bone preparation more difficult and generates more heat in this bone type.[37,30,45]

The final placement of the implant in relation to the crest of the ridge is related to its design and the bone density. A one-stage surgical approach is often used in D1 bone. The implant may be placed so that the external

WWW.HIGHDENT.IR

Figure 29-21 The implant in D1 bone may be placed with the external hex above the bone. A one-stage surgical approach is often used.

Figure 29-22 D2 bone has a dense to porous cortical crest, and inner trabecular bone is coarse. It is found most often in the mandible.

hex (or smooth crest module) is above the bone (Figure 29-21). A permucosal element (PME) may be added and permit the implant to heal above the soft tissue, thus eliminating a second-stage surgery. The crest module of the implant is often smooth for approximately 0.5 to 2 mm and provides minimum support to the implant system once it is loaded. The D1 dense compact bone is often of decreased height. Therefore the actual support system of the implant may be increased in division C–h limited-height bone type by not countersinking the smooth portion of the implant crest module below the crest of the ridge (see Figure 29-21). The smooth portion of the implant body may be placed above the ridge if no load is applied to the implant during initial healing, and the risk of micromovement during this period is minimal. A crestal drill is used corresponding to the final implant placement, often short of the final depth, to permit placement of the smooth crest module above the crestal bone.

It should be noted that this approach to increase implant body surface area within the bone is beneficial only when the implant body extends the entire height of available bone and only the smooth portion of the implant crestal module is above the bone. For example, for 11-mm bone height, a 13-mm threaded implant with a 2-mm smooth crest module may be used, leaving the 2-mm smooth crest module above the bone. There may be an increase of more than 35% surface area for load resistance in this example because this increases the implant design load to all 11 mm of bone, rather than using a 10-mm implant with 8 mm of thread. However, if a 10-mm implant were placed with the crest module above the bone, the same bone implant area would be obtained as the 10-mm implant level with the bone, once crestal bone height was lost from the biological width and loading.

Bone Healing

Many of the cutting cones that develop from monocytes in the circulating blood and are responsible for bone remodeling at the implant interface come from the blood vessels found in well-vascularized trabecular bone, which has a greater capacity for regeneration than compact bone. Therefore in some aspects cortical bone requires greater healing time compared with trabecular bone.[33]

On the other hand, because of the load-bearing capability of D1 bone and the excellent bone-implant contact, prosthetic loading of D1 bone may start before the completion of the initial healing phase. Conditions that contribute to a lack of movement during healing are primordial to achieve a direct bone-implant interface. D1 bone is strong and often able to resist micromovement regardless of whether an implant is loaded. As a result, immediate implant loading is often possible when multiple implants are splinted together, without compromise to the overall survival rate of the implant.[64,65] However, it is usually safer to wait for a longer healing period rather than immediate load, unless some other treatment plan criteria affects the decision. Most often, a blend of treatment conditions result in a minimum 3-month unloaded healing period in this bone type.

Once the bone-implant interface is established, it exhibits the strongest load-bearing properties of any bone type. As a result, progressive bone loading is not necessary to develop a stable condition. The restoring dentist may proceed as rapidly as desired to the final prosthesis.

Dense-to-Thick Porous Cortical and Coarse Trabecular Bone (D2)

The second density of bone found in the edentulous jaws (D2) is a combination of dense-to-porous cortical bone on the crest and coarse trabecular bone on the inside (Figure 29-22). The Hounsfield values on reformatted CT images are 750 to 1250 units for this bone quality. The tactile feeling when preparing this bone density is similar to preparations in spruce or

WWW.HIGHDENT.IR

white pine wood. The D2 bone trabeculae are 40% to 60% stronger than D3 trabeculae. This bone type occurs most frequently in the anterior mandible, followed by the posterior mandible. On occasion it is observed in the anterior maxilla, especially for a single missing tooth, although the dense-to-porous cortical bone is then found primarily on the lingual surface of the implant site.[66] The minimum ideal implant height for a V-thread implant design in D2 bone is usually 12 mm, for a 4-mm-diameter implant.

Advantages of D2 Bone

D2 bone provides excellent implant interface healing, and osteointegration is very predictable. Most implant systems refer to this density of bone for their usual surgical protocol (Figure 29-23). The dense-to-porous cortical bone on the crest or lateral portions of the implant site provide a secure initial rigid interface. Osteoplasty to gain additional width of bone before implant placement or countersinking below the crestal bone does not compromise support because the lateral cortices and coarse internal trabecular bone provide rigid fixation. The implant may even be placed slightly above the crest of the ridge with decreased compromise or risk of movement at the interface during healing, compared with softer bone types. The intrabony blood supply allows bleeding during the osteotomy, which helps control overheating during preparation and is most beneficial for bone-implant interface healing.[33]

Implant Osteotomy

The rotations of the drill during the implant site preparation should be approximately 2500 rpm. Sharawy et al. demonstrated that, regardless of the drill design or method of irrigation, 2500 rpm prepared bone at a lower temperature than slower speeds.[39] Copious cooled sterile saline irrigation is used during the bone preparation. The surgeon should allow the cutting surface of the drill to contact D2 bone fewer than 5 of every 10 seconds. Ideally, a pumping up-and-down motion is used to prepare the osteotomy and provide constant irrigation to the drill cutting surface. It also maintains a constant drill speed and reduces the friction time against the bone, all of which reduce heat. The surgical assistant counts for 5 seconds while the drill is progressing in the bone. When the surgeon stops or lifts the hand piece for more than a few seconds, the counting may begin again. If the assistant counts to 5 seconds and the drill is still in the bone, a gentle touch on the back of the surgeon's hand is a reminder to pause a few moments before proceeding. The irrigation should continue while the pause occurs. Not only can this method decrease heat, but constant irrigation flushes debris out of the osteotomy. The time in contact with bone and the amount of irrigation are two very important factors to reduce thermal damage to the bone.

The drill sequence for D2 bone is similar to D1 bone. A 2.0-mm twist drill is used to initiate the process, followed by a 2.5-mm twist drill. The final osteotomy diameter of the implant determines the final drill used. A 3.75-mm implant body most often uses a 3.0-mm drill and a bone tap or a 3.2-mm drill for a self-tapping implant insertion. A 4.0-mm implant body often uses a 3.4-mm drill for the final osteotomy preparation. The heat generated is less with a three-drill sequence (e.g., 2.0 mm, 2.4 mm, 3.2 mm) compared with a two-drill sequence (e.g., 2.0 mm, 3.2 mm) because less bone is removed with each drill in the prior scenario.

A crestal bone drill should be used for most implant designs in D2 bone (Figure 29-24). Because cortical bone is present on the crest of the ridge and the crest module of the implant enlarges to 4.1 mm, the crestal bone drill reduces the mechanical trauma to the bone upon implant insertion. Novaes et al. found a median average 1.5 mm less marginal bone loss after a 3-month healing period when a crestal bone drill was used, compared with implant insertion with no crestal drill

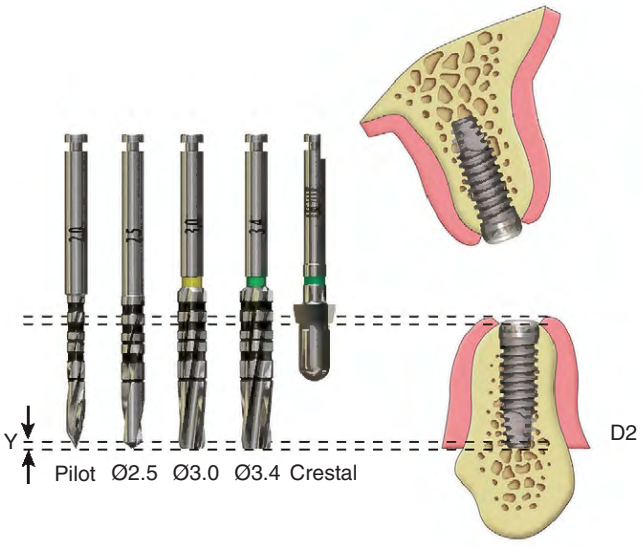

Figure 29-23 The standard drill protocol used by manufacturers is usually osteotomy preparation in D2 bone.

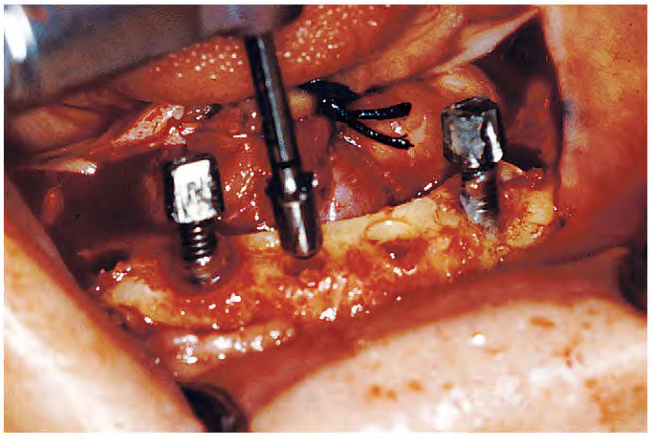

Figure 29-24 A crestal drill is used in D2 bone to prepare the cortical bone for the implant crest module, which is wider than the implant body.

WWW.HIGHDENT.IR

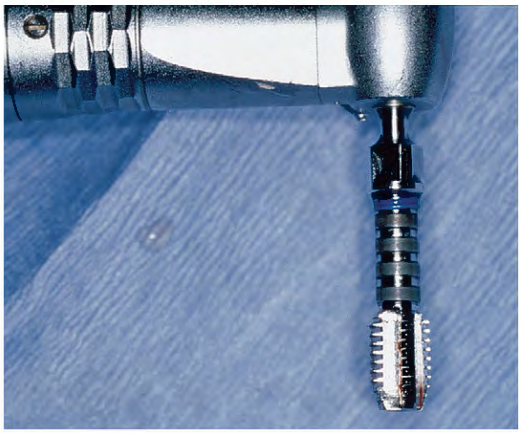

Figure 29-25 A bone tap is used with a high-torque, low-speed hand piece in D2 bone, when the thread depth is deep or the thread shape is square.

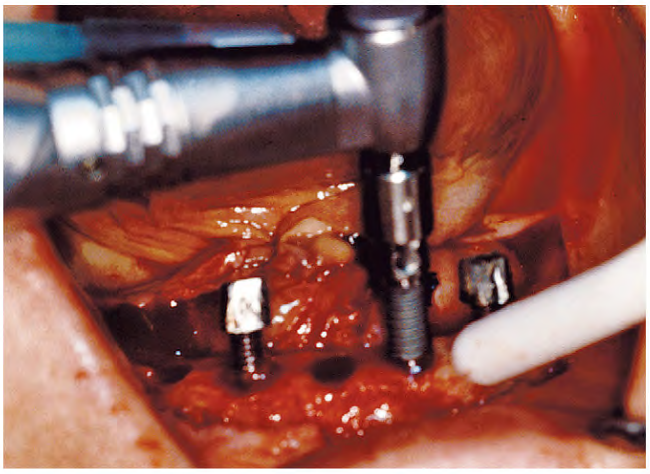

Figure 29-26 A high-torque, low-speed handpiece is used to thread the implant into the pretapped osteotomy in D2 bone.

after the final osteotomy preparation.[58] Sharawy et al. showed that D2 bone with an osteotomy depth of 8 mm could be prepared in 4 to 8 seconds, dependent upon drill design and rpm.[39] Therefore the osteotomy depth should not proceed slowly, creating additional heat. Enough pressure should be placed on the handpiece to proceed at least 5 mm every 5 seconds.

A bone tap may be used when the implant body engages the lateral or apical cortical bone. A hand piece at 30 rpm may be used to tap the D2 bone. This process is faster than using a hand ratchet as in D1 bone, and it is more precise because the direction and advancement of the tap is more precise with a hand piece. Irrigation is used during this process (Figure 29-25).

The use of a bone tap for D2 bone is dependent upon the final osteotomy size, the implant body size, the depth of the thread, and the shape of the thread. When the final osteotomy is 3.0 mm (e.g., Brånemark implant) and the implant body is 3.75 mm, a bone tap should be used in D2 bone. On the other hand, when the final osteotomy is 3.2 mm and a similar 3.75-mm implant body with apical flutes for bone debris (e.g., Zimmer) is used, the implant may be inserted without a pretapping process. A Steri-Oss implant may have a thread depth of 0.2 mm, compared with a Brånemark of 0.6 mm. A final osteotomy preparation of 3.2 mm for Steri-Oss, with a small thread depth (compared with a 3.0-mm preparation and 0.6-mm thread depth) means the Steri-Oss does not require a bone tap before the implant insertion. The square thread shape and the thread depth of BioHorizons dental implants combine to indicate a bone tap procedure before implant insertion in D2 bone. Before inserting the implants, the osteotomy is suctioned to remove bone debris, blood, and irrigation to minimize hydrostatic pressure during implant insertion.

The implant may be threaded into position with a low-speed (less than 30 rpm), high-torque (75 N-cm) hand piece, rather than using a hand ratchet. The hand piece allows a more precise implant rotation, and a constant pressure ensures the implant will progress into the site without risk of stripping the bone within the threads (Figure 29-26). During this process, the irrigation may be stopped so the patient does not attempt to close the mouth and swallow, which may contaminate the implant and cause it to be pushed off the axis of the implant osteotomy.

A threaded implant placed in the anterior mandible engages the cortical bone at the edentulous crest and often the lingual lateral side. In division C–h bone, the implant may also engage the apical cortical region. This provides immediate stability and proven long-term survival. The D2 density of bone in the posterior mandible does not provide apical cortical bone, as the inferior alveolar nerve limits implant height. The angulation or cortical bone above the submandibular fossa of the posterior mandible often permits the use of the mandibular lingual plates to this effect. Several implant designs have proven effective at 95% for as long as 10 years when placed into coarse trabecular alveolar bone with a cortical crest in the mandible. In posterior areas, larger-diameter threaded implant designs are suggested to increase the surface area and decrease stress, especially in the crestal regions.

When the anterior maxilla presents this bone density, it is treated similarly to the D2 mandible. A threaded implant should engage the palatal cortical plate rather than the labial cortical bone, which is thinner and porous. When this occurs, a bone tap is usually required to form the implant threads in cortical bone. Otherwise, the implant will be pushed more labial, even stripping the facial plate. The anterior maxilla usually has less available bone height than the anterior mandible. As a result, the apex of the implant may engage the thin cortical plate of the floor of the nose when a solid, traditional screw-type system is used. This is not indicated

WWW.HIGHDENT.IR

Figure 29-27 The bone-implant contact is approximately 70% in D2 bone after initial healing and is excellent for load-bearing capability.

if a hollow, cylinder implant is selected, as perforation of the bone and periosteum may compromise the ability to form bone in the internal basket. Hollow, basket-type implants are not recommended in areas where soft tissue may invade the basket.[67] As the greatest stresses after healing are primarily transmitted around the crest, the primary advantage of the apical end of the implant engaging cortical bone is initial stability during healing.

Healing

The excellent blood supply and rigid initial fixation of D2 bone permits adequate bone healing within 4 months. The lamellar bone–implant interface is more than 60% established at the 4-month healing interval. BIC is approximately 70% at this point in time, especially when cortical bone engages the lateral and lingual portions of the implant (Figure 29-27). Abutment placement and prosthodontic therapy may then commence. It should be noted that the time frame for initial bone healing is based on the density of the bone, not on the location in the jaws. Therefore a 4-month rigid healing phase is adequate for porous cortical and coarse trabecular (D2) bone, even when found in the maxilla. Progressive bone loading is usually not required for D2 bone, although an increase in BIC takes place during the initial loading period.

Thin Porous Cortical and Fine Trabecular Bone (D3)

The third density of bone (D3) is composed of thinner porous cortical bone on the crest and fine trabecular

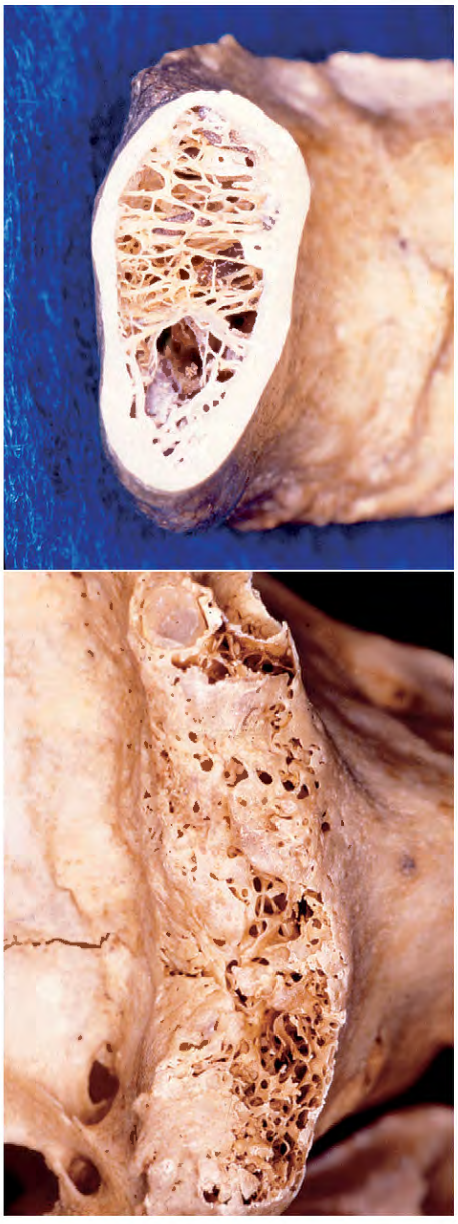

Figure 29-28 D3 bone has a thin, porous cortical crest and fine trabecular bone within the alveolus. It is frequently found in a posterior mandible.

bone within the ridge (Figure 29-28). The mandibular arch usually has more crestal cortical bone than the maxilla (Figure 29-29). The CT-reformatted images may have a range of 375 to 750 Hounsfield units. This bone quality provides the surgeon with a tactile sense similar to drilling in compressed balsa wood. The trabeculae are approximately 50% weaker than those in D2 bone. D3 bone is found most often in the anterior maxilla and posterior regions of the mouth in either arch. It may also be found in the Division B edentulous ridge modified by osteoplasty to provide adequate width for a root form implant placement. Sinus grafts are often D3 bone in the posterior maxilla after a healing period of 6 months or more.[68,69] D3 bone is least prevalent in Division C–h or D anterior mandibles. The ideal minimum

WWW.HIGHDENT.IR

Figure 29-29 Bone-implant contact is in the 50% range for D3 bone.

implant height in D3 bone for a V-shaped or square thread implant design is at least 12 mm when 4 mm in diameter. Larger-diameter implants (5 mm or 6 mm) are more essential in D3 bone in the molar regions than in the previous categories. A roughened implant body (such as acid etched or resorbable blast media) presents advantages in this bone density, regardless of design, to compensate for the limited initial bone contact and decreased bone strength inherent in the trabecular architecture.

The porous cortical layer is thinner on the crest and labial aspect of the maxilla, and the fine trabecular pattern is more discrete in wide edentulous sites. The D3 anterior maxilla is usually of less width than its mandibular D3 counterpart. The D3 bone is not only 50% weaker than D2 bone, the BIC is also less favorable in D3 bone. These additive factors can increase the risk of implant failure. Therefore, small-diameter implants are not suggested in most situations. Instead, bone spreading in this bone density is mechanically easier to perform and allows the placement of greater-diameter implants. The increased-diameter implants lead to improved prognosis, especially when lateral forces or greater force magnitudes are expected. In addition, bone spreading compacts the trabecular bone and increases its density after initial healing.

Advantages of D3 Bone

The main advantage of D3 porous compact and fine trabecular bone is that the implant osteotomy preparation time and difficulty is minimal for each drill size and is usually less than 10 seconds. The crest module drill and bone tap may be eliminated in the surgical protocol. Blood supply is excellent for initial healing, and intraosseous bleeding helps cool the osteotomy during preparation. As a result, this bone density may give the highest surgical survival (Table 29-1).

Table 29-1 Osteotomy Preparation

	OVER-HEATING	TIME	FINAL SIZE DRILLS, NUMBER, SPEED	CREST MODULE DRILL	TAP	INSERTION	HEALING	STAGE II UNCOVERY
D1	++++ Highest risk	1 sec in, 2 sec out "bone dance"	Increase number in sequence. Increase speed 2500 rpm	Yes	Yes (hand ratchet)	Above crest; hand piece unthread $^1/_2$ turn	Lamellar bone; decreased blood supply	3 to 4 months (immediate load)
D2	++ High risk	5 sec out of 10 sec in bone	Manufacturer's protocol; 1500-2500 rpm	Yes	Optional hand piece	At or above crest; hand piece	Ideal	4 months
D3	+		Decrease final size; decrease number; 2500 rpm	No	Optional* hand piece	At or below crest; handpiece	Excellent blood supply; risk of early movement (+)	5 months (rough surface implants)
D4			Minimum number; decrease final size; osteotome	No	No	Below crest; hand piece	Risk of micromove-ment (+++)	6 months (rough surface implants)

+, Degree of risk.

WWW.HIGHDENT.IR

Box 29-2 Disadvantages of Porous, Compact Fine Trabecular (D3) Bone

Bone Anatomy
Anterior maxilla often is narrow

Osteotomy
Lateral perforation
Oversize by mistake
Apical perforation

Bone-Implant Contact
Approximately 50%
Additional implant

Implant Placement
One time
Level with thin crestal cortical bone
Greater risk of load during healing
Use high-torque handpiece to insert self-tapping threaded implant

Implant Design
Titanium plasma spray (TPS) or hydroxyapatite (HA) coated
Increased cost
Threaded implant
Greater surface area, but more difficult to place
Press-fit
Easier to insert
May expand bone
If bullet-shaped, has less surface area

Healing Period
Six months to increase lamellar bone and mineralization
Progressive loading more important than for D1 or D2

Disadvantages of D3 Bone

D3 bone also presents several disadvantages (Box 29-2). It is more delicate to manage than the previous two bone density types because its preparation is so easy.

Bone preparation in D3 bone should be 2500 rpm and must be made with constant care of direction to avoid enlargement or elliptical preparation of the site. In the Sharawy et al. study, 2500 rpm prepared the bone at a lower temperature than slower rpm (1225 and 1667 rpm)[39] (Figures 29-30 and 29-31). The preparation time for D3 bone was less than 8 seconds for an 8-mm osteotomy depth, regardless of the rpm. However, the temperature remained elevated for 30 to 50 seconds (Figure 29-32).

A common mistake that causes an elliptical site to form is the use of a finger rest during the osteotomy. Because the drill is often longer than 20 mm, a finger rest results in an arched pathway of the drill into the bone. In dense bone, the side of the drill encroaches

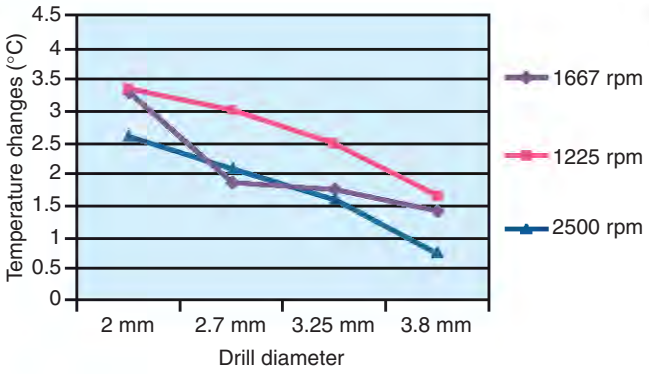

Figure 29-30 The internally irrigated drill of Steri-Oss prepared an 8-mm-deep osteotomy in D3 bone at a lower temperature when the rpm was 2500, compared with 1225 or 1667 rpm.

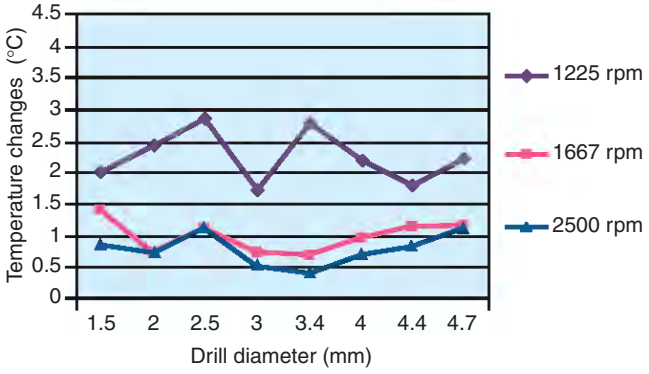

Figure 29-31 The externally irrigated drill of BioHorizons prepared the bone at a lower temperature than the internally irrigated drills; it was lowest at the 2500 rpm speed and highest at 1225 rpm.

upon the dense cortical crest, which opposes the movement and stops the rotation before the crestal osteotomy is enlarged. In D3 bone the arc pathway is not stopped and the osteotomy at the level of the crestal bone is of greater diameter than the drill. If the implant design does not increase at the crestal region, the surgical defect created around the top of the implant may heal with fibrous tissue rather than bone and cause an initial bony pocket.

To improve rigid fixation of traditional root form designs during healing, the opposing thin cortical bone of the nasal or antral floor is often engaged in the maxilla or the apicolingual plate in the mandible, when immediate loading is considered. If the original implant height determined before surgery does not engage the opposing cortical bone, the osteotomy is increased in depth until it is engaged and even perforated. Slightly longer implants are placed in this approach to further increase surface area of support. However, it should be remembered that this technique improves stability during healing but does not decrease the crestal loads to bone after healing. Instead, implant crest module design and the crestal one third of the implant body design are necessary to decrease stress when the implant prosthesis is loaded.

WWW.HIGHDENT.IR

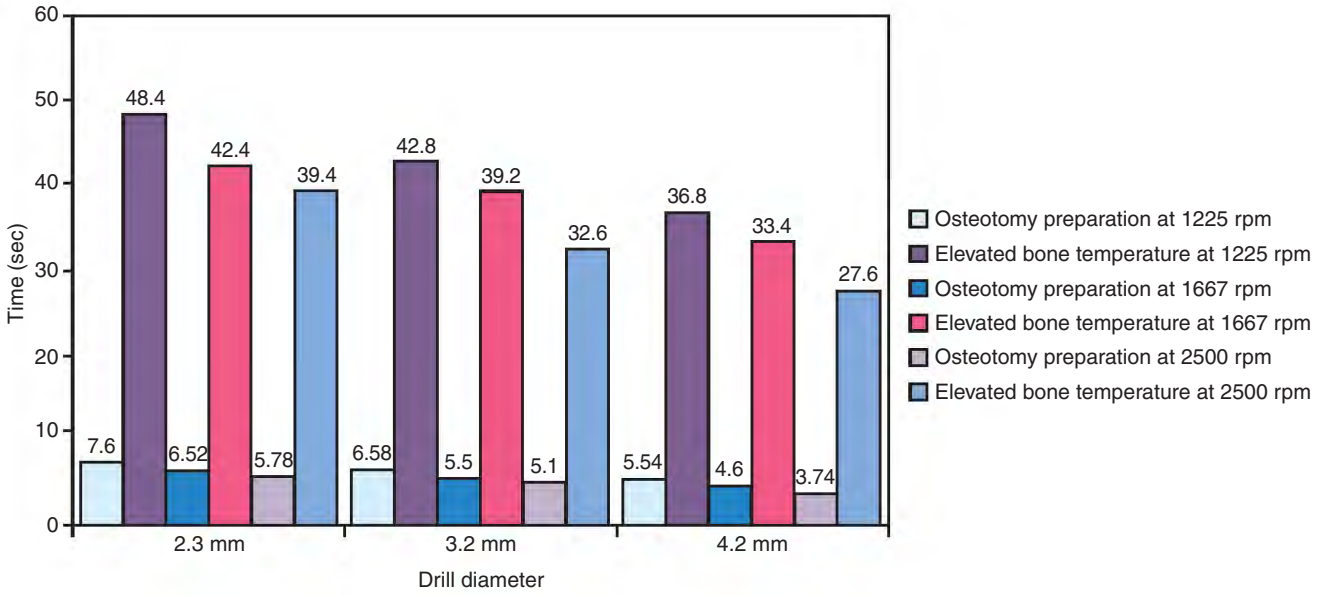

Figure 29-32 The duration during which the temperature was elevated was related to the rpm, with slower rpm being less efficient and associated with a longer elevated temperature.

Figure 29-33 The drill sequence for D3 bone is shortened when compared with standard D2 osteotomy preparation.

The surgeon must be careful to avoid undesired lateral perforations of the cortical bone during osteotomy procedures, especially on the thin, labial porous cortical plate of the maxilla. A common mistake is the stripping of the thin facial plates during the osteotomy. The initial and intermediate drills proceed through the fine trabecular bone without incident (Figure 29-33). However, the lingual aspect of the end-cutting drill hits the thick palatal cortical bone within the osteotomy, which resists preparation, and pushes the drill facially, which may strip the facial plate. A very firm hand, which prevents lateral displacement of the drill and hand piece during the implant osteotomy and does not permit the drill to move facially, is mandatory to prevent this unwanted complication.

A crestal bone drill should not be used in D3 bone. The thin, porous cortical bone on the crest provides improved initial stability of the implant when it is compressed against the crest module of the implant. Unlike D1 and D2 bone, the final drill diameter (3.0 to 3.4 mm for a standard-diameter implant) is of benefit for the 4.1-mm to 4.2-mm crest module dimension to compress the weaker bone. The compressed soft bone not only provides greater stability, it heals with a higher BIC, which is a benefit during the initial bone-loading process.

A bone tap is usually not indicated in D3 bone when Division A bone volume is present. D3 fine trabeculae are 50% weaker than D2 trabeculae, and when the implant is threaded into position, it compresses the bone. This provides improved initial stability and increases the BIC during initial healing. Bone compaction is a benefit when the bone density is poor.

Because crest module drills and a bone tap are usually not used in D3 bone, the number of steps and time of preparation are reduced. The final-size drill should not be passed more than once in the osteotomy to avoid oversizing the preparation. When the residual crest of bone is less than 6 mm wide, a round bone spreader may be tapped into the implant site after the initial 2-mm twist drill to obtain the final osteotomy dimension.[68] The less dense D3 bone easily expands and often permits larger-diameter implants to be inserted.

On the other hand, a complication often occurs when inserting the threaded implant into the prepared bone site of the anterior maxilla. The threaded implant does not completely thread into the more dense palatal plate of bone in this region, and the implant is pushed

WWW.HIGHDENT.IR

facially, often stripping the facial bone as the implant is threaded into position. Although a bone tap in Division A bone volume is usually not necessary in D3 bone, the practitioner may have to both prepare the palatal aspect of the osteotomy separately with a side-cutting drill (e.g., Lindemann drill) to widen this final dimension more palatal, and often should tap the osteotomy in the anterior maxilla with a bone tap to ensure a smooth, atraumatic insertion of the threaded implant in the proper position (Figure 29-34).

A hand ratchet should not be used to tap D3 bone. When a hand ratchet is used, the bone tap is pulled in the direction of the rotating arm of the ratchet. This causes the tap to distort and widen the top of the osteotomy and impair proper bone contact with the crest module of the implant. In addition, the hand ratchet and tap technique do not counter the effect of the more dense bone on the palatal aspect, which forces the tap more facial toward the softer bone. This causes the implant to be positioned more facial than originally prepared and may even strip the thin cortical plate on the facial aspect of the osteotomy.

In abundant bone volume, the implant may self-tap the soft, thin, trabecular bone to enhance initial stability. An implant with a wider crest module can compress the crestal bone when inserted without using a countersink drill. The implant should not be removed and reinserted, as initial rigid fixation may be compromised. If the only cortical bone is on the crest of the ridge, as in a posterior mandible, the implants are not countersunk below the crest in this density of bone. The thin, porous cortical plate provides greater initial stability than the fine trabecular bone underneath. This is especially important in the posterior mandible of a clenching parafunctional patient, as bone torsion occurs during heavy biting pressures.

For a threaded implant, a low-speed (30 rpm), high-torque hand piece should be used rather than a hand wrench for self-tapping implant insertion. This decreases the risk of oversizing the osteotomy with an elliptical implant insertion, which usually results from hand wrench placement in softer bone. A firm hand during hand piece insertion also can prevent this implant from being pushed facially, away from the thicker lingual cortical plate. Tightening a threaded implant to increase fixation once completely inserted is not recommended, because stripping of the threads and decreased fixation may occur.

A roughened surface condition or coating on a threaded implant body is advantageous in this soft bone condition, to enhance initial stability and the amount of initial trabecular bone at the bone-implant interface. The amount of bone initially at the bone-implant interface is reduced in comparison with bone types D1 and D2. If the lingual and apical cortical bone are not engaged at the time of implant placement, less than 50% of the implant surface may actually contact bone.

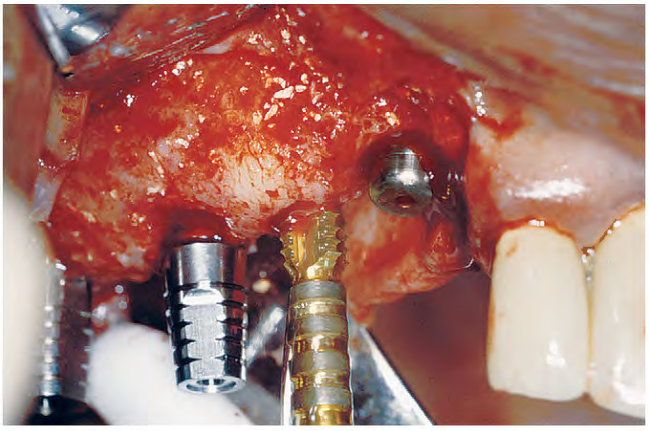

Figure 29-34 A bone tap may be indicated in specific D3 bone conditions, such as the anterior maxilla with dense palatal cortical bone. Otherwise, the threads of the implant do not engage the palatal plate and the implant is pushed into a more facial position.

An additional implant may be used to improve load distribution and prosthodontic support during the early loading period.

Healing

The time frame for atraumatic healing is usually 5 or more months. The actual implant interface develops more rapidly than D2 bone; however, the extended time permits the regional acceleratory phenomenon (RAP) from implant surgery to stimulate the formation of more trabecular bone patterns. In addition, the more advanced bone mineralization within the extra months also increases its strength before loading. An extended gradual loading period is also recommended to further improve this bone density during the initial bone loading.

Fine Trabecular Bone (D4)

Fine trabecular (D4) bone has very little density and little or no cortical crestal bone. It is the opposite spectrum of dense cortical (D1) bone. The most common locations for this type of bone are the posterior molar region of a maxilla in the long-term edentulous patient, or in an augmented ridge in height and width with particulate bone or substitutes, or in a sinus graft. It is rarely observed in the mandible but on occasion does exist. These edentulous ridges are often very wide but have reduced vertical height. This bone type is also present after osteoplasty in wide D3 ridges because the crestal cortical bone is removed during this procedure.

The tactile sense during osteotomy preparation of this bone is similar to stiff, dense Styrofoam or soft balsa wood. The bone trabeculae may be up to 10 times weaker than the cortical bone of D1. The BIC after initial loading is often less than 25% (Figure 29-35). A CT scan with reformatted images of D4 bone has a Hounsfield number of less than 375 units.

WWW.HIGHDENT.IR

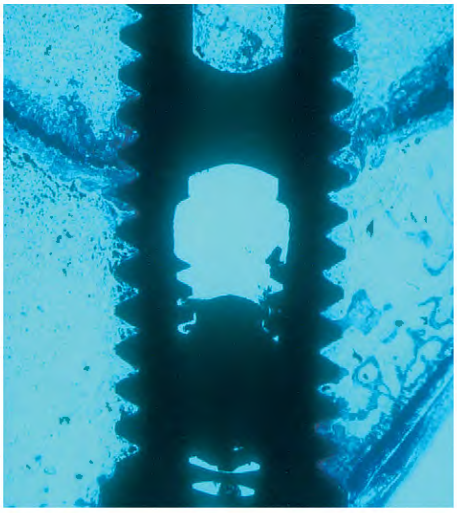

Figure 29-35 The posterior maxillary region may be D4 bone, with BIC after initial loading no greater than 25%.

Implant Design

Needs coating

The ideal implant height in D4 bone for a V-shaped thread implant design approaches 15 mm. Power thread implant designs may use implants as short as 12 mm. The requirement for minimum height of available bone is greater in D4 bone than in other types. Sinus grafts are often indicated to ensure adequate height for ideal implant surface area of support. In addition, sinus grafts permit the implant to engage the original sinus floor composed of a thin porous cortical bone, which helps further stabilize the implant.

Division B implants are not suggested in this bone type. Bone spreading is easiest in this bone density, and larger-diameter implants are suggested whenever possible. A roughened surface or hydroxyapatite (HA) coating is almost mandatory to improve the amount of bone-implant contact in this bone quality after initial healing.

Disadvantages of D4 Bone

Fine trabecular bone presents the most arduous endeavor to obtain rigid fixation. Bone trabeculae are sparse and, as a result, initial fixation of any implant design presents a surgical challenge (Box 29-3). The implant surgeon should not prepare D4 bone with rotating drills, which use an extraction technique to remove bone preparation of the osteotomy (Figure 29-36). The initial drill to determine site depth and angulation is the only one that should be used in this bone type, after which osteotomes may be used with a surgical mallet or hand piece to compress the bone site, rather than remove bone, as the osteotomy increases in size (Figures 29-37 to 29-39). The compaction technique of the site is prepared with great care. The bone site is easily distorted, resulting in reduced initial stability of the implant. The final osteotomy diameter is similar to the D3 preparation. The residual ridge is easily expanded in this bone type. The osteotomy may both compress the bone trabeculae and expand the osteotomy site.

The implant should self-tap the bone or shape the implant receptor site while being seated with a slow-speed, high-torque hand piece (Figure 29-40). A hand wrench is contraindicated. The pressure on the implant during insertion corresponds to the speed of rotation, and the implant proceeds to self-tap the soft bone. It is difficult to thread an implant in soft bone in difficult

WWW.HIGHDENT.IR

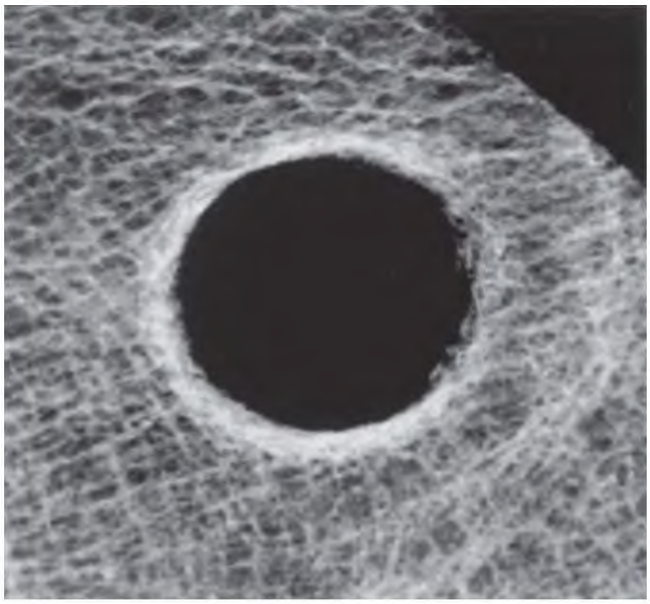

Figure 29-37 A bone compaction technique to prepare the implant site, compress the bone, and make it more dense.

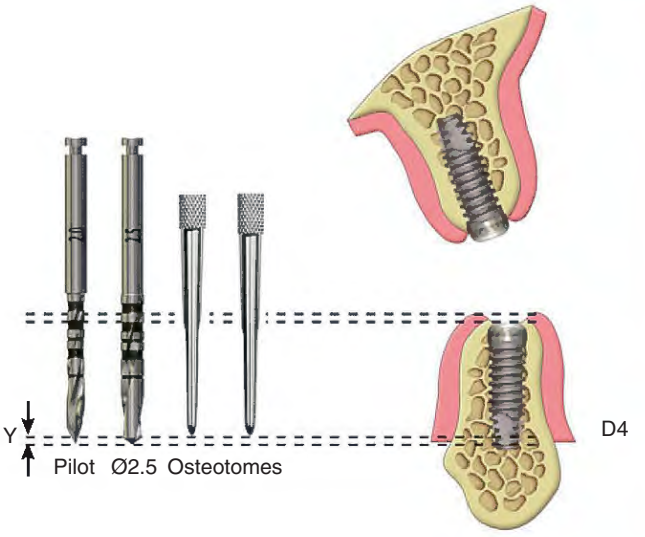

Figure 29-38 Osteotomes of increasing size may be used in D4 bone to compress the residual bone, making it more dense to provide enhanced initial support the implant.

access regions. If there is any cortical bone in the opposing landmark, it is engaged to enhance stability and simultaneously ensure the maximum length of implant. An implant with a greater crestal diameter presents the added benefit to further compress the crestal bone for stability.

Once inserted, the implant should not be removed and reinserted; instead, one-time placement is mandatory. The implant is countersunk in this bone if any risk of loading is expected during healing (e.g., under a soft tissue–borne denture). Countersinking the implant

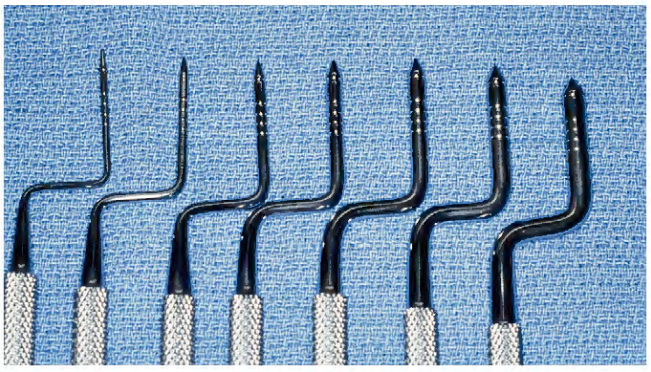

Figure 29-39 Bone compaction instruments are used after the initial pilot drill to prepare the osteotomy.

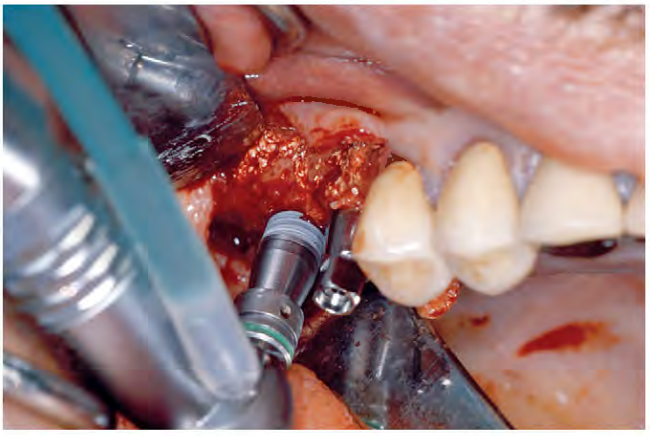

Figure 29-40 A slow-speed, high-torque hand piece is used to thread the implant into position for D4 bone. No crestal bone drill or tapping procedure is indicated in this soft bone. This ensures the implant osteotomy is not widened by the hand movement and ratchet.

below the crest reduces the risk of micromovement during healing in this very soft bone (Figure 29-41). No countersink drill is used before countersinking.

Additional implants are placed to improve implant-bone loading distribution and prosthodontic rehabilitation, especially during the first critical year of function. For fixed restorations, one implant is used for each buccal tooth root replaced, and no cantilever on the prosthesis is used with this bone density. An additional implant may be placed at the time of surgery in the second molar region to further improve support during the first critical year of loading. The implant of choice in the wide posterior maxilla with D4 bone is a greater diameter, roughened surface or HA-coated threaded implant. When properly inserted, the HA-threaded implant can be more stable and provides greater surface area. The larger-diameter implant offers greater surface area for support, further compresses the fine trabecular bone for greater initial rigidity, has a greater chance to engage the lateral regions of cortical bone for support, and improves stress transfer during loading.

WWW.HIGHDENT.IR

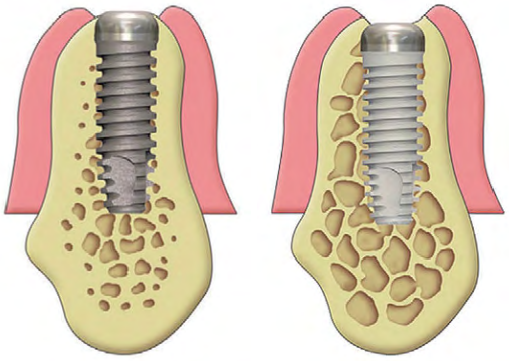

Figure 29-41 In D4 bone, the implant is often countersunk below the crest of the ridge, wherever a soft tissue-borne restoration is worn during the initial healing phase. In D2 bone, the implant is usually placed at the crest of the bone.

Healing

The healing and progressive bone loading sequence for D4 bone require more time than the other three types of bone. Time is needed to allow bone to remodel at the surface and to intensify its trabecular pattern. The additional time also allows a more advanced bone mineralization and increased strength. Six or more months of undisturbed healing is suggested. The compression technique for surgery, the extended healing time, and progressive bone loading protocol allow the remodeling of this bone into a more organized and load-bearing quality similar to D3 bone before the final prosthetic loading of the implants.

SUMMARY

Bone remodels in relation to the forces exerted upon it. Depending on the location of the edentulous ridge and the amount of time the area has been edentulous, the density of bone is variable. Clinically, the surgeon can correlate the hardness of the trabecular bone and the presence of a cortical plate with four different densities of bone. The typical locations of these different densities, the alteration in surgical technique with each type, and the advantages and disadvantages of each have been related to each density classification. The dense cortical bone of D1 is the strongest bone, approximately 10 times greater than D4 bone, and is the most difficult to prepare. The thick, porous cortical and coarse trabecular D2 bone is twice as strong as D3 bone and is ideal for implant support. The thin, porous cortical and fine trabecular D3 bone is similar to preparations in compressed balsa wood. The fine trabecular bone of D4 is similar to osteotomies in dense Styrofoam. The initial drills may be used to distinguish among the four bone density types.

Type D1 bone heals with a lamellar bone interface and has the greatest percentage of bone at the implant body contact regions. Type D2 bone heals with woven and lamellar bone, is adequately mineralized at 4 months, and often has approximately 70% bone in initial contact after healing with the implant body. An ideal length, V-shaped, threaded-screw implant should have 12-mm minimum height. Type D3 bone has about 50% bone at the initial implant interface after healing and benefits from a roughened surface on the screw-shaped implant body to increase initial fixation and bone contact. A minimum of 12-mm implant height is typically required for initial fixation and loading. An additional 1 month (total of 5 months) is used for initial bone healing, compared with D2 bone, to permit a greater percentage of bone trabeculae to mineralize and form around the implant. D4 bone density has the least amount of trabeculae at implant placement. The minimum implant height of a V-shaped thread design is approximately 15 mm, and HA coatings or a roughened surface should be used on the implant body. Compressive thread designs may gain stability and optimum stress distribution with implants 12 mm long and should be rough or HA coated. Additional time for bone healing and incremental bone loading will improve the density and result in implant survival similar to that of other bone densities.

Chapter 30

Posterior Single-Tooth Replacement: Surgical Guidelines

Carl E. Misch

Seventy percent of the dentate U.S. population is missing at least one tooth. Compared with past generations, single-tooth replacement will most likely comprise a larger percentage of prosthetic dentistry in the future. In 1960 the average American older than age 55 had just seven original teeth. Today the average 65 year old has 18 teeth, whereas the baby boomers can expect to have at least 24 teeth left when they reach age 65. Currently the first teeth lost are usually between the ages of 35 and 54 years. Almost 30% of the 50 to 59 year olds examined in a U.S. national survey exhibited either single or multiple posterior edentulous spaces bordered by natural teeth.[1] Treatment to replace single teeth in the posterior regions represents nearly 7% of the annual dental care reimbursement from insurance companies, and total estimated treatment costs for all patients missing a posterior tooth approximate $10 billion U.S. each year.[2,3]

POSTERIOR MISSING TOOTH

The first molars are the first permanent teeth to erupt in the mouth and are often the first to decay. The adult patient typically has had one or more crowns fabricated to restore the integrity of the tooth and replace previous large restorations. Longevity reports of crowns have yielded very disparate results, with the mean life span at failure reported to be 10.3 years. The primary cause of failure of the crown is endodontic therapy, porcelain or tooth fracture, or uncemented restoration, which leads to decay. The posterior tooth is at risk for extraction as a result of these complications.[1-9] Replacement of the posterior tooth is frequently necessary, and at least one of the adjacent natural teeth are virgin or minimally restored more than 80% of the time. Therefore, a traditional three-unit fixed partial denture to replace a single tooth would remove the enamel on a completely healthy tooth and begin a cascade of potential complications, which often leads to loss of the tooth.

SINGLE-TOOTH IMPLANTS

From 1993 to the present, single-tooth implants have become the most predictable method of tooth replacement and therefore the treatment of choice. There are more refereed reports in the literature than for any other tooth replacement method. Becker et al. reported a more than 90% success rate in a study over 4 years of 282 molar implants.[10,11] Simon et al. followed 70 molar implants over a period ranging from 6 months to 10 years with a 97.1% success rate.[12] Levin et al. reported in 2006 on single-molar replacement with implants from 6 to 125 months (>10 years) with a 93.6% success rate.[13]

A 10-year report by Priest indicated the posterior single tooth was more than 97% successful.[3] More important, there were no adjacent teeth lost from endodontic failure or causes, and only one tooth required endodontic therapy after implant insertion. This report clearly identifies the adjacent teeth to be least at risk when the missing tooth is replaced with an implant. In a 2007 study, Misch et al. reported a 99% survival rate (11 initial healing failures and three late failures) for 1377 posterior single-tooth implants for as long as 10 years.[14] A review of the literature by Goodacre et al. from 1981 to 2003 found single-tooth replacement with an implant had the highest implant prosthesis survival rate and averaged 97% survival.[15] The most common complication reported was abutment screw loosening, which did not cause the prosthesis or implant to fail. In a consensus statement, Salinas et al. reported pooled success for single-tooth restorations exceeded the success rate of traditional fixed partial dentures.[16]

IMPLANT BODY SELECTION

The implant body for a posterior single-tooth implant should include specific features to reduce complications. The most common problem associated with a single

WWW.HIGHDENT.IR

tooth is abutment screw loosening.[10,11,15,16] The higher the torque used to tighten the screw, the less the risk of loosening. Crest module and abutment connection designs, which decrease forces to the abutment screw, are also indicated. The implant must have an antirotational feature (e.g., an external or internal hex). The greater its height or depth, the less force transmitted to the abutment screw. However, the diameter of the implant is more significant to reduce the stress. Accuracy of component fit, the abutment screw design, and number of threads on the fixation screw are other critical features.

The implant body should be made of titanium alloy to reduce the risk of long-term fracture, as it is four times more resistant to fracture than grade 1 titanium and twice as strong as grade 3 titanium. Sullivan reported a 14% implant fracture rate for single molars fabricated on standard-diameter Nobel Biocare implants (grade 1 titanium) and concluded that this is not a viable treatment.[17] A threaded implant provides greater functional surface area than a cylinder, and a tapered implant provides less surface area than a parallel-walled implant body. When implant bodies are internal hex designs, the dimension of the implant in the posterior regions should be at least 4 mm or more in diameter to increase the outer body wall thickness and reduce the risk of long-term body fracture.

The ideal diameter of a single-tooth implant is dependent upon the mesiodistal dimension of the missing tooth and the buccolingual dimension of the implant site. When the facial bone thickness is inferior to 1.4 mm, bone loss may result and implant failures may occur with greater frequency.[18] Horizontal bone loss around the implant causes increased probing depths or increased risk of soft tissue shrinkage. These may affect the bacterial flora or cervical esthetics of the soft tissue drape. This may be why gingival recession around wide-diameter implants has been noted to be greater than with a standard diameter.[19,20] The ideal implant size is 1.5 to 2 mm from an adjacent tooth and has at least 0.5 mm of bone on the lateral aspects of the implant body. The ideal implant diameter in the intratooth posterior region should be at least 3 mm less than the mesiodistal dimension of the missing tooth (from cement-enamel junction [CEJ] to CEJ) and 3 mm narrower than the buccolingual dimension of bone. As a general rule, the molar implant should be larger in diameter than a premolar implant.

PREMOLAR IMPLANT REPLACEMENT

The most ideal posterior tooth to replace with an implant is the first premolar, in either arch. The vertical available bone usually is greater than any other posterior tooth positions. In the maxilla, it is almost always anterior or below the maxillary sinus, and the mandibular first premolar is almost always anterior to the mental foramen and mandibular neurovascular complex. The bone trajectory for implant insertion is more favorable in the mandibular first premolar than for any other tooth in the arch.

The maxillary premolars are often in the esthetic zone of patients with a high smile line. The need for bone grafting before maxillary first premolar implant placement is very common, as the thin buccal facial plate is often lost during the extraction process. Implant placement without bone grafting may result in a recessed emergence profile that, in the past, was corrected with a facial ridge lap crown, which does not allow proper hygiene or probing and should be avoided. To ensure proper esthetics and avoid the need for a ridge lap, the implant body often is positioned under the buccal cusp to improve the cervical emergence profile of the maxillary premolar crown.

The natural premolar tooth root is 4.2 mm in diameter on average at a distance of 2 mm below the CEJ. As a consequence, the most common implant diameter is about 4 mm at the crest module. This also provides approximately 1.5 mm of bone on the proximal surfaces adjacent to the natural teeth when the mesiodistal space is 7 mm or greater. However, when the mesiodistal dimension is only 6.5 mm, a 3.5-mm implant is suggested.

The maxillary canine root is often angled 11 degrees distally and presents a distal curve 32% of the time, which may extend over the shorter root of the maxillary first premolar. The mandibular canine also may have a distal inclination. The implant body is often longer than the natural tooth root of a premolar tooth. The surgeon may inadvertently place the implant parallel to the second premolar and, consequently, into the natural canine root. This may not only result in endodontic therapy of the canine, but also may cause root fracture and loss of the tooth (Figure 30-1, *A*). Therefore in the first premolar region, care is taken to evaluate the canine angulation. The first premolar implant may need to be placed parallel to the canine root and may need a shorter-than-ideal implant. A tapered implant body at the apical one third also may be of benefit, to further decrease the risk of inadvertently engaging the canine root (Figure 30-1, *B*).

The second premolar apex may be located over the mandibular neurovascular canal or maxillary sinus. This results in a reduced bone height compared with the anterior region of the jaws and a shorter implant.

MOLAR IMPLANT REPLACEMENT

The molar mesiodistal dimension usually ranges from 8 to 12 mm, depending on the original tooth size and the amount of mesial drift of the second molar before implant placement. When one 4-mm-diameter implant is placed to support a crown with a mesiodistal dimension of 12 mm, this may create a 4- to 5-mm cantilever on the

WWW.HIGHDENT.IR

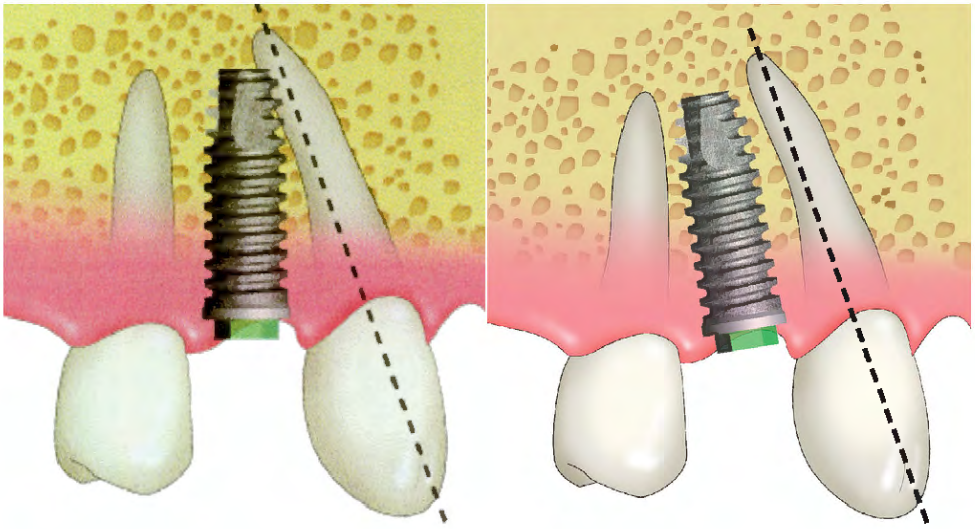

Figure 30-1 **A,** A maxillary canine root is often slanted 11 degrees distally and has a distal curvature 32% of the time. When the implant is placed parallel to the first premolar, it may inadvertently encroach upon the canine root. **B,** A maxillary first premolar implant may need to be parallel to the canine.

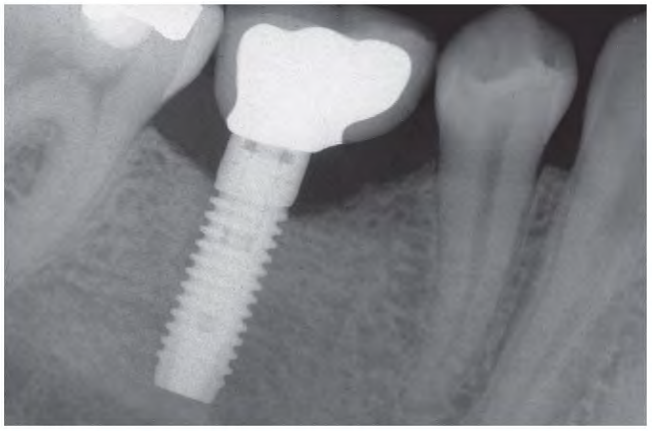

Figure 30-2 When a mesiodistal space is 14 mm, standard 4-mm-diameter implants will have a 5-mm cantilever, which increases the force to the cement, abutment screw, marginal bone, and implant body. Therefore an increased risk for biomechanical complications occurs.

marginal ridges. The magnified occlusal forces (especially important in parafunction) may cause abutment screw loosening, an exaggerated emergence profile on the crown, bone loss, and implant body fracture (Figure 30-2).

The most common complication of one regular 4-mm-diameter implant to replace a molar is abutment screw loosening. When the mesiodistal dimension permits, two 3.5- to 4-mm-diameter implants should be considered to restore the region to improve stress reduction and, in turn, reduce the incidence of abutment screw loosening. In a 3-year report of posterior first-molar replacements, Balshi et al.[21,22] found implant screw loosening was a common complication when one implant replaced the tooth (48%) and was reduced to 8% when two splinted implants replaced the first molar. Other studies found the one-wide diameter implant had greater screw loosening than two splinted implants.[23,24] A 50% decrease in mesiodistal and buccolingual stress was found between a 5-mm and two splinted, standard-diameter implants.[24] Therefore, whenever possible, two splinted implants should be used to replace a larger single-molar space.

As mentioned earlier, Sullivan reported a 14% implant fracture rate for single molars on a standard, 4.1-mm implant.[17] Rangert et al. reported overload-induced bone resorption appeared to precede implant fracture in a significant number of single-molar implants, which were 4 mm in diameter.[25]

When the mesiodistal dimension of the missing tooth is 8 to 12 mm with a buccolingual width greater than 7 mm, a 5- to 6-mm-diameter implant body is suggested to reduce the stress to the implant system. Langer et al.[26] also recommended the use of wide-diameter implants in bone of poor quality or for the immediate replacement of failed implants. The larger-diameter implant does not require as long an implant, which also is a benefit because of the reduced posterior vertical bone height due to anatomical limitations. When possible, a larger diameter implant (or two splinted, traditional-size implants) should be inserted to enhance the mechanical properties of the implant system through increased surface area, stronger resistance to component fracture, increased abutment stability, and enhanced emergence profile for the crown.

When the posterior space is 14 mm or greater, the largest implant diameter for two adjacent implants may be calculated by subtracting 6 mm (1.5 mm from each tooth and 3 mm between the implants) from the intratooth distance and dividing by 2 (Figure 30-3).

$$\frac{16\,\text{mm} - 6\,\text{mm}}{2} = 5\,\text{mm for each implant.}$$

WWW.HIGHDENT.IR

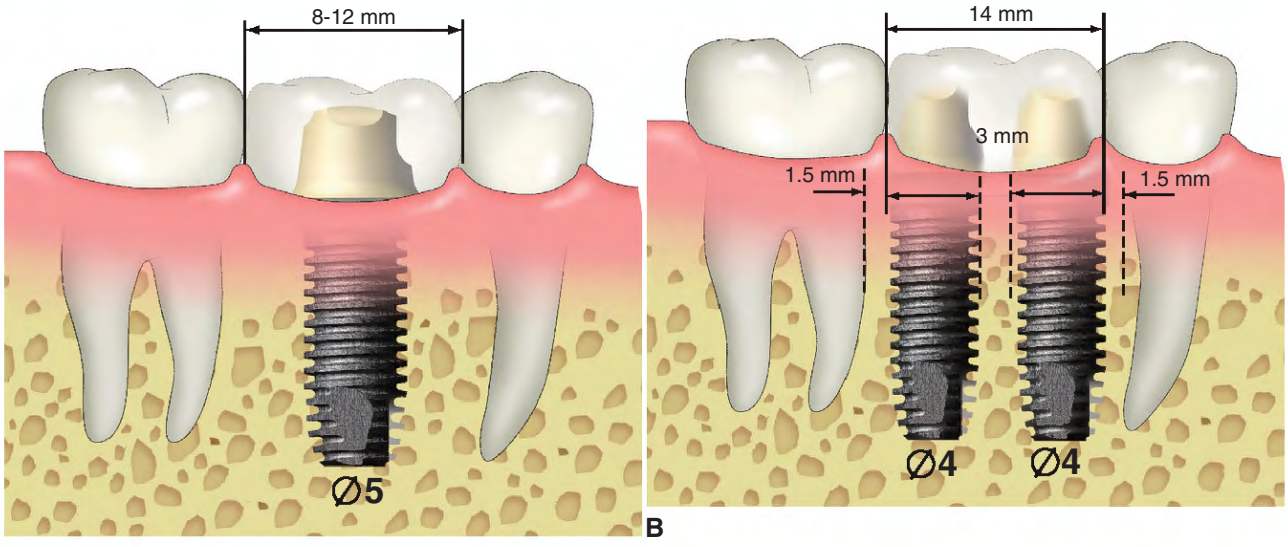

Figure 30-3 When the intratooth space is 14 mm, the ideal implant size is 14 mm – 6 mm (1.3 mm from each tooth and 3 mm between the implants) ÷ 2 = 4 mm for each implant.

It should be noted the diameter used is the crest module dimension, which is often 0.2 to 0.35 mm greater than the implant body dimension (i.e., 4.1/3.75 mm for Nobel Biocare SteriOss, 3-I, LifeCore). The two implants should be 3 mm apart, because the width of the crestal defect around an implant is usually less than 1.5 mm. The two adjacent implants 3 mm or more apart will not convert the angular defect next to each implant into a horizontal defect, which may increase sulcus depths or cause a loss of papilla height.[27] When possible, two regular-size or one regular and one large-diameter implant are suggested when replacing molars. The space is usually restored with two premolar-size crowns, rather than a large molar with a furcation (Figure 30-4).

When the posterior mesiodistal space between teeth is 12 to 14 mm, the treatment plan of choice is less obvious. A 5-mm-diameter implant may result in cantilevers up to 5 mm on each marginal ridge of the crown. However, two implants present a greater surgical, prosthetic, and hygiene risk. The first option is to slightly reduce the standard implant diameter to 3.5 mm, rather than 3.75 or 4.0 mm. The primary space requirement is reduced to 13 mm of space, instead of 14 mm. Additional space also may be gained in several ways:

1. Enamoplasty of the adjacent teeth proximal contours to increase the mesiodistal dimension of the missing tooth. It is not unusual that the distal natural tooth has tipped toward the edentulous space. An enamoplasty may be even more effective in these cases to increase space (Figure 30-5).
2. Orthodontics to upright a tilted second molar or increase the intratooth space. One anterior implant

Figure 30-4 **A,** When the intratooth space is 14 to 20 mm, two implants are used to restore the space. The implants are positioned 1.5 to 2.0 mm from each tooth. **B,** The two implant crowns to restore a space 14 to 20 mm are splinted together and usually made the size of premolars.

WWW.HIGHDENT.IR

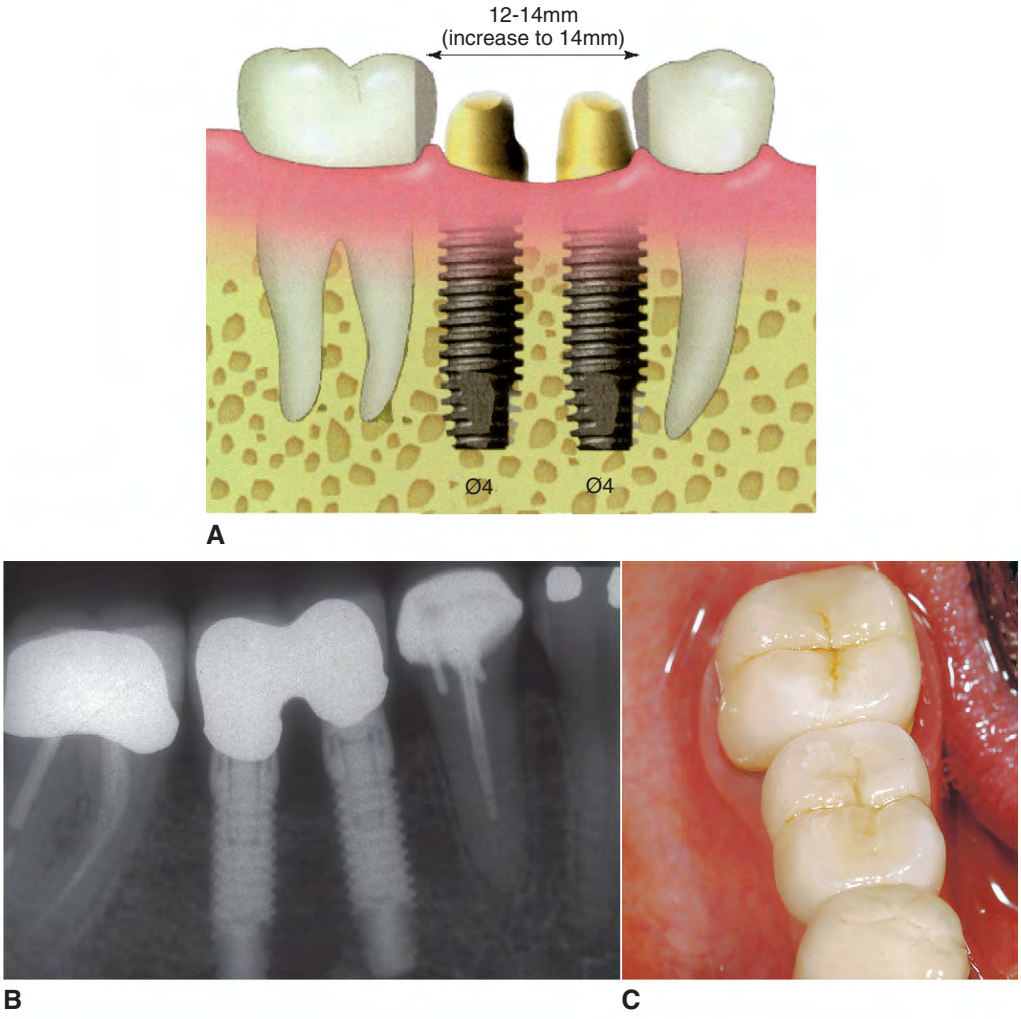

Figure 30-5 **A,** When 12 to 14 mm of space is available, the mesial and distal contour of the adjacent teeth is modified to gain addition space. **B,** A periapical radiograph of two 3.7-mm implants to replace one molar, in which the proximal contours of adjacent teeth were reduced. **C,** An intraoral view of the mandibular first molar, replaced by two 3.7-mm implants (BioHorizons Maestro Dental Implants).

may be placed and an orthodontic spring incorporated in the transitional crown. The spring pushes the distal tooth more distal and, after orthodontic movement, the second implant may be inserted with less risk and improved hygiene between each implant. Another option is to reduce the space orthodontically and place only one implant and crown.

3. The implants may be offset with one implant placed buccal and the other implant on a diagonal toward the lingual[28] (Figure 30-6, *A*). The diagonal dimension increases the mesiodistal space by 0.5 to 1 mm. In the mandible, the most anterior implant is placed to the lingual aspect of the midcrest and the more distal implant is placed to the facial aspect to facilitate access of a floss threader from the vestibule into the intraimplant space. The occlusal contacts also are slightly modified on the buccal aspect of the mesial implant to occlude over the central fossa (Figure 30-6, *B*). In the maxilla, the anterior implant is placed facially and the distal implant palatally to improve esthetics. The distal occlusal contact is placed over the lingual cusp and the mesial occlusal contact is located in the central fossa position. The cervical esthetics of the maxillary molar are compromised on the distal half of the tooth to the benefit of greater intratooth distance and easier access for home care. This maxillary implant placement requires the intraimplant furcation to be approached from the palate, rather than the buccal approach, as the mandible.

POSTERIOR SINGLE-TOOTH IMPLANT SURGERY

The ideal location to begin a surgical experience in implant dentistry is a posterior single tooth, out of the esthetic zone, and in abundant bone volume. Surgical success rates for single-tooth implants are often more than 98%. University reports show predoctoral students

B

Figure 30-6 **A,** When the mesiodistal space is 12 to 14 mm, the implants may be offset to increase space between the implants. In the mandible *(left)* the distal implant is positioned more buccal and the mesial implant more lingual. In the maxilla, the mesial implant is more buccal and the distal implant is more lingual. **B,** An intraoral view of a mandibular first molar with offset implants. The distal implant is more buccal, which facilitates floss threader insertion for oral hygiene.

have achieved excellent results in these conditions.[28-31] For example, Bell et al. reported no failure in 120 implants during a 4-year period with selected predoctoral dental students.[28] Cummings et al. found senior predoctoral dental students had no implant failures of 71 implants during 5 years.[29]

Posterior single-tooth implants may be technically easier and have less risk than performing an endodontic treatment on a tooth with a single canal. Rather than working on a diseased pulp with different local conditions, an implant surgery is in healthy bone and an ideal clinical situation. In endodontics, the files and obturation should be within 0.5 mm of a tooth apex. Implants may be prepared and inserted 0.5 to 10 mm from an opposing landmark. Endodontics requires the removal of necrotic debris from an oblong canal, with lateral canals and root curvatures or dilacerations. An implant osteotomy is round in diameter and made with round-diameter drills and always a straight channel. Endodontics requires obturation with a plastic material, able to fill irregular-diameter and shaped canals. Underfills may result in failure of the procedure. Implant round-diameter osteotomies are obturated with a round-diameter implant precisely fabricated for the size of the osteotomy. Underfills of the osteotomy will fill in with bone next to the implant, with no clinical consequence. An implant surgery may be completely aborted at almost any time, and several months later the bone conditions are healed and similar to the original bone site conditions.

Table 30-1 Comparison Between Two-Stage, One-Stage, and Direct One-Stage Surgeries

TOPIC	TWO-STAGE	ONE-STAGE	DIRECT ONE-STAGE
Bone anatomy visual control	Yes	Yes	No
Osteotomy visual control	Yes	Yes	No
Cover screw/ PME	Below tissue	Above tissue	Above tissue
Bone graft	Yes	Maybe	No
Exposure to intraoral bacteria	No	Yes	Yes
Surgical appointments	2	1	1
Prosthetic connection/ implant platform level	At or below tissue More difficult	At or above tissue Easier	Above tissue Easier
Reposition keratinized facially	Yes	Yes	No
Transitional appliance	Yes	Yes-No	Yes-No
Stage II needed	Yes	No	No

PME, Permucosal healing extension.

SURGICAL PROCEDURE

There are three approaches for posterior single-tooth implant surgery: (1) two-stage surgery, (2) one-stage surgery, and (3) direct, one-stage surgery (Table 30-1).

Two-Stage Surgery

In an early learning curve, the two-stage surgical approach offers several advantages. This method provides direct vision of the crestal bone width and length. The direct observation of crestal bone ensures adequate width of bone is available for implant placement. The width of bone is often reduced after initial socket healing. If

WWW.HIGHDENT.IR

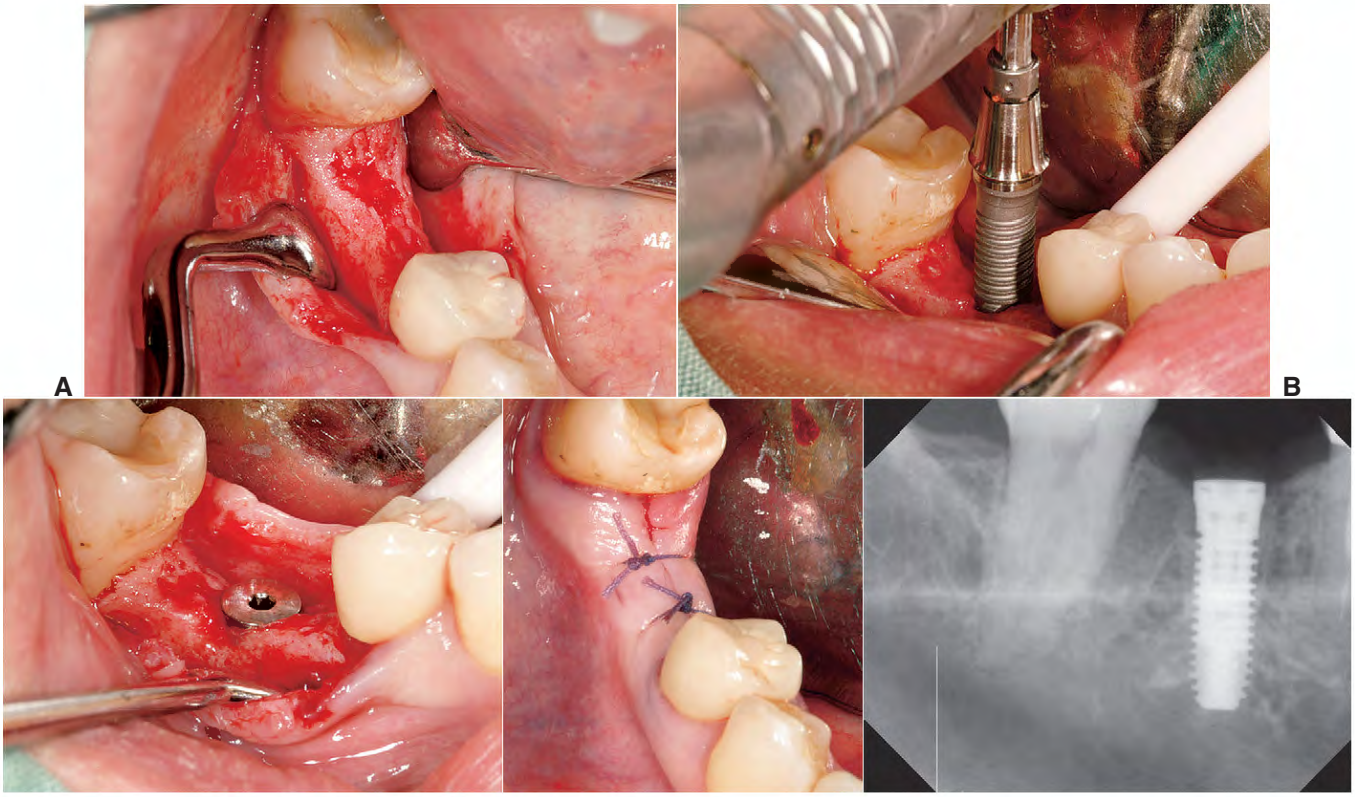

Figure 30-7 **A,** A two-stage surgery reflects the soft tissue and directly observes the underlying bone. **B,** A single-tooth implant is threaded into the osteotomy (BioHorizons Internal Dental Implant) for a posterior single-tooth replacement. **C,** A low-profile cover screw is inserted into the implant body. **D,** The first-stage surgery uses primary closure over the implant site during initial bone healing. **E,** A periapical radiograph of the implant in position to replace a single molar.

inadequate, a bone graft should be performed before implant insertion. In more experienced situations, the implant may be inserted at the same appointment as the bone graft. The implant is inserted at or slightly below the crest of bone in this technique. A low-profile cover screw is then inserted into the implant body. The tissues are then approximated over the implant for primary closure. A removable transitional prosthesis may be delivered post surgery when in the esthetic zone and in the absence of a bone graft (Figure 30-7).

The advantages of this approach include: (1) direct observation of crestal bone volume before osteotomy; (2) direct observation during osteotomy preparation; (3) ability to bone graft the site at the time of implant placement; (4) implant body healing at or below the crest of bone, which reduces risk of early loading during initial bone healing; (5) local hygiene issues or anaerobic bacterial infiltration are not critical factors during initial healing; and (6) the ability to deliver a soft tissue–borne transitional appliance in the esthetic zone.

The technique requires a second-stage surgery to uncover the implant body. The advantages of this procedure are the crestal and facial region may be directly evaluated and minor defects corrected before beginning the prosthetic reconstruction. On occasion, soft tissue has invaded the crestal zone of the implant, and a one-stage approach does not evaluate the region before restoration. The facial plate of bone may also resorb during initial healing and may be grafted at the reentry surgery.

One-Stage Surgery

A one-stage surgery uses a similar incision and reflection technique to observe directly the crestal bone volume. However, at the conclusion of the implant surgery, a permucosal healing element (PME) is placed into the implant body. The implant body also is usually placed slightly above the crest of the bone. The soft tissue is then placed around the PME (Figure 30-8). The advantages of the one-stage surgery are:

1. The soft tissue matures while the bone interface is healing. This permits the restoration to be fabricated with complete assessment of the soft tissue profile. In the two-step procedure, the soft tissue is less mature when the prosthesis is fabricated, as a stage II surgery is required to uncover the implant and place a PME or abutment.
2. A second surgical procedure and suture removal appointment are not necessary. This saves the patient

WWW.HIGHDENT.IR

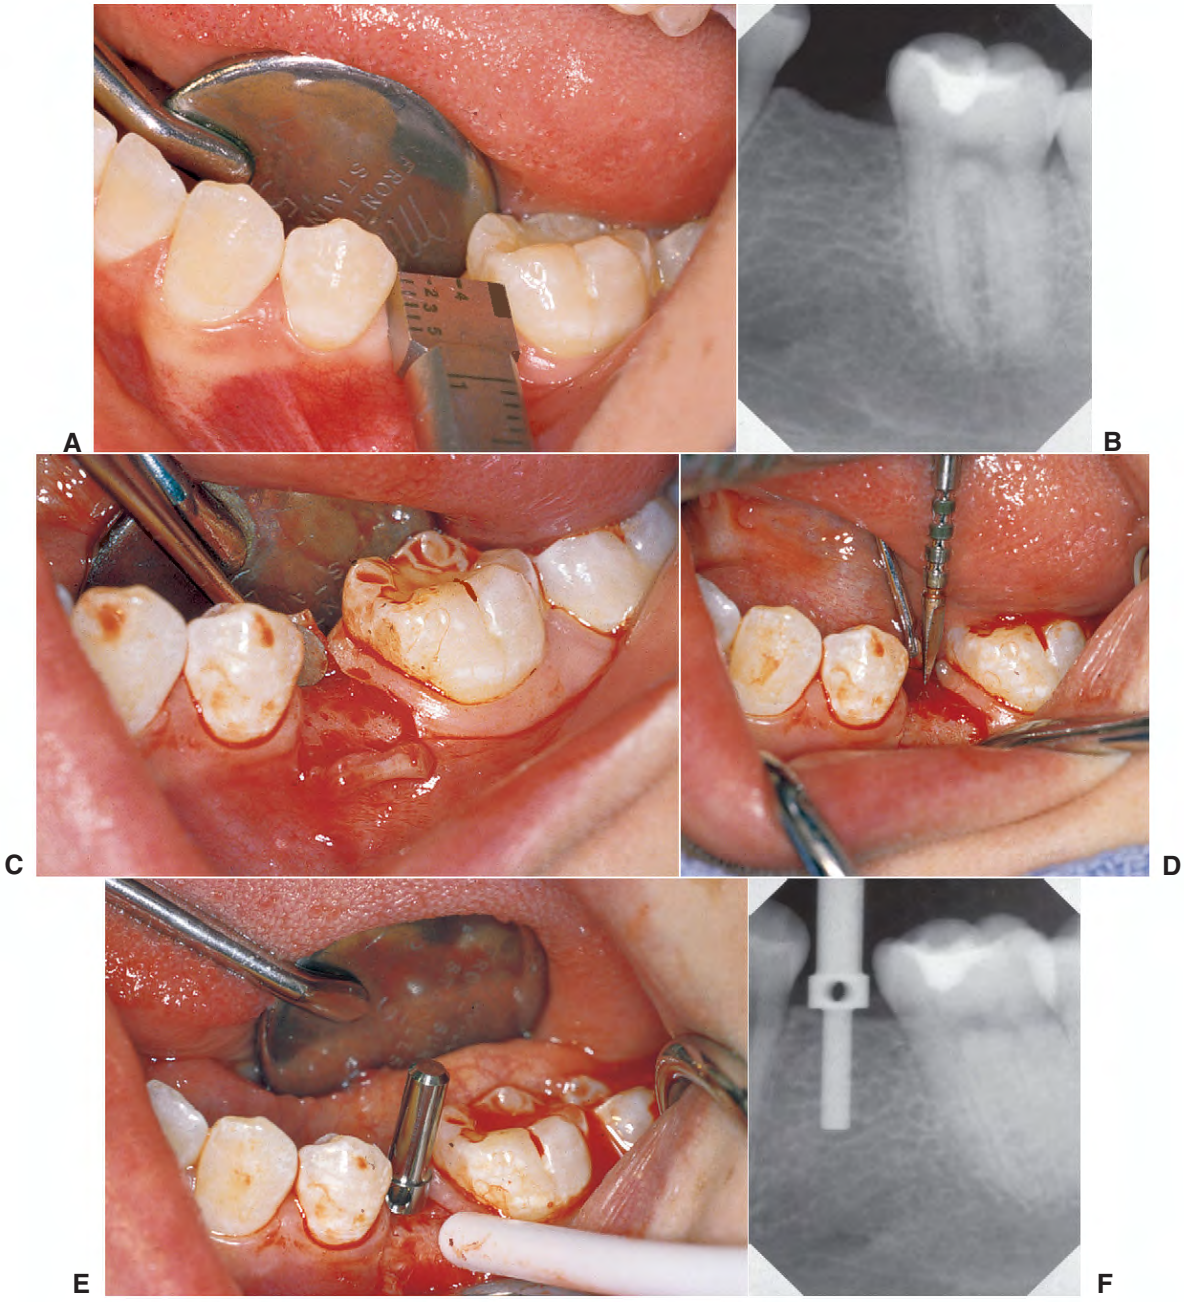

Figure 30-8 **A,** The mesiodistal dimension of a missing tooth for a single-tooth implant should be at least 6.5 mm in the posterior region of the mouth (measured between the CEJs). This permits an implant at least 3.5 mm in diameter. **B,** A periapical radiograph is used to evaluate available bone height. It should be at least 11 mm from the crest to the opposing landmark (i.e., the mandibular foramen and mandibular canal). **C,** In the present case, a one-stage surgical approach may be selected instead of a direct one-stage approach to reposition the keratinized tissue facially. The soft tissues are reflected for direct observation of the bone volume and dimension during the preparation of the implant osteotomy. **D,** A 2-mm-diameter, end-cutting starter drill is used initially under copious cooled sterile saline. **E,** A 2-mm-diameter, 9-mm-long force direction indicator with a 4-mm-diameter "stop" is placed in the osteotomy. **F,** A periapical radiograph is made of the force direction indicator (depth gauge). The adjacent roots are evaluated in relation to the device, and the distance from the opposing landmark is evaluated.

No second-stage incision or tissue reflection is needed in this case. **O,** Final prosthesis delivery. **P,** Periapical radiograph of final restoration.

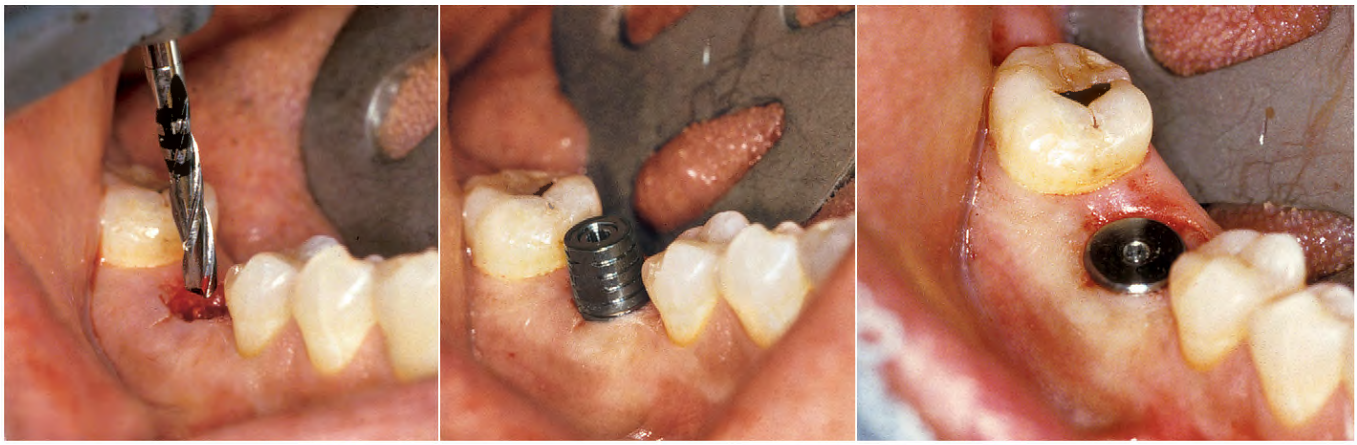
discomfort and the surgeon two appointments (stage II uncovery and suture removal).

3. The abutment to implant connection may be placed above the crest of bone in the one-stage surgery. This higher location of the implant-abutment connection may reduce some of the early crestal bone loss in a developing implant interface. In addition, Weber observed an improved hemidesmosome soft tissue–implant connection when the components above the bone were not removed and reinserted, as when the healing gap connection is below the bone.[32] Depending upon crest module design, the one-stage surgical approach may have less early crestal bone loss.
4. The higher-profile implant body also allows the restoring dentist to attach the prosthetic abutment with greater ease and tactile ability. Impression caps also may be inserted when the abutment connection is above the bone, which further simplifies the restorative procedure (Table 30-1).

An advantage of the one-stage surgery, compared with a direct or flapless one-stage approach, is the attached keratinized tissue may be repositioned to ensure an adequate zone on the facial aspect of the PME and implant abutment. In addition, direct observation of the bony crest permits bone grafting and a precise implant crest module position relative to the crest because it can be directly observed. In theory:

1. The higher-profile PME is more at risk of loading during healing, especially when an overlying soft tissue–borne transitional restoration is worn. Therefore a disadvantage may be a higher healing failure rate. However, clinical studies of one-stage surgery indicate similar implant survival rates in good bone volumes and quality.
2. The amount of keratinized tissue should be adequate to reposition at least 1.5 mm to the facial aspect of the PME healing cap.
3. When a bone graft is considered at the time of implant insertion, primary closure of the soft tissues improves the environment to grow bone. Therefore the one-stage approach is less indicated under these conditions.
4. The implant PME may be unesthetic when the maxillary esthetic zone of the mouth is in a premolar site.

WWW.HIGHDENT.IR



A B C

Figure 30-9 **A,** A direct one-stage surgery uses a flapless approach. A core of soft tissue is removed over the implant site. The osteotomy is prepared in the center of the core. **B,** The implant is threaded into position. It is often difficult to determine the position of the implant in relation to the crest of the bone, as it is not directly visible below the soft tissue. **C,** A permucosal healing element (PME) is threaded into position and seals the soft tissue opening.

Direct (Flapless) One-Stage Surgery

The one-stage surgical approach may be modified with a direct flapless surgical approach. This technique does not reflect the crestal soft tissue. Instead, a core of keratinized tissue (the size of the implant crest modale diameter) is removed over the crestal bone. The implant osteotomy is then performed in the center of the core of the exposed bone. This technique requires no sutures around the PME. The advantages of this technique are similar to a one-stage surgical approach. In addition, there is less soft tissue trauma because the tissues are not reflected. As a result, discomfort, tenderness, and swelling are usually minimal (Figure 30-9).

The primary disadvantage of the direct approach is the inability to assess the bone volume before or during the implant osteotomy or insertion. Therefore this technique should only be used when the bone width is abundant (>8 mm). Bone grafting needs and procedures cannot be precisely evaluated. The soft tissue around the implant site should be ideal in amount of attached keratinized mucosa, as the soft tissue pouch is over the bone site, not in a region related to the soft tissue. Often, the keratinized tissue is reduced on the buccal half of the ridge and the tissue punch may inadvertently remove all the keratinized tissue on the facial aspect of the implant. As the crest of the ridge is below the soft tissue, it is difficult to see lines on the drill to access the depth of drilling. Therefore stops on the drill are particularly beneficial. The surgeon also has trouble assessing the location of the implant crest module in relation to the crest of bone because it is also below the soft tissue. In addition, the interdental papillae may not be elevated with this technique. Therefore the soft tissue drape should be ideal in volume of keratinized tissue, both faciolingually and mesiodistally.

STEP-BY-STEP SURGERY

Implant Site Evaluation

The missing tooth space is first evaluated from a mesiodistal dimension, at the level of the CEJ of each adjacent tooth. This dimension should be at least 6.5 mm in width. The selected implant diameter is 3 mm narrower than this dimension (i.e., at least 3.5 mm). The buccolingual crestal dimension is then evaluated with the soft tissue intact. The edentulous site should be at least 9 mm wide with the tissue intact to consider a direct (flapless) one-stage surgery (assuming the tissue thickness in each site is 1 mm). When a smaller dimension is present a one- or two-stage procedure is indicated and the ridge most often will require a bone graft, either before or in conjunction with implant insertion. If the facial aspect of the implant body is exposed at insertion, a two-stage approach is indicated, along with a membrane bone graft.

A periapical radiograph is then used to evaluate the missing tooth site. The minimum radiographic bone height should be 11 mm from the crest of the ridge to the opposing landmark (i.e., mental foramen and mandibular canal in the mandible and maxillary sinus in the maxilla). This dimension permits a 9-mm-long implant to be inserted at least 2 mm above the opposing landmark in the mandible. The roots of the adjacent teeth should not invade the vertical column of bone

WWW.HIGHDENT.IR

in the implant site. The 6.5-mm minimum mesiodistal dimension should exist for at least 11 mm between the adjacent roots. The minimum implant length selected is usually 9 mm, and the longest length is at least 2 mm less than the available bone height dimension in the mandible, closer in the maxilla, and may even proceed to the sinus floor.

Soft Tissue Reflection

Once the bone volume is assessed and the implant surgical option is identified (i.e., two-stage, one stage, direct), the implant procedure may commence. In the one- or two-stage approach, the soft tissue reflection is similar. A scalpel (#12 and/or #15) is used to incise the mid-crestal tissues. At least 1.5 mm of keratinized tissue should be left on the buccal to this incision line.

The incision line most often is extended through the interproximal and sulcular tissues of the adjacent teeth. This permits complete assessment of the crestal bone volume when the tissues are reflected. A Buser or Molt elevator is used to make a full-thickness soft tissue reflection and expose the crestal bone and a few millimeters of the lateral aspects of the implant site. The buccolingual dimension of bone is measured and confirmed to be greater than 7 mm in width. If the site is less than 7 mm wide, a division B membrane and layered-approach bone graft are used to augment the site, either in conjunction with implant insertion or as a separate surgical procedure before placing the implant.

Implant Osteotomy

A 2-mm-diameter, end-cutting starter drill is used in the mesiodistal and buccolingual centers of the crestal bone for implants in the mandible or out of the esthetic zone in the maxilla. The osteotomy is made with an electric motor at a preferred speed of 2500 rpm under copious amounts of chilled saline irrigant. The osteotomy is made 7 to 9 mm deep in the bone (Figure 30-10, *A*).

Once the initial osteotomy is prepared, it is assessed for proper position. If incorrect, the hole may be "stretched" to the proper location by a side-cutting Linderman bur (Figure 30-10, *B*). This bur makes the hole oblong toward the corrected center position. The following end-cutting drills may then be positioned into the correct position and create a round osteotomy of proper size before implant placement.

A 2-mm-diameter direction indicator (depth gauge) is then inserted into the osteotomy and the angulation and position assessed (Figure 30-10, *C*). When the "stop" on the direction indicator is the same size as the implant (i.e., 4-mm diameter), the final implant position buccolingual and mesiodistal also may be assessed, making sure it is at least 1.5 mm from each tooth and 1.5 mm from the outer crestal cortical plates. If it is too far in any direction, a side-cutting Linderman drill may stretch the osteotomy toward a more proper position. A periapical radiograph is made with this measuring tool. The radiograph ensures the proper angulation and position of the implant relative to the adjacent tooth roots. The final diameter of the implant may now be selected using the guidelines presented earlier. The opposing landmark is also evaluated. The implant is most often placed 2 mm or more from the mandibular neurovascular canal or 0.5 mm from the floor of the maxillary sinus and at least 9 mm in length. Although implants may be inserted closer than 2 mm of these landmarks without compromise, the 2-mm surgical rule is a common safe position in the mandible. When the opposing landmark is 14 to 17 mm farther away from the depth gauge and the osteotomy may be safely made deeper than 9 mm, the pilot 2-mm diameter drill may be reinserted into the osteotomy and prepared to a 12- or 15-mm length. Rarely is more than a 15-mm-long implant required.

When the opposing landmark is safely beyond the end of the osteotomy depth, the drills often proceed end-cutting 1 to 2 mm beyond the eventual depth of the implant. The slight recess area in the apical end of the osteotomy serves several purposes:

1. Bone debris may fill the region during a self-tapping implant body placement, because the threads scrape the bone as the implant is inserted. As a result, when the implant comes to its final position, the bone debris does not impede its progress.
2. The implant may be rotated in final position to align the flat section of the antirotation crest module, which helps identify the position location of prosthetic components.
3. The lingual border of the osteotomy is often higher than the facial bone level. A stop used on a drill for the implant length prevents the drill from proceeding to the facial crest, and the crest module height will be determined by the higher lingual plate of bone, which positions the facial aspect of the implant platform above the bone.

A 2.5-mm-diameter, end-cutting twist drill is then used in the initial osteotomy to the depth established. The drill also rotates at 2500 rpm with copious amounts of chilled sterile saline. The osteotomy location and angulation are reassessed at this point. A slight correction of position or angulation with a Linderman drill is possible with little consequence or risk. A 3-mm-diameter twist drill is then used (depending upon implant design and final diameter) to the desired length, followed by a 3.4-mm twist drill. Once again, the proper location and angulation of the osteotomy is verified (Figure 30-10, *D*, *E*, *F*, *G*). This is the final diameter for a 4-mm-diameter implant (BioHorizons Dental Implants). The final osteotomy diameter for a 4-mm-diameter implant is related to the implant diameter and manufacturer. For example, a Zimmer implant uses a 3.2-mm diameter for a 4-mm-diameter implant. Most implant drill kits clearly

A 2-mm-diameter, end-cutting starter drill is used under copious sterile saline. **B,** A 2-mm-diameter, 9-mm-long force direction indicator is positioned into the initial osteotomy. **C,** A side-cutting Linderman drill is used to modify the initial osteotomy started with the pilot drill. **D,** A 2-mm-diameter pilot drill is inserted into the initial osteotomy and prepares the bone from 12 to 15 mm when the opposing landmark permits. A 2.5-mm, then a 3-mm drill sequence prepares the osteotomy. **E,** A 3-mm side-cutting twist drill widens the osteotomy. **F,** A 3.4-mm-diameter, end-cutting twist drill is used to prepare the final diameter for a 4-mm implant body. **G,** An implant drill kit with color coding most often identifies the drill sequence and the final diameter related to each implant size (BioHorizons Maestro Dental Implants).

Continued

identify the drill sequence and final osteotomy diameter related to each diameter implant (Figure 30-10, *H*).

Most implant crest modules are larger in diameter than the implant body. The larger diameter often requires a side-cutting crest module drill in D1 or D2 crestal bone situations to prepare the crestal aspect of the implant osteotomy. This drill is not used when the bone density is poor (D3, D4) (Figure 30-10, *I*).

In dense bone types, some implant thread designs require a bone tap or thread former to prepare the threads in the bone before implant insertion (Figure 30-10, *J*). When the bone is soft (D3 or D4) or implant thread design is shallow (e.g., 0.2 mm versus 0.5 mm), a thread former is not required. Most often for single-tooth implants, the thread formers or taps should use a high-torque, slow-speed handpiece and be rotated at less than 30 rpm into the bone. Irrigation is also of benefit to help lubricate and clean the bone tap and osteotomy site of debris during this process.

The implant site may then be prepared for implant insertion. The osteotomy is lavaged and aspirated to remove bone debris and stagnant blood. This reduces

the risk of these materials being forced into the bone marrow spaces or neurovascular channels during implant insertion, thus causing hydrostatic pressure. This pressure may increase the devital zone of bone around the implant or even cause short-term anesthesia when the implant site is in the vicinity of the mandibular canal.

The implant is rotated less than 30 rpm into position by a low-speed, high-torque hand piece or a hand ratchet (Figure 30-10, *K*). The implant should not require a torque greater than 35 N-cm while threading into position. If this is necessary, the implant should be unthreaded and a bone tap used before insertion. The implant is usually inserted slightly above (one stage) or below (two stage) the crest of the bone, depending upon a two-stage or one-stage surgical approach, as previously described. The implant should be rigid upon placement, with no observable mobility under slight compressive forces. The implant should not be tightened into the osteotomy, such as a nut onto a bolt. A torque value up to 35 N-cm is considered safe with most threaded implant designs. However, excessive pressure to the bone may cause pressure necrosis and increase the devital zone of bone around the implant during healing. When in doubt, the implant may be unthreaded one half turn with a hand ratchet, to ensure it is not too tight within the osteotomy.

A postinsertion periapical radiograph is made once the implant is in final position. The radiograph is evaluated as to implant depth and the opposing landmark, the adjacent roots and the position of the crest module and the crest of the bone. Any correction is most easily made at this time, rather than attempting to modify the position at a later date.

It should be noted that the implant surgery may be aborted at any stage of the procedure. Unlike a crown preparation or endodontic therapy, an aborted procedure will allow the bone to reform in the osteotomy and allow the procedure to be performed with a similar condition as the initial surgery at a later date. Therefore if the implant position is not within the range of ideal, it may be removed, and a new implant reinserted several months later in a more ideal position.

The abutment mount of the implant body is then removed. When a two-stage implant insertion is used, a low-profile cover screw is inserted into the implant body (Figure 30-10, *L, M*). When the cover screw is in final position, it may be slightly tightened, loosened, and

WWW.HIGHDENT.IR

tightened again. The implant should not rotate during this procedure. A similar procedure is performed with a PME, when a one-stage or direct surgical approach is used. In the posterior of the mouth, a one-stage surgical approach is used most often.

In a one- or two-stage surgery, two interrupted sutures approximate the soft tissue for primary closure. Most often a 4-0 polyglycolic acid (PGA) material is used. Slight pressure to the approximated tissues for 4 to 6 minutes decreases bleeding and improves the adaptation of the tissue to the bone and PME. When not in the esthetic zone, no transitional device is worn. Postoperative instructions include the use of periodic ice to the region for 3 days, and postoperative medication is similar to a routine extraction. The sutures are removed after 10 to 14 days, although 7 days are usually sufficient. The most common undisturbed healing time for a single-tooth implant before restoration is 4 months. At this point, the hard and soft tissues are adequately healed and the final restoration may commence (Figure 30-10, *N*).

In the past, the most common choice to replace a missing posterior tooth was a three-unit fixed partial denture. The choice of not replacing the tooth is a more frequent option for mandibular second molars, but this option also may be selected when the intratooth space is small and the occlusion prevents migration. Today, with the improvements in implant materials, design, surgical approach, and prosthetic guidelines, and with reported success rates greater than 97%, the use of implants to replace a single tooth is often the treatment of choice. Improved hygiene, less risk of decay of the adjacent teeth, less endodontic risk, less risk of adjacent tooth loss, maintenance of bone, and prosthesis longevity all favor an implant restoration compared with the three-unit fixed partial denture prosthesis.

Posterior single-tooth implant surgery in abundant bone is one of the easier processes in implant surgery. It is often easier than performing endodontics for a single rooted tooth. Early learning curves are short, and very high surgical success rates are rapidly obtained. The guidelines within the chapter for implant body size (width and length) have proven that predictable long-term surgical success for single-tooth implants is more than 99%.

Chapter 31

Root Form Surgery in the Edentulous Anterior and Posterior Mandible: Implant Insertion

Carl E. Misch

The primary goal of root form surgery is to insert an endosteal implant into the available bone of an edentulous site in the proper location and angulation so that it may be used as a prosthetic abutment. An endosteal implant, made of biocompatible material, will predictably obtain rigid fixation when specific surgical principles are followed. The soft tissue should cover or approximate the implant for primary healing. The bone should receive as little trauma as possible. The smaller the devital zone, which forms around an implant subsequent to surgical trauma, the more likely rigid fixation will occur. The bone should initially be within 30 to 40 µm of the implant body,[1] which should be rigidly fixated and not move during healing. Movement of 100 µm or more to the bone-implant interface has been shown to result in intervening fibrous tissue.[2] The surgical site should remain free of infection, which may result in a bacterial smear layer on the implant body and impair the development of a close bone-implant contact during healing. The health, volume, and density of the recipient bone are critical to the preparation, fixation, and healing of an endosteal implant.

Figure 31-1 The most common position for root form implants in an edentulous mandible is between the mental foramina.

There are more than 100 types of root form implant designs readily available on the commercial market. A consistent philosophy is the desire for clinical rigid fixation corresponding microscopically to a direct bone-implant interface, without intervening fibrous tissue on a major portion of the implant body.[3] The surgical procedures for endosteal root form placement are described in this book by region, bone volume, and bone density. This chapter addresses a generic surgical approach to the anterior and posterior mandible in adequate volume (Division A or B) and quality of bone (D2) for the placement of a screw-type root form implant.

SURGICAL APPROACH TO THE ANTERIOR MANDIBLE

The most common location for root form implants in the completely edentulous mandible is between the mental foramina, in the region of the mandibular symphysis (Figure 31-1). The prosthesis type and amount of support for the patient force factors and bone density are first determined. If a fixed or RP-4 prosthesis is planned, most often five root form implants are usually indicated (see Chapter 14) in the A, B, C, D, and E positions (starting from the right of the patient to the left).[4] Posterior implants may also be indicated, depending on the existing force factors and other parameters.

Panographic radiographs or computed tomography (CT) scan imaging is evaluated for potential pathology, bone volume, and anatomical landmarks such as mental foramina and crest of ridge. A lateral radiographic view may be taken with a transitional prosthesis in place, which permits the evaluation of bone volume in height, the angulation of the bone in the midline, and the crown/remaining bone height ratio. A surgical template is fabricated before surgery to indicate the incisal edge position of the final restoration and help determine

proper implant location and angulation for the specific prosthesis (see Chapter 13). A standard surgical setup is prepared (see Figure 31-56).

Patient Preparation

The patient is prepared for surgery following the pharmacologic protocol typical for implant surgery (see Chapter 21). Because two carpules have a higher "hit" rate for block anesthesia, compared with one carpule, bilateral mandibular block anesthesia is administered with both lidocaine 2% 1:100,000 epinephrine and a long-acting anesthetic, such as bupivacaine (Marcaine) 0.5% with 1:200,000 epinephrine (Box 31-1). The use of a long-acting anesthetic is beneficial in three ways: (1) the added volume of anesthetic increases the success of the mandibular block; (2) a full arch mandibular implant insertion surgery may last 2 hours; therefore repeated injections at the end of the surgery are less indicated; and (3) in addition, long-acting anesthetics may reduce postoperative pain. In fact, it is advantageous to readminister the long-lasting block anesthetics at the conclusion of the surgery when its duration is longer than 1 hour.[5]

Akinosi Technique

The Akinosi technique (closed mouth) for mandibular anesthesia is preferred in the completely edentulous patient, because the occlusal plane and opposing premolar position used as references for the traditional Halsted dental injections are unavailable or inaccurate (Figure 31-2).[6] The Akinosi block procedure is administered with the mouth in an almost closed position or, because the patients often wear a denture, in an approximate occlusal vertical dimension. In addition, it is a benefit when the patient positions the jaw toward the side of the injection (i.e., slide the jaw to the right for a right mandibular block). A long, 27-gauge needle is used in the syringe. The needle is bent 30 degrees near the base, so the needle direction on a horizontal plane will be away from the midline. This is advantageous because the ramus flares lateral as it proceeds distal. The syringe and needle are placed parallel to the occlusal plane, at the height of the maxillary mucogingival junction. The needle penetrates approximately half its length (25 to 30 mm) before aspiration and injection of anesthetic. There is no bony landmark.

The Akinosi block is usually less painful for the patient, because the anesthetic fluid is injected into the top of the pterygoid triangular space, which has more room for the solution. In addition, the top of this triangular space has fewer muscle fibers in the pathway of the injection compared with the penetration site of the Halsted block and therefore is associated with less discomfort (Box 31-2).

Additional injections of anesthesia with the administration of local anesthetic (such as lidocaine 2% with epinephrine 1:100,000) by infiltration in the labial, lingual vestibules, and the inferior border of the

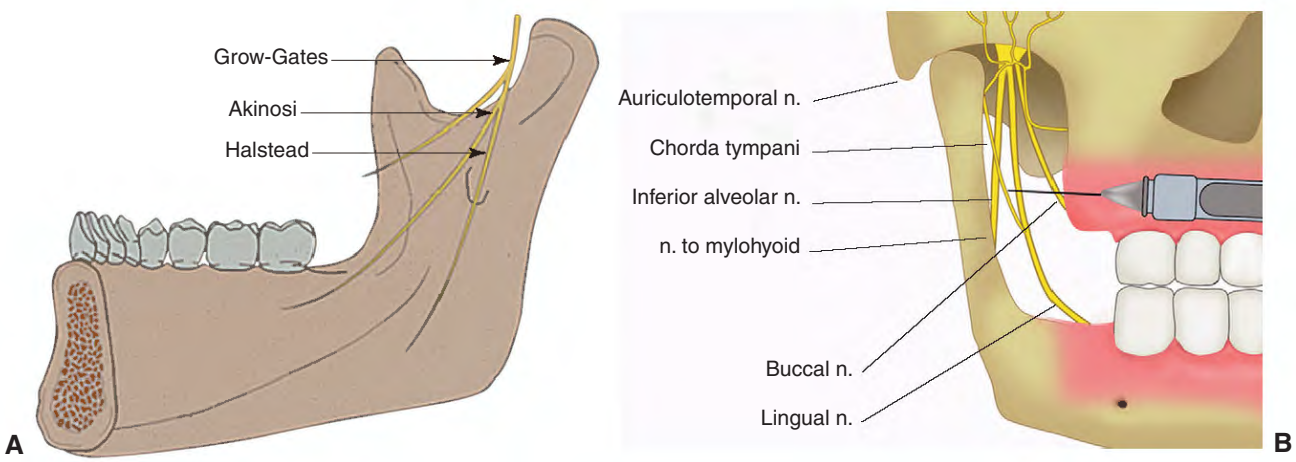

Figure 31-2 **A,** The Akinosi block procedure for local anesthesia is more effective than the traditional dental injection in the edentulous patient. **B,** Akinosi technique: The patient's mouth is almost completely closed or at the approximate occlusal vertical dimension in a denture wearer. The cheek is retracted with the free hand to expose the posterior teeth. The syringe is aligned parallel to the occlusal plane of the maxillary molars, and the needle is positioned level with the mucogingival junction of the maxillary second and third molars. The needle is inserted into the buccal mucosa as close as possible to the medial surface of the mandibular ramus to a depth of 25 to 30 mm without contacting bone. After careful aspiration, the anesthetic solution is deposited, approximately halfway between the mandibular foramen and the neck of the condyle into the middle of the pterygomandibular space.

- Reduced pain

anterior mandible are also required, because the inferior third of the mandible is innervated by cervical nerves (C2-C3). Typically, the injections are in the facial sites in front of the mental foramina and the midline, whereas the lingual injections are lingual to each canine region.

An extraoral and intraoral scrubbing and draping of the patient are then performed. The benefit of aseptic technique is well documented in general.[7] However, a controversy exists regarding "sterile" versus clean surgical technique for endosteal implant placement.[8,9] Both the clean and sterile techniques use instruments, implant components, and hand pieces that are sterile. An actual sterile environment cannot be achieved within the oral cavity[10,11]; therefore the term *aseptic* is often used.

A primary issue is the need to use sterilized gloves, gowns, patient drapes and covers for the light, hand piece cord, and evacuation tips. In addition, can the surgeon and assistant touch nonsterile items in the operating room? Scharf and Tarnow compared sterile versus clean conditions with 386 implants in 92 patients.[12] Success rates were within 0.5% for the mandible and 1.6% for the maxilla. Kraut placed 2620 implants with a clean technique with a 1.26% surgical failure at implant uncovery and 0.5% early implant failure after function.[9] Therefore these reports suggest the clean technique is adequate for implant surgery.

Brånemark Surgical Approach

The original Brånemark surgical approach was used in a hospital environment, with an aseptic protocol similar to orthopedic implants. There are several advantages to this approach. Normal skin flora, including *Staphylococcus epidermidis* and *Staphylococcus aureus,* are able to adhere to implanted biomaterials.[13-15] A bacterial smear layer may develop, which will be difficult for the body to remove by phagocytosis or bone cell activity. Antimicrobial mouth rinses (e.g., chlorhexidine) significantly reduce bacterial count in the saliva for more than 4 hours.[16] Chlorhexidine has been shown to reduce microbial complications when used perioperatively.[17,18] Povidone-iodine alcohol solutions have antibacterial properties used in preoperative site disinfection.[19] Although a sterile technique is not possible within the mouth, scrubbing around and within the mouth with these agents reduces the risk of a bacterial smear layer by inadvertent contamination by direct contact with the implant or indirectly via a glove or instrument.

The clinical decision for an aseptic versus clean environment rests with the individual clinician, because documentation exists for either approach. However, it is prudent to reduce the risk of infection preoperatively and postoperatively. Although rare, infection may occur as a postoperative complication. Intraoral surgery is assimilated to a class II or clean contaminated surgery. Incidence of infection for class II surgery is 10% to 15%, but can be reduced to about 1% if appropriate technique and prophylactic antibiotics are prescribed.[20] The risk of infection with endosteal implants when preoperative and postoperative antibiotics are used appears to be even less.[9,21,22]

What Is Clean?

The question remains: What is "clean"? In one office, "clean" may result in the doctor looking for instruments in a drawer, adjusting a chair, touching the mask, moving the patient's hair out of the operative site, and so on. Therefore the issue appears to be not whether sterile gloves and gowns are used, but what protocols are in place to reduce the risk of contamination reaching the implant. It is prudent to train the staff and doctors in aseptic technique to reduce these risks. Training for an aseptic protocol relative to intraoral and extraoral scrubs and touching only sterile or scrubbed regions within the operatory are prudent to decrease risk.

More invasive procedures such as sinus bone grafts exhibit a range of postoperative infection from 3% to 20%.[23,24] Based on this, the author suggests that an aseptic surgical procedure be used for most sinus surgeries. For full-arch implants or bone grafts, larger regions of tissue are exposed with increased risks to patients if infection occurs, so aseptic technique should be considered. In many dental offices the staff needs constant retraining for procedures that are not often performed. The routine aseptic surgical approach ensures the quality and consistency of the asepsis when it is most indicated.

Intraoral and extraoral scrubbing with iodine, povidone-iodine (Betadine), or 0.12% chlorhexidine gluconate may be performed by a scrubbed assistant. A surgical scrub and gowning is performed by the doctor during the patient preparation. On return to the operating room, the patient's final drapes are positioned. The surgical gloves are rinsed and wiped with sterile saline to remove any powder or contaminant that may be inadvertently transmitted on the implant surface during the subsequent surgery. Infiltration with 2% lidocaine with 1:100,000 epinephrine into the labial and lingual mucoperiosteum evaluates the depth of anesthesia and provides some initial hemostasis. In

WWW.HIGHDENT.IR

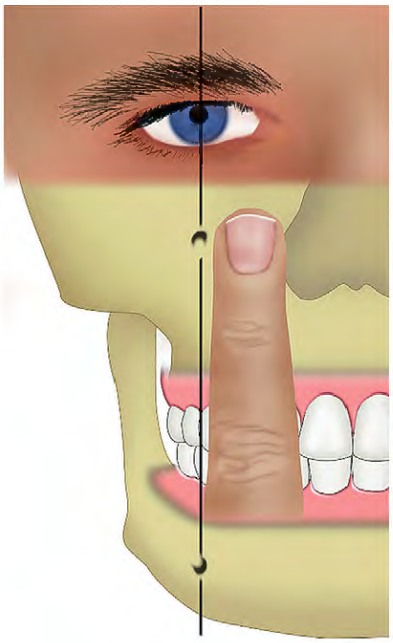

Figure 31-3 The position of the mental foramen may be approximated by drawing an imaginary vertical line from the pupil or using one finger width lateral to the nose through the infraorbital and mental foramina.

addition, when the local anesthetic is placed under the periosteum along the crest of the ridge, a hydroelevation of the soft tissue may help initial reflection of the soft tissue.

Incision

After anesthesia is achieved, the soft tissues and ridge height are evaluated. The lingual aspect of the mandible is palpated for undercuts and compared with the radiographic diagnostic images. Identification of the approximate position of the mental foramen facilitates the incision line design in moderately to severely atrophied mandibles and allows a more rapid reflection in regions around this landmark. The mandibular foramen region may be located by several methods. Palpation for the depressed foramen has been advocated, but is the most variable.[7] The overlying tissues usually prevent adequate feeling to identify the foramen with certainty.

Before the patient is surgically draped for the procedure, an imaginary line may be drawn between the pupils of the eyes. A perpendicular line may then be drawn through each pupil (Figure 31-3). This vertical line passes through the infraorbital foramen and mental foramen. A surgical pen is used to mark the gingival tissue over the mental foramen region. If the patient is draped and the eyes cannot be used as a landmark, the foramen region corresponds to a vertical line drawn one fingerwidth distal to the ala of the nose and slightly distal to the corner of the mouth.

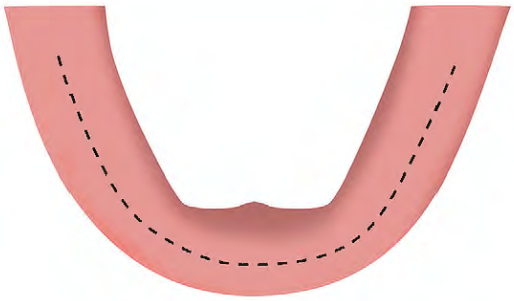

Figure 31-4 The initial incision bisects the keratinized gingiva on the crest of the ridge and extends from the first molar region to the contralateral first molar region. An accessory incision may be added off the midline to facilitate reflection and mental foramen identification.

Because suture line opening is the most common immediate postoperative complication, the surgical incision is designed to minimize this problem. If the crest of the ridge is above the floor of the mouth and there is greater than 3 mm of attached, keratinized gingiva on the crest of the ridge, a full-thickness incision is made, bisecting the attached tissue and scoring the bone on the crest of the ridge from the first molar region on one side to the anterior region and to the contralateral first molar region (Figure 31-4). If less than 3 mm of attached gingiva exists on the ridge, the full-thickness incision is placed so that at least 1.5 mm of the attached tissue is to the facial aspect of the incision line. This zone of attached tissue on the facial flap provides greater resistance for the sutures against tension of the mentalis muscle in the anterior region and buccinator muscle in the molar-premolar regions, which often cause the incision line opening. In addition, the blood vessels from the lingual artery may not cross over the crest of the ridge, but instead stop within the attached tissue.[25] As a result, an incision made facial to the attached tissue may cause partial ischemia to some of the crestal tissue. In addition, the incision in unkeratinized facial tissue also severs larger blood vessels, which increases bleeding and decreases vision during surgery. The incision should be done in one pass through the mucosa and periosteum and precisely score the periosteum. Additional scoring of the crestal bone after the initial incision design is usually beneficial. Areas of soft tissue invagination in prior extraction sockets are excised so as to create a clean margin for the flap, devoid of epithelium.

SOFT TISSUE REFLECTION—LANDMARK IDENTIFICATION

A periosteal elevator (e.g., Molt 2-4, Molt A-1, Molt 7 or 9) is used to reflect a full-thickness flap. The mucoperiosteal flap is first reflected on the lingual aspect, which is typically less tenaciously attached to the underlying bone. The lingual reflection begins in the

WWW.HIGHDENT.IR

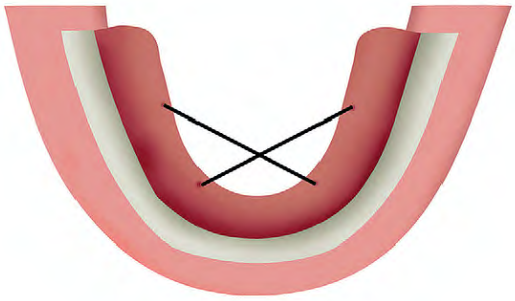

Figure 31-5 A periosteal elevator is used to first reflect the lingual full-thickness soft tissue flap. Two 2-0 sutures may then be used as retraction sutures, placed from each canine position to the contralateral molar site.

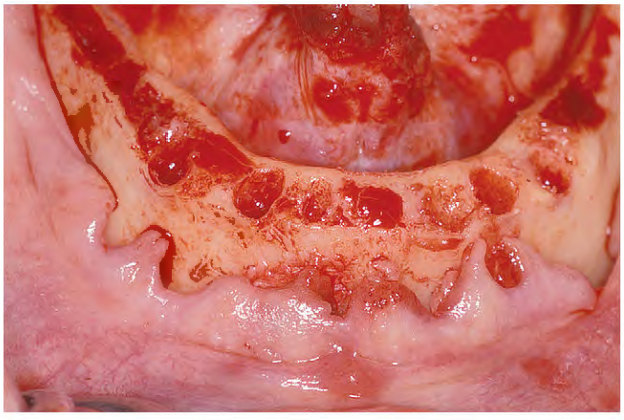

Figure 31-6 After the lingual flap is tied back with retraction sutures, the facial full-thickness tissue flap is reflected from the bilateral first molar region.

regions of the canine and proceeds to the molar region on the same side. The contralateral canine to molar region is then reflected. This phase of the procedure most often is performed within a few seconds. The lingual flap between the canines is then reflected. This region is more difficult to reflect, because some of the tissues are embedded into the residual alveolar crest. Retraction (tie-back) sutures with 2-0 silk are then used to keep the lingual flap out of the surgical site. The right lingual canine region is tied to the left molar area, and vice versa. The sutures engage at least 5 mm of tissue, with care taken to avoid the submandibular duct. The lingual flap retraction improves visibility, negates repeated surgical assistant retraction efforts during the procedure, and reduces trauma to the thin lingual periosteal tissues (Figure 31-5).

After a full-thickness periosteal flap is reflected, the periosteum must regenerate from the unreflected portion before this structure can participate in crestal bone healing.[26] Although adequate reflection to identify all bony landmarks is necessary, overzealous reflection increases soft tissue trauma and may delay bone callus formation around the implant, which may contribute to crestal bone healing.

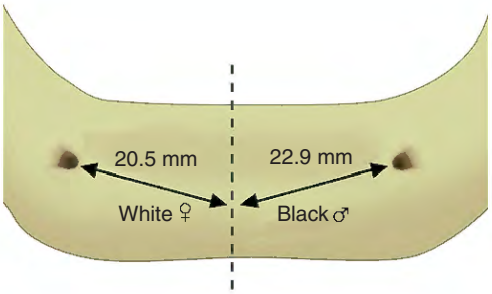

Figure 31-7 The mental foramen is approximately 22 mm from the midline; however, there is a slight variation, depending on race and sex.

The facial flap is then reflected. The exact location of the mental foramina and associated nerves, arteries, and veins are identified (Figure 31-6). These are essential surgical landmarks. An anthropometric analysis of the position of the mental foramina was performed by Cutright et al.[27] The average distance from the midline was 2.2 cm, which means the usual distance between the foramina is 44 mm. Because at least 7 mm of mesiodistal bone are usually required for each 4-mm-diameter implant, the average anterior mandible has room for six implants. However, the mental foramina position is variable, depending on race, sex, and skull size. The average interforamen distance for black males was 45.8 mm; white males, 45 mm; black females, 43.8 mm; and white females, 41 mm. Therefore white females often do not have room for six implants between the foramina (Figure 31-7).

When the mental foramen position is related to a tooth position, it may reside as far anterior as the canine to first premolar position, or as far distal as the second premolar to first molar root position.[28-31] The farther distal the foramen (and neurovascular canal), the farther distal the most distal implant (A and E sites) and the better the biomechanics for the prosthesis. When the foramen resides in its most distal position, six implants may be positioned between the foramina. When the foramen resides in its most anterior position, only four implants may be inserted to leave 3 mm of space between each implant. The most common mental foramina sites are between the first and second premolar roots, but they may be present below either the first or second premolar root. Under this condition, five implants may be positioned between the foramina.

Because the primary incision was extended to the first molar region, the approach to the foramina can proceed from both anterior and posterior, which facilitates their identification. After the periosteum is reflected off the residual crest, a moist surgical sponge can be used to wipe the periosteum off the dense labial cortical plate around each foramen. This permits rapid and safe exposure of the nerve complex without trauma from instruments. Soft tissue reflection is limited in the mandibular symphysis region to avoid ptosis of

WWW.HIGHDENT.IR

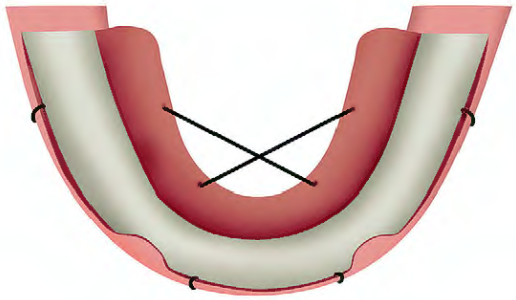

Figure 31-8 The facial full-thickness soft tissue flap is then reflected. The mental foramen contents are identified, along with the crest of the anterior ridge, both anterior and posterior to the position of the foramen. The tie-back sutures may be positioned both behind and in the front of the foramen on each side.

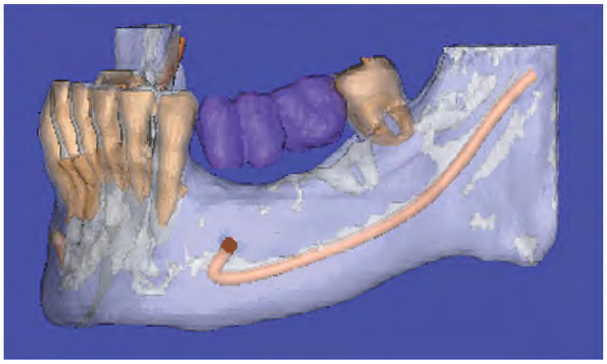

Figure 31-9 An anterior loop to the mandibular canal occurs when the canal proceeds inferior to the foramen, passes under the foramen for 1 to 3 mm, and then curves superior and distal to exit the foramen.

the chin, which may occur after overzealous reflection of the mentalis muscles' lower attachments in moderately to severely atrophied mandibles. Tie-back sutures may be positioned to retract the facial flap during surgery. Most often these are placed in front of the mental foramen (Figure 31-8). All fibrous tissue is removed from the crest of the edentulous ridge. A bone rongeur, followed by a moist surgical sponge rubbed across the crestal surface, eliminates most fibrous adhesions.

If the mandibular canal approaches the foramen at the same height, the nerve always enters the distal portion of the foramen. When this is clearly identified on the panoramic radiograph, the foramen is used as the distal landmark. The panoramic radiographs or CT images are observed to visualize a possible anterior loop of the mandibular neurovascular canal. A mandibular loop occurs when the mandibular neurovascular canal approaches the foramen from below, proceeds anterior to the foramen about 1 to 3 mm, and curves upward and distal to enter the medial aspect of the mental foramen (Figure 31-9). This has been observed almost 12% of the time for a distance of 1 to 3 mm on panoramic radiographs.[32] On the other hand, Rosenquist dissected 58 inferior alveolar neurovascular bundles and identified a 1-mm anterior loop

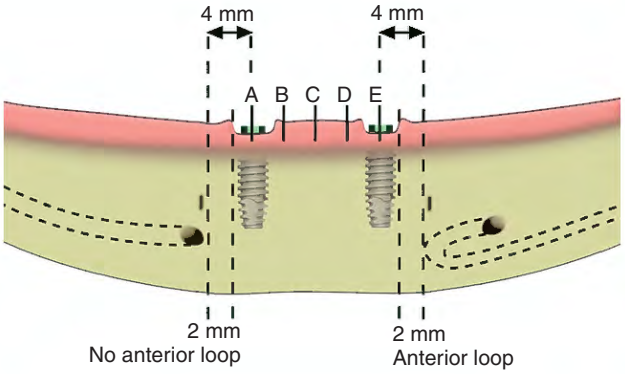

Figure 31-10 The position of the distal implant between the foramen is affected by the presence of an anterior loop. The goal is to have the implant 2 mm in front of the mandibular nerve. When an anterior loop is present, the distal implant is placed farther mesial.

in 43 cases.[33] A study on dry skulls noted anterior loops of 2 mm or more on 92% to 96% of the specimens.[34] Surgical dissection provided by Solar et al.[35] showed an anterior loop in 60% of mandibles ranging from 0.5 to 5 mm. Neiva et al. identified loops in 88% of cases with a range of 1 to 11 mm.[36] Dissection studies with comparison to radiographs were performed by Bavitz et al.,[37] who reported 54% of loops in periapical radiographs, but only 11% where verified by dissection. Other studies concurred with the conclusion that a high percentage of false-positive or false-negative findings may occur.[38,39] For such a topography, the most distal anterior implants are placed 2 mm anterior to the anterior loop, which becomes the landmark rather than the mental foramen itself (Figure 31-10).

It should be recognized that the inferior alveolar nerve complex is in the facial aspect of the bone as it exits the foramen. Therefore an implant placed in this region is most often lingual to the nerve, because the crest of the ridge is more medial than the foramen. As a result, even when a panoramic image may indicate that the implant is in the position of an anterior loop of the mandibular nerve, it most likely resides lingual to the nerve, with no paresthesia evident. Only CT scan imaging properly indicates the spatial relationship between these elements.

On occasion, the nerve complex around the foramen is not clearly identified on traditional films. An anterior loop may or may not be present. A CT scan of the region may provide the information needed. Another option is to determine whether there is an anterior loop during surgery. A curved Naber's 2N probe may be gently inserted inside and along the bone on the distal half of the foramen to determine whether the nerve proceeds from the posterior region directly into the foramen. If no nerve entry is felt along the distal half of the foramen, the nerve must loop anteriorly and enter from the anterior aspect (Figure 31-11). Probing the anterior half of the foramen is not diagnostic, because the mental

WWW.HIGHDENT.IR

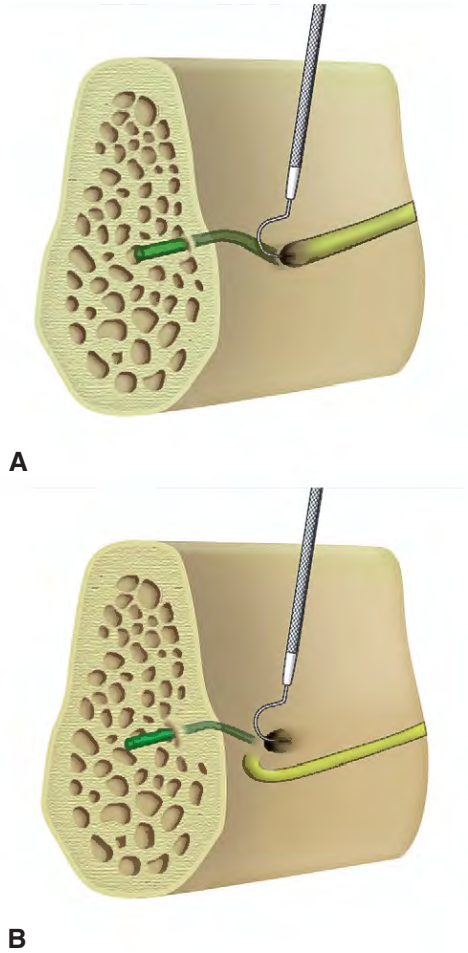

Figure 31-11 **A,** Naber's 2N probe may be used to determine the presence of an anterior loop to the mandibular canal. The probe is gently inserted along bone on the distal one-half of the foramen. **B,** If no nerve canal entry is palpated, the nerve must enter the foramen from the anterior aspect and an anterior loop is present.

nerve complex continues anteriorly from the foramen to innervate anterior teeth and bone, regardless of whether there is an anterior loop. Therefore there is always a canal entering the anterior portion of the foramen.

The incisive branch of the inferior alveolar nerve continues within the bone from the position of the foramen to the midline, where it may have some crossover from the contralateral side. This nerve complex innervates the mandibular anterior teeth, but does not provide feeling to the chin or lower lip. Therefore it does not cause paresthesia, even when violated with a drill or implant.

A score mark is made with a rotary instrument facial to the crest of the ridge to delineate the most anterior position of the mandibular nerve over each mandibular foramen. This score mark may correspond to the foramen or the anterior loop of the canal, whichever is more anterior. These marks position the boundaries of the posterior surgical implant placement. The most distal portion of the implant is ideally placed 2 mm anterior to this border to allow for surgical error.

The bone width at the crest is then evaluated. If it is greater than 6 mm, the crown height of the prosthesis is less than the available bone height (crown/implant ratio <1), and the direction of load to the implant body is within 30 degrees, a Division A bone volume is present. The prosthesis type is considered. An RP-4 or RP-5 prosthesis requires a minimum of 12 mm of crown height space from the occlusal plane to the crest of bone to fabricate the prosthesis and superstructure bar. If the crown height space is insufficient, an osteoplasty is indicated. An FP-1 restoration requires between 9 and 12 mm crown height space from the occlusal plane to the bony crest. If the crown-height space is greater, and the patient demands an FP-1 prosthesis, an augmentation procedure may be required before surgical placement of implants.

The available bone in the anterior mandible is often Division B, with similar crown-to-bone height relationships as Division A, but the residual crest bone is 2.5 to 6 mm in width, with the ridge usually more lingual. The surgical options are osteoplasty, augmentation, or small-diameter implants, depending on the prosthesis type and the force factors of the patient.

The first premolar region, usually just anterior to the mental foramen (A and E positions), is often narrower than the other anatomical sites in the mandible. As such, special attention relative to width is noted in this region. A smaller-diameter implant may be necessary in this site. As a result, a distal cantilever may need to be reduced compared with when a regular or larger-diameter implant is used. This is also the area in which the anterior loop of the mandibular canal may be present. To its benefit, the bone angulation in this area is more vertical in relationship to the occlusal plane.

An osteoplasty of the crest of the ridge is often indicated, especially in Division B bone. The osteoplasty eliminates any fibrous tissue on the crest and ensures adequate width for implant placement. A bone caliper is used to measure the amount of bone to be removed in height. This caliper may also ensure there is adequate height to place implants after the osteoplasty in Division B bone. The osteoplasty may be accomplished with a bone rongeur or a high-torque hand piece with a surgical 703 bur or a crestal reduction bur under copious cooled saline irrigation, until greater than 6-mm width of bone is obtained. If several millimeters of bone must be removed to obtain the necessary width, additional resorption is probable during healing. Countersinking the crest module of the implant slightly below the remaining bone crest is considered in these instances to account for this resorption and to prevent premature loading of the implant through the soft tissue–borne interim prosthesis during healing.

The prosthesis must replace the vertical bone height removed during the osteoplasty. If a fixed prosthesis is the final prosthesis, care is taken to carefully evaluate the amount of bone reduced. Whenever an osteoplasty

WWW.HIGHDENT.IR

is performed, the bone is harvested and stored in sterile saline in case an autogenous graft is required during a later step of the surgical procedure.

When an osteoplasty is performed, the complete anterior section of the mandibular crest is reduced, not just the implant locations. The soft tissue will not follow abrupt contour changes on the crest. Instead, the gingival tissues form a thicker tissue in these regions. If the osteoplasty is done irregularly, when the abutment is placed, a greater sulcus depth occurs in the thicker tissue regions with the related complications of the increased risk of anaerobic bacteria. In addition, if a cantilever is planned for the final restoration, the osteoplasty should extend beyond the anterior ridge, under the cantilever length. Otherwise, the superstructure will need to be raised above the higher bone contour in the posterior region, which may compromise artificial tooth or attachment positions over the bar.

Implant Site Preparation

Rotary instruments are used to prepare the implant site. Regardless of implant design or manufacturer, several surgical concepts are crucial for initial rigid fixation. A primary criterion is to limit thermal or mechanical trauma to the surrounding hard tissues (Box 31-3).[40-55] Bone is very susceptible to heat.[40] Heat is generated by the drill during the implant osteotomy. A major method to reduce the bone temperature during drilling is the use of cooled irrigation.[41,42] A secondary method to reduce heat and thermal trauma is related to the amount of bone removed with each drill.[41,45] Therefore sequencing drill diameters should prepare the final osteotomy site. The drill speed and time during which the bone is prepared is one of the major factors related to bone trauma.[48,49] Additional factors such as internal versus externally cooled drills are less important.[48,55] A detailed discussion of these factors is presented in the bone density—a surgical approach (see Chapter 29).

Implant Site Location

Most often, five implant sites are planned between the mental foramina for mandibular overdentures or full-arch fixed prosthesis, and are labeled A, B, C, D, and E, because they do not always related to tooth positions. Regardless of the number of implants (i.e., 2 to 8) being placed at the initial surgery, all five sites are determined. This permits insertion of additional implants in the future (if needed) to upgrade a prosthesis type or to solve complications. A No. 6 round bur or sharp pilot drill marks the initial implant site location in the midline (C position), unless an FP-1 prosthesis is planned. If the intended prosthesis is FP-1, the center implant is placed off the midline toward the most distal foramen by 2.5 to 3 mm.

Box 31-3 Factors Critical to Minimal Heat During Osteotomy Preparation

- Cooling fluid
- Bone quality
- Minimum volume of bone removed by each drill (incremental drill diameter)
- Drill: sharpness, design
- Frequency/time of contact
- Depth
- Pressure
- Speed

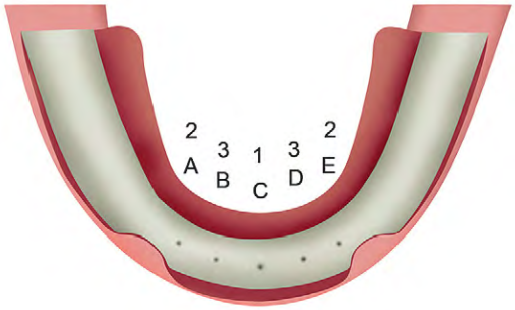

Figure 31-12 After the anterior mandible is reflected and the crest prepared for implants, five implant sites are planned. The first site (C) is usually in the midline, the sites A and E are positioned 4 mm in from of the foramen, then the B and D positions are selected. Each site should be at least 7 mm apart from center to center.

After the midline implant site (C) is determined, the boundary score lines on the crest of the ridge that correspond to the anterior limit of the mandibular canal are identified. A pilot hole is made with a No. 6 round bur or pilot drill placed 4 mm medial to each distal score line (if the implants are 4 mm in diameter) to determine the center of the most distal A and E implants. This provides 2 mm of surgical error away from the boundary that identifies the mandibular nerve during bone preparation and implant placement. The distance between the midline pilot hole and distal pilot holes are then equally divided for the B and D implants. They also can be mapped with a measuring tool. The distance between each implant center site should be at least 7 mm, or 3 mm between the 4-mm-diameter implant bodies. Larger-diameter implants require more than 7 mm between each center pilot hole (i.e., 8 mm for 5-mm-diameter implants) (Figure 31-12).

The initial pilot drill is used at a depth of 5 mm and evaluates the density and thickness of cortical bone on the crest of the ridge, if any remains after the osteoplasty. It can also be used for initial bone preparation in the narrow ridge. This end-cutting bur can prevent lateral perforations because it will roll away under light pressure from the harder inner cortical plate and stay within the softer trabecular bone. A No. 6 bur

WWW.HIGHDENT.IR

or a Lindemann drill may also stretch a hole in any direction to improve its final position. For example, if the initial bur hole is too lingual, the #6 or Lindemann bur can be used in the initial site to create an oblong hole more facial. As long as the initial hole is less than 2 mm from the ideal site, the final osteotomy and implant will completely obtund the initial erroneous pilot hole. In this way, the ideal location is finalized before the initial osteotomy is begun.

The surgical guide template is placed in position, and the faciolingual location and ideal angulation for the implants are determined. Ideal angulation is perpendicular to the plane of occlusion and corresponds to the cingulum of the teeth for a screw-retained bar or prosthesis, or to the incisal edge for cement-retained fixed prostheses. The template is then removed so that the facial and lingual contours of bone may be observed during site preparation.

The center implant site (C) is prepared first with the 2.0-mm-diameter pilot drill for the initial depth of bone preparation of 9 mm (Figure 31-13). This position should be perpendicular to the occlusal plane. If one marginal crest of bone is higher than the other (usually the lingual), the osteotomy depth is measured from the most inferior edge such that the implant body is positioned slightly below the lingual crest of the ridge.

A direction indicator (parallel pin) is placed into the center implant site (Figure 31-14). Angulation is checked in a labiolingual and mesiodistal direction with the surgical template, which may be facilitated with guidance from an assistant (preferably standing over the midline at the foot of the chair) (Figure 31-15). The osteotomy is often not prepared while the template is in place. The implant site must have adequate bone on the labial and lingual aspects. This requires direct vision and careful observation of both cortical plates while preparing the bone. A pumping motion is used to prepare the site to the radiographically determined depth; however, this dimension is reevaluated and may be changed at this time. The bone density is noted during the initial osteotomy preparation. The procedures described in this chapter are for D2 bone density.

Threaded root form implants are provided in several preestablished heights, dependent on the specific system. The ideal length of a threaded implant should be between 12 and 15 mm long in D2 bone. Because most stresses occur at the crest in favorable bone density, after an optimum implant length is obtained for each bone density, rigidly fixated implants do not appear to gain further clinical advantage when adding only length. In natural teeth, the periodontal ligament allows stress dissipation away from the crest, yet their length does not increase from the front to the back of the mouth (even though greater forces are generated in the posterior regions). Similarly, the need for longer implants or implants that engage the opposing cortical plate with an implant in a two-stage healing process is not supported in the literature.

After the initial sites are prepared with the pilot drill, small-diameter (2 mm) direction indicators are used in the initial implant preparations to evaluate the need for any minor adjustments (Figure 31-16). The surgical template is inserted to evaluate implant

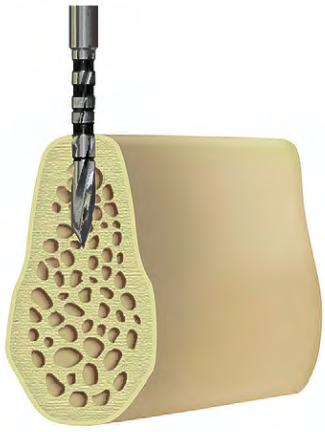

Figure 31-13 A 2-mm-diameter pilot drill is used to prepare the center implant site for 9 mm, perpendicular to the occlusal plane.

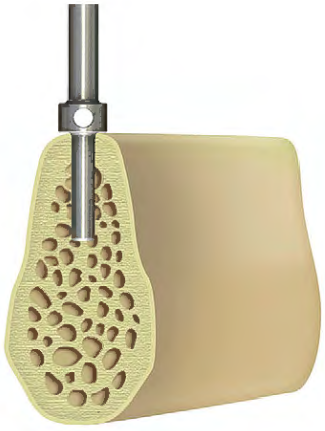

Figure 31-14 A direction indicator (parallel pin) is inserted into the center implant site.

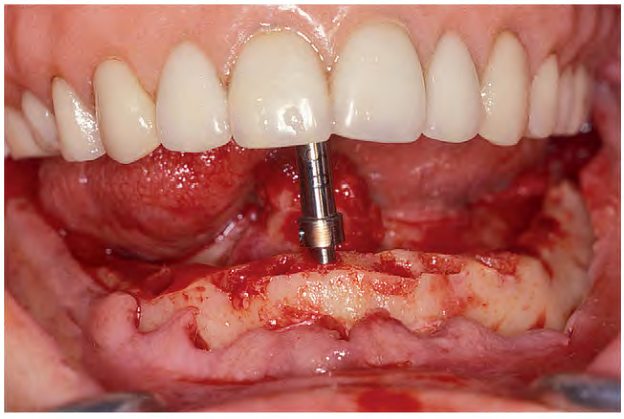

Figure 31-15 The direction indicator is evaluated for angulation and proper position.

WWW.HIGHDENT.IR

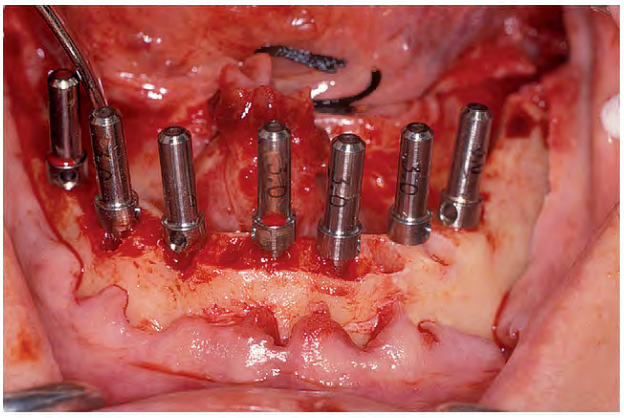

Figure 31-16 The pilot drill is used to prepare the initial sites, starting with the center, then A and E, then B and D, using the center parallel pin as a guide.

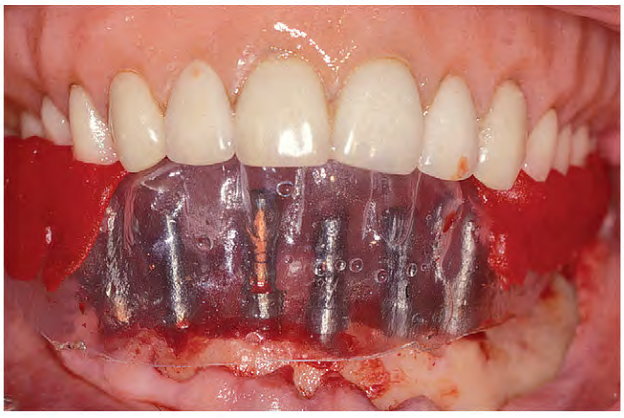

Figure 31-17 Small-diameter direction indicators are placed in the initial sites. A surgical template is inserted with the parallel guide pins in place to evaluate the future implant angulation and position.

angulation and position (Figure 31-17). If the angulation is incorrect by less than 20 degrees, it can usually be corrected with the next drill in the sequence provided by the manufacturer. If the angulation is to be modified by more than 20 degrees, a side-cutting drill (e.g., Lindemann) rather than end cutting is most efficient. These side-cutting drills also can stretch the initial osteotomy laterally to improve the implant position. If the angulation is beyond 30 degrees to an axis perpendicular to the occlusal plane, or if the osteotomy is too lingual or facial in relation to the incisal edge, correction of the initial osteotomy should precede any further bone preparation. The oblong osteotomy prepared to correct the problem of poor position or angulation is obliterated and made round again with successive drills of incremental diameter.

After the direction indicator confirms proper implant position, the osteotomy is made to the full depth of the planed implant size (Figure 31-18). It is usually better to drill 1 mm deeper than needed (i.e., 13 mm for a 12-mm implant) when the opposing landmark permits. If the opposing landmark is perforated before obtaining the desired length of the osteotomy, the osteotomy length before perforation is noted, and a shorter-length implant is selected. Ideally, the implant should not perforate the mandible to avoid irritation of the soft tissue, especially for a sharper apex implant design, where even slight perforation may irritate the tissues. If the implant has an open basket design, a perforation may trigger fibrous tissue ingrowth within the basket, rather than bone.

On occasion, bleeding from the osteotomy site may be copious, especially in the midline site, even though no bone perforation has occurred. An artery enters the lingual plate below the genial tubercles in the midline, and an anterior branch of the mandibular neurovascular canal continues beyond the foramen. The surgeon should confirm that no perforation through the lingual plate or inferior border has occurred. The majority of

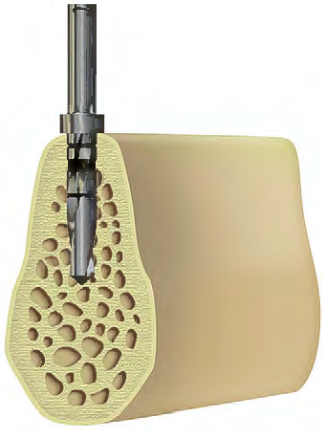

Figure 31-18 After the position and angulation is acceptable, the osteotomy sites may be made to the full depth of the desired implant size.

time, this bleeding is of no surgical consequence. It is also not associated with any soft tissue paresthesia after surgery. If the bleeding is causing concern for vision or total blood loss, a collagen sponge may be placed into the site, along with a drill or direction indicator to help obtund the site. Elevation of the head and pulling the tongue out to reduce flood flow to the lingual artery is also of benefit until the platelet plug forms and reduces the bleeding. If the osteotomy is completed, an implant may also be introduced into the site and will crush the walls of bone and halt the bleeding process.

The anterior mandible may present a significant undercut on the lingual aspect between the foramina. Life-threatening hemorrhage has been reported when a drill perforates the lingual plate of the sublingual region of the mandible and injures a sublingual or submental artery, especially in the canine region.[56-59] If perforation of the lingual cortical plate is associated with arterial bleeding, it is critical to identify its origin (Table 31-1). Bleeding in the floor of the anterior region of the mouth can originate from the lingual artery, facial

WWW.HIGHDENT.IR

Table 31-1 Treatment of Hemorrhage at Implant Osteotomy Site

BLEEDING SITE DURING IMPLANT OSTEOTOMY	ARTERIES	TREATMENT
Posterior mandible	Mylohyoid	Finger pressure at the site
Middle lingual of mandible	Submental	Surgical ligation of facial and lingual arteries
Anterior lingual of mandible	Terminal branch of sublingual or submental	Compression, vasoconstriction, cautery, or ligation
Invading the mandibular canal	Inferior alveolar artery	Bone graft

artery, or one of its branches. The submental artery originates from the facial artery, runs along the inferior border of the mandible, and meets at the midline. Pressure over the genial angle notch (just anterior to the masseter muscle) stops this type of bleeding. If the injured artery stems from the lingual artery, the bleeding will be reduced when the tongue is pulled out, thus placing pressure against the lingual artery where it crosses over the hyoid bone. Elevating the head is also of benefit. After the bleeding is reduced, it may be stopped by collagen sponges or hemostasis after clot formation, or rarely by surgical ties or electrocautery (see Complications).

A critical step in obtaining rigid osseous fixation after initial implant placement is to maintain a rigid bone-implant interface without micromovement between the time of original placement and the second stage of surgery. The implant does not have to be submerged below the bone to achieve this result. The implant does not even need to be below the soft tissue to obtain this type of interface.[60,61] However, the clinician should recognize situations such that the higher the implant is placed above the bone, the greater the risk factors for trauma that may result in movement at the interface during initial healing. As a result, when an overlying soft tissue–borne prosthesis is worn, it may be advantageous to countersink the implant below the bone. On the other hand, when a prosthesis abutment is added to the implant crest module below the bone, approximately 0.5 mm of soft tissue forms below the abutment-to-implant connection.[62] Therefore, if the crest module of the implant was below the crestal bone at the time of surgical placement, crestal bone loss will occur when the abutment is added.

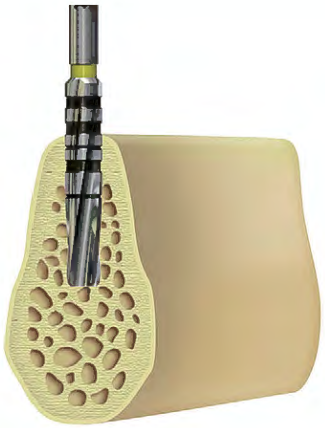
The implant surgeon should select the crest module position of the implant in relationship to the crestal bone on an individual basis. If the cortical bone and the overlying tissue is thick, and the patient has no parafunctional habits to apply stresses to the implant during healing, the implant and healing cover height are less critical and the platform of the crest module is often placed level with the crestal bone in more dense bone. Most often, the implant crestal module–abutment connection region should be placed 0 to 0.5 mm below the bone level in D2 bone, rather than countersinking the implant several millimeters below crestal bone. As a result, for most external hex systems, the hex connection and healing cover remain slightly above the bone. If the overlying tissue is thin, the superior cortical plate was removed during an osteoplasty, or the remaining bone is of softer quality such as fine trabecular (D4), the implant and healing cover should be placed below the bone crest. As a result, the osteotomy must be 1 mm deeper before implant insertion to permit the crest module to be below the bone. As a result, the final bone osteotomy depth is variable by ±1 mm for each patient condition.

After the center site is initially prepared, the most distal implant sites are prepared next, using the direction indicator in the center osteotomy for parallelism in all planes. Direction indicators may then also be placed in the distal sites, and the implant surgeon proceeds to the intermediary implant site locations in a similar fashion. Direction indicators may also be used to tamponade profuse bleeding from an implant bone drilling site until the implant is placed. This technique is useful in maintaining adequate vision and decreasing surgical blood loss.

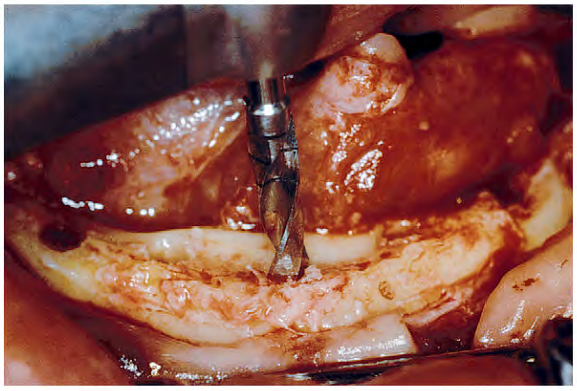
If a bone drill becomes locked in the bone during preparation, the hand piece should not be wiggled back and forth to disengage the drill. This may increase the size of the bone preparation, cause injury and necrosis to the bone, or separate the drill above or below the bone. Instead, the rotation of the drill in the hand piece is reversed, or the drill is disengaged from the engine and rotated counterclockwise with a forceps.

Drills of intermediate diameter are used next for the implant bone preparation. Gradual increases in drill diameter reduce the amount of pressure and heat transmitted to the bone, especially in presence of dense and thick cortical bone. Lavelle has shown the heat generated from a drill can be transmitted more than 3 mm away from the osteotomy site and reach temperatures higher than 50° C under copious irrigation.[50] The 2.0-mm initial drill is followed by a 2.5-mm drill, and then a 3.0- or 3.4-mm drill (Figure 31-19). Some manufacturers do not use an intermediate drill; however, a decrease in the heat and trauma generated is found with the intermediate drill.[53] The softer the bone, the fewer the number of intermediate drills

WWW.HIGHDENT.IR



A



B

Figure 31-19 A sequence of osteotomy drill preparation is dependent on implant diameter and design, but often uses a 2.0 mm initial drill, followed by 2.5 mm, 3.0 mm and 3.4 mm as a final dimension.

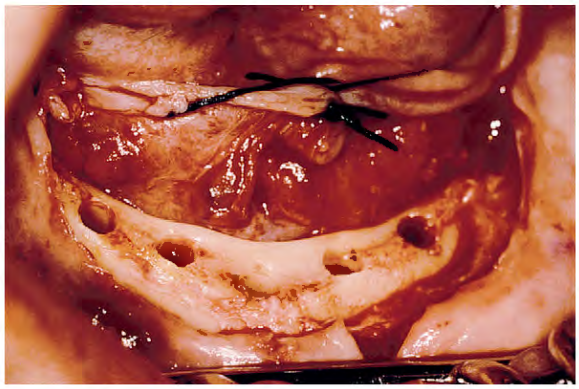


Figure 31-20 The final drill diameter is the most critical for the osteotomy, because the bone next to this drill will be in direct initial contact with the implants.

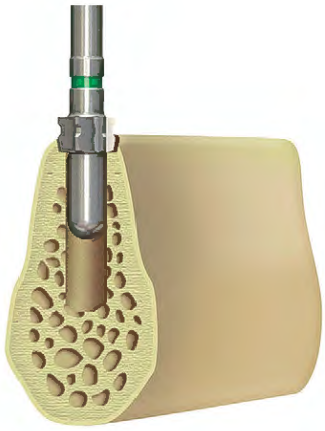

Figure 31-21 A crest module drill is often used in the anterior mandible, because cortical bone is present on the crest.

needed. Direction indicators are placed in bone sites medial or lateral to implant sites being prepared. Minor corrections in angulation should be accomplished during these intermediate drilling steps.

The final drill diameter is used to prepare the implant receptor site under copious irrigation (Figure 31-20). This step is the most critical for initial implant insertion and healing. The bone surrounding this drill will be in direct contact with the implant. When the final drill preparation is not precise, the implant-bone region may be incongruent and gaps may decrease initial stability, which may lead to early failure. A lesser initial contact with the host bone also decreases the percentage of new bone-implant contact formation.[54] Therefore a constant pressure and direction is used with the final drill to ensure a precise, round osteotomy is prepared along with direction indicators in adjacent sites to maintain the proper angulation. A summary of potential problems during implant osteotomy preparation and suggested solutions is presented in Table 31-2.

The crestal collar region of any system, regardless of dimension, should be placed in contact with crestal cortical bone. Many implants present a wider crest module design than the implant body. When the implant is placed below the bone, these systems may need an additional step in the bone preparation, with a crestal countersink drill to increase the osteotomy diameter only in this region (Figure 31-21). If there is no marginal cortical bone, and especially if the trabecular bone is soft, the implant is inserted without a crest countersink drill procedure. This compresses the marginal rim of bone and adds rigidity to the implant during initial healing.[63]

If a threaded implant system has been selected to support the prosthesis, the clinician should decide whether or not to tap the osteotomy before implant insertion. Very dense bone (D1) requires a bone tap for the entire implant height. D2 bone may also require a bone tap, especially if the implant is made of a softer grade of titanium. With thick inferior cortical plates at the apex of the osteotomy, a bone tap is also required for the entire height. If only the superior cortical plate is dense and provides initial rigidity of the implant, the bone tap is used only in this section. Studies concentrating on threaded implants inserted with and without a bone tap have shown that implants with precut threads in dense bone achieved a higher

WWW.HIGHDENT.IR

Table 31-2 Possible Problems Encountered during Root Form Surgery and Suggested Solutions

PROBLEMS	SOLUTIONS
Improper pilot hole/location	Create a new pilot hole with round bur No. 6 or stretch the existing hole with a No. 6 drill or a side-cutting drill (e.g., Lindemann).
Improper drilling angulation	Start a new direction with the pilot drill and 1.5-mm drill and continue with remaining procedures. Use a side-cutting drill to redirect the osteotomy. Use the assistant/doctor force direction indicators or template to regularly check direction during the osteotomy preparation.
Elliptical/eccentric preparation	Continue the surgical procedures and try to use the planned implant. If the implant is loose on seating, use a wider-diameter implant if possible. If not, pack the osteotomy with autogenous graft, compress it, and place implant again. If the angle with the adjacent implant is greater than 30 degrees, remove the implant and allow the surgical site to heal for approximately 6 months. Place the implant at a later date.
D1 bone density	Prepare osteotomy with a constant pumping motion to avoid overheating and use higher torque and speed. Use new drills and profuse irrigation with incremental drill sequence. Use bone tap with hand ratchet.
D3-D4 bone	Push the drill as it rotates at decreased speed. Do not bone tap. Insert implant with hand piece.
Perforated buccal or lingual bone plates	Stop drilling as soon as less than 1.0 mm of bone is lateral to the drill. Use an osteotome with a tapered end to expand the osteotomy, rather than removing the bone with a drill.
Threads exposed at crest of ridge	If implant threads are exposed coronally, graft autogenous bone harvested intraorally with rongeurs or a trephine bur over the region.

Figure 31-22 A bone tap is used at less than 30 rpm with a high torque hand piece or hand ratchet and copious irrigation in D1 or D2 bone before implant insertion. The bone tap may be used selectively only in the crestal region, when the underlying trabecular bone is soft and the implant does not engage cortical bone at the apical region of the implant.

percentage of bone-implant contact during the healing phase,[64] and greater bone trauma was identified with the self-tapping implant. In the cases of a fine trabecular bone, especially in the absence of crestal cortical plate, a bone tap is contraindicated because this decreases the initial stability of the implant.[63]

Whenever the bone tap is required, it should be used to prepare the bone at very slow speed (less than 30 rpm) with copious amounts of irrigant. This may be accomplished with a hand ratchet or a slow-speed, high-torque, contra-angle hand piece (40:1 to 100:1 reduction) (Figure 31-22). It is imperative that the angulation and light vertical pressure used on the ratchet or hand piece follow the same path as the final drill preparation for the entire depth. Otherwise, the tap may inadvertently stray in the trabecular bone and compromise the final implant placement. The direction indicators in adjacent sites are very beneficial in helping to maintain the correct angulation. A hand ratchet rather than a high-torque hand piece should be used in D1 bone to prevent hand piece breakage or wear.

The hand position of the surgeon is important in maintaining constant force and direction on the hand ratchet or hand piece during the threading process. When using a ratchet, one hand holds the ratchet while the thumb of the other hand is placed directly over the tap, the index finger retracts the lip for improved access and vision, and the middle finger is placed under the mandible in the direct path of the osteotomy. Care must be taken to let the handle of the ratchet rotate around the insertion pin, not pull or lever the pin and connected tap as it rotates. Using a hand piece to tap the implant site in D2 bone or the apical end in a D3 site presents some advantages, such as a relative ease of constant direction, especially in softer bone. The bone tap should be cleaned with saline before each new site is prepared.

WWW.HIGHDENT.IR

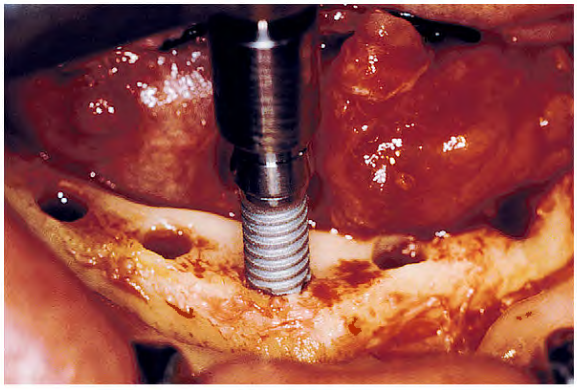

Figure 31-23 The high-torque hand piece is used to thread the implant into the anterior mandible at less than 30 rpm.

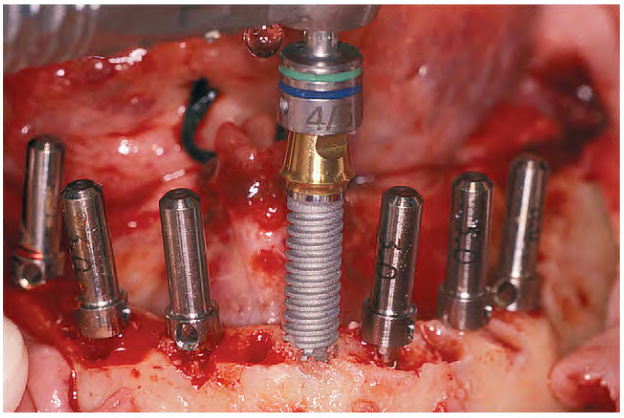

Figure 31-24 The hand piece insertion of the implant occurs after the osteotomy has been suctioned, to remove any debris or fluid, which may create hydrostatic pressure or friction during the insertion process.

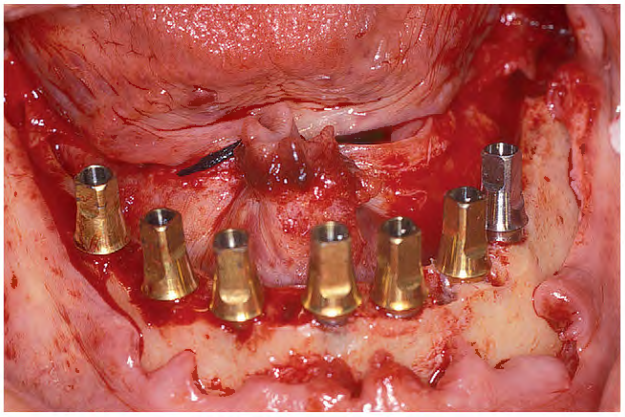

Figure 31-25 Five anterior implants have been threaded into position between the mental foramina, and two implants are inserted over the top of the foramen.

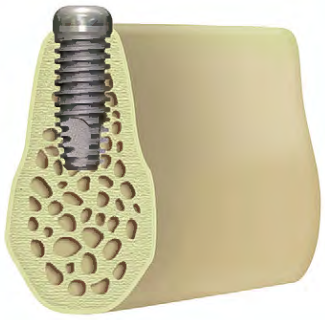

Figure 31-26 The first-stage cover screw is inserted into the implant body. This prevents soft or hard tissue growth over the implant platform during healing and protects the antirotational hex for abutment connection.

Implant Placement

The implant sites are flushed with saline to remove any debris and suctioned to reduce hydrostatic pressure during implant insertion. The implants are now ready to be threaded into position at a speed similar to the bone-tapping procedure (Figures 31-23, 31-24). The direction-indicator pins may still be needed in adjacent sites to guide the implants in the correct angulation in soft trabecular bone. The implant surface has been prepared by the manufacturer to be clean and uncontaminated. Handling the implant body is poor protocol and may alter the surface chemistry. Instead, the implant is placed directly into the implant site by means of a preattached insertion mount. Some manufacturers require the surgical team to attach the implant mounts before placement, but this procedure complicates the process with no benefit.

After the first threads of the implant body engage the bone, the same speed used to tap the bone is used to insert the implant. The surgeon's hand position is identical to that maintained during the bone tapping procedure. Sterile saline may be used after the implant has begun its descent into the implant osteotomy, but is not suggested. The patient may attempt to swallow as a result of the irrigant and during this process may close and change the angulation of the implant. The hand ratchet is used at the end of implant insertion to check the final stability of the implant body. The surgeon should not overtighten the implant in place. Excessive tightening of the implant in its final position may cause microfractures and compromise the entire implant thread-to-bone profile and interface development. When in doubt, the implant should be slightly unthreaded so as to decrease pressure at the developing interface. The marginal cortical bone should seal the implant periphery without voids or cracks. If any defects are present, the bone chips harvested from the drills or from an osteoplasty are used to fill any deficit (Figures 31-25, 31-26).

On rare occasions, the implant may not be rigid after implant placement. A mobile implant may not heal predictably with a direct bone interface. The implant may be fixated by inserting it deeper in the osteotomy or by the placement of a larger-diameter implant. In addition, the lateral cortical plates may be compressed with a mallet and blunt instrument to compress the bone against the implant. The surgical decision to

WWW.HIGHDENT.IR

obtain rigid fixation is based on the width and height of bone available.

The internal aspects of the implant bodies are thoroughly irrigated to remove any blood or debris before the placement of the cover screw. The first-stage cover screw is then inserted into the implant body. An antibiotic paste may be placed on the threads of the cover screws before their insertion. In theory, this paste helps seal the cover screw–implant body connection and decrease the risk of bacteria growth within the implant body during healing. However, no clinical study is available to confirm this hypothesis. The cover screw is threaded to final position, then loosened and tightened again. The implant should not rotate during this process. When the cover screw is threaded into position, care is taken not to overtighten it. The stress transmitted may rotate the implant body and also complicate the cover screw removal at the second stage of surgery.

Soft Tissue Adaptation

The crestal bone is evaluated for any sharp edges, and a rongeur or bone file is used as indicated. The surrounding bone is also evaluated, because final soft tissue contour is directly dependent upon its topography. The surgical site is thoroughly irrigated with saline to remove any debris or bone fragments. The lingual retraction sutures are cut and removed. The tissues are approximated without tension, and a 3-0, resorbable, horizontal mattress interrupted suture is placed at the midline. An interrupted horizontal mattress or a continuous suture is placed on the distal aspect of the midline suture. It is important that the labial periosteum be joined to the lingual periosteum. Surface epithelium should not contact the periosteum along the suture line, because this may result in delayed healing and incision line opening. The sutures should be placed approximately 3 to 5 mm from the incision line, and 3 to 5 mm apart.

A firm pressure is applied to the reflected soft tissue for 4 minutes after the suturing is completed. This helps prevent bleeding under the soft tissue flaps and helps the tissue adhere to the bone, because fibrin released from the blood is natural tissue glue. A postoperative panoramic radiograph is taken at the conclusion of the procedure.

Because the anterior implants and primary healing covers are often placed after an osteoplasty, the labial flange of a removable prosthesis is overextended and needs to be shortened. The internal surface of the prosthesis is aggressively relieved 3 to 5 mm. A soft tissue conditioner replaces the acrylic. The tissue conditioner is also relieved over the implant sites so that the prosthesis is not in contact with the soft tissue directly over the implant sites. The patient may wear the denture during the healing process; however, the less it is worn, the less likely premature loading of the implant will occur. Incision line opening is a possible consequence of wearing the denture during the first 2 postoperative weeks; however, this is rarely a problem if the denture is properly modified and the patient wears it primarily for social encounters. The patient should not use denture adhesives or other products that may enter the incision line. The denture should not be worn at night, and the patient is instructed to coat it with petroleum jelly or soak it in water to maintain the pliable nature of the conditioner.

SURGERY IN THE POSTERIOR MANDIBLE–DIVISION A

There are 20 million Americans missing all of their mandibular teeth, and 40 million partially edentulous people are missing all their posterior teeth in one or more quadrants (Figure 31-27). Therefore 60 million people are candidates for implants in the posterior mandible. A primary indication for root form implants is the Division A posterior mandible. Dental implants are rarely inserted in the mandibular second or third molar location, and the first premolar is anterior to the mental foramen. Therefore the posterior mandible is primarily concerned with the second premolar and first molar region.

On occasion, surgery in the posterior region of the mouth is complicated by a small crown height space, especially when opposing teeth are present. The implant drills and hand piece require a space of at least 20 mm to the bony crest, so the osteotomies may be prepared with proper angulation. In addition, the implant and insertion tools often require at least 20 to 25 mm of space. This may be most difficult in the second molar region because the amount of space decreases posteriorly. If opposing teeth have extruded, the occlusal plane should be corrected before implant placement to increase the crown height space for surgery. On

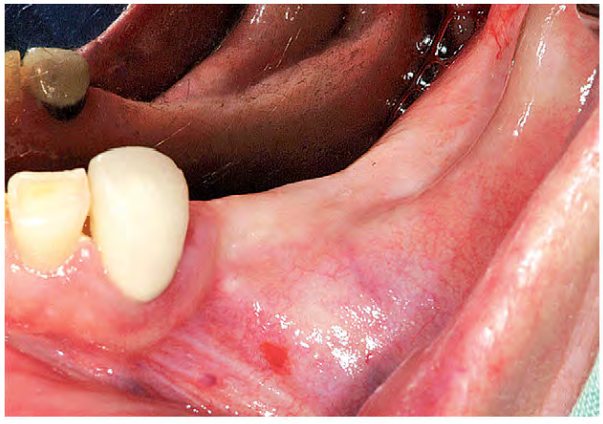

Figure 31-27 The posterior mandible is often missing multiple adjacent teeth.

WWW.HIGHDENT.IR

occasion, a shorter-length implant may be indicated to reduce the crown height space needs of the surgery.

The posterior mandible has greater initial width than the anterior mandible. As such, Division A bone is more commonly found early after tooth loss. The Division A bone has a height measurement that is determined from the crest of the edentulous ridge to the opposing landmark of the mental foramen or mandibular inferior alveolar nerve, artery, and vein. The ideal bone height includes 2 mm of surgical "safe zone" above the landmarks to decrease the risk of paresthesia by inadvertent violation of the structures. Therefore a 12-mm-long implant requires 14 mm of available bone height and a 9-mm-long implant requires 11 mm of bone height. The ideal length of an implant in the posterior regions is 12 mm or more; however, 9 mm has proven predictable when implant width, number, or design is also considered (Figure 31-28).[65] After the resorption of the edentulous ridge has evolved into Division B, it may last for more than a decade, so this condition is also often observed. Unlike the anterior mandible, the posterior mandibular Division B bone is less likely to be modified to Division A by osteoplasty, because the mandibular canal is on average 12 mm above the inferior border of the mandible and rarely permits enough crestal bone reduction to increase the width and still have enough height of bone for the Division A criteria. Therefore bone augmentation in Division B posterior mandibles is often warranted.

Many aspects of the surgical approach are similar to root form surgery in the anterior mandibular region. However, because the mandibular canal is the opposing landmark, rather than a thick cortical plate such as in the anterior regions, attention is specifically brought to the neurovascular complex.

The study models of the patient are duplicated, and a diagnostic wax-up of the final prosthesis is made. This step is important in determining the position of the abutment posts for the prosthesis (including the plane of occlusion, the height of the abutment for cement, and whether it is adequate for long-term cement retention), the need for pontics, the angulation of the post in relation to the abutment teeth, and the mesiodistal position of the implant. The study models, diagnostic wax-up, panoramic radiograph, and other diagnostic images are all available at the time of surgery.

Figure 31-28 A panoramic image of an edentulous posterior mandible, missing both premolars and molar. There is abundant bone height above the mandibular canal. Most often, the position of the mandibular canal may be observed in the first molar site.

The patient is premedicated, as suggested for any implant surgery, and anesthetized using an Akinosi block with both lidocaine 2% with 1:100,000 epinephrine and a long-acting anesthetic. Postoperative discomfort is reduced with long-acting anesthetic agents. The patient is prepared for surgery with a preoperative intraoral and extraoral Betadine or chlorhexidine scrub. The surgical team also scrubs and gowns in the standard aseptic method.

SOFT TISSUE REFLECTION

The surgical region is checked for regional anesthesia with local infiltration of 2% lidocaine with 1:100,000 epinephrine. Local infiltration also provides hemostasis and improved visibility during the soft tissue incision. In addition, when the local anesthetic is injected on the crest of the ridge and under the periosteum, a hydroelevation of the tissue may help the initial tissue reflection.

The primary incision is made on the crest of the ridge from the retromolar papilla (at the base of the pad) to the anterior tooth abutment. If there is 3 mm or more of attached gingiva on the crest of the edentulous ridge, the incision bisects this tissue. This places half of the attached gingiva width on each side of the cover screws or low-profile permucosal extensions. If there is less than 3 mm of attached keratinized tissue on the crest, the incision is made more lingually so at least 1.5 mm of the attached tissue is placed to the facial aspect of the implant abutments. In this way, the buccinator muscle is separated from the incision line and does apply tension and cause opening of the incision line during the initial healing, and gingival complications are reduced over the long term. The crestal incision is often continued in the sulcus and interproximal of the posterior teeth to the ipsilateral canine (Figure 31-29).

A secondary incision is made lateral to the retromolar pad and up the ascending ramus, to the height of the occlusal plane, and just below the two attachments of the temporalis muscle (Figure 31-30). On rare occasion, the buccal artery crosses over the ramus in this region and may be severed during the vertical release incision. This artery is a branch of the maxillary artery. Therefore a hemostat is readily available and clamps the soft tissue on the lingual aspect of the flap if excessive bleeding is noted. After 10 minutes, the hemostat may

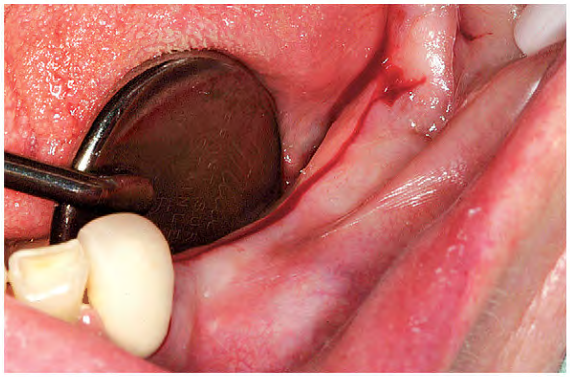

Figure 31-29 The posterior incision line is made on the crest of the edentulous ridge and often extends to the distal of the canine.

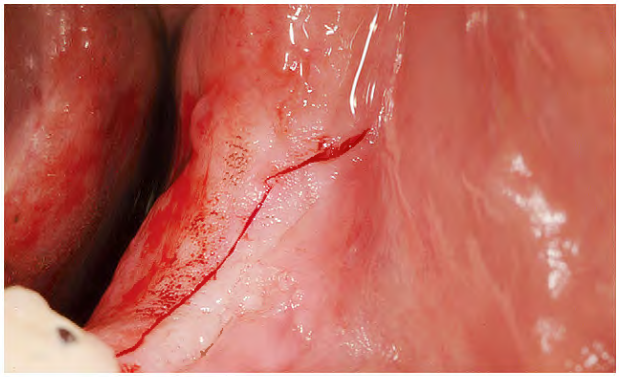

Figure 31-30 The distal release incision extends lateral to the retromolar pad, along the ascending ramus.

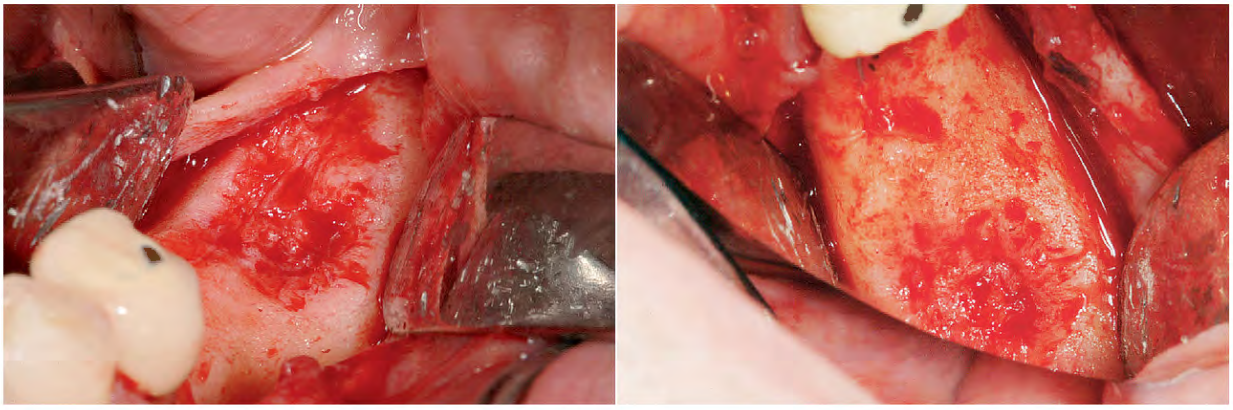

A B

Figure 31-31 **A,** The lingual flap is first reflected off the crest. **B,** The facial flap is reflected and, when a computed tomography scan is not available, usually exposes the superior aspect of the mental foramen.

be released and the bleeding will be arrested. Usually a secondary vertical release incision is also made just distal to the mandibular canine (which includes the distal papilla), which is always anterior to the mental foramen.

The lingual flap is first reflected only a few millimeters beyond the lingual crest of the ridge. Almost all concavities in bone of the posterior mandible occur on the lingual aspect in conjunction with the submandibular fossa. Therefore the region should be palpated and evaluated with a CT scan when available before osteotomy preparation. A full-thickness periosteal flap is then reflected on the facial, exposing the underlying crest and lateral surface of the edentulous mandible in the region of the foramen (Figure 31-31). When a CT scan of the region is not available and intraoral radiography is not easily present, the facial reflection should expose several millimeters of the lateral aspect of the edentulous ridge and the superior portion of the mental foramen. By exposing this area, the implant surgeon is less likely to inadvertently perforate the bone, which would result in fibrous tissue formation next to the implant in the region. In addition, the mental foramen is almost always identified in mandibular posterior surgery to determine the zone of safety above the mandibular canal when a CT scan is not available before surgery.[32]

The retromolar papilla should be elevated to the lingual to expose the underlying bone when implants may be placed in the mesial aspect of the second molar. The bone under the papilla in this area is usually more than 5 mm wide and 5 mm in length. The region is palpated just inferior to the retromolar pad to identify the submandibular anatomic landmarks. Severe undercuts inferior to this region are typical. As a result, root form implants are rarely placed under the papilla, but its reflection improves vision and access in the mesial half of the second molar area.

MANDIBULAR NERVE LOCATION: CLINICAL ZONE OF SAFETY

The risk of mandibular canal penetration during endosteal implant placement in the posterior mandible is a serious concern. At the time of surgery, intrusion into the mandibular canal results in an increased risk of hemorrhage, visibility impairment, and increased

WWW.HIGHDENT.IR

potential of fibrous tissue formation at the surface of the implant. More important, the patient experiences altered nerve sensation in the form of anesthesia, paresthesia, or hyperesthesia. This may affect the patient's lifestyle during eating, kissing, and applying lipstick and is a common cause for litigious action against the implant dentist. Consequently the surgical boundary is often set conservatively 2 mm above the mandibular canal to establish a surgical zone of error.

Procedures to Identify the Mental Foramen

A common approach to identify the existing available bone above the inferior alveolar canal is to start at the foramen, because this is the location in the posterior mandible where the reduction of the vertical height of bone begins. Compared with the anterior mandible, where the opposing landmark is the inferior border of the mandible, the posterior mandible is limited by the foramen and inferior alveolar complex.

The anteroposterior position of the mental foramen is variable and may correlate as far forward as the apex of the first premolar to as far distal as below the mesial root of the first molar. In a study by Cutright et al., the mental foramen location variance was different for white and black populations (Figure 31-32).[27] Mandibles for whites had the foramen farther forward, with 5 of 76 mandibles being under the first premolar (6.6%), 24 between the premolars (31.6%), 39 below the second premolars (51.1%), and 8 between the second premolar and first molar root (10.5%). Mandibles of black people had the foramen between the premolar 11 of 78 times (14.1%), below the second premolar 41 times (52.6%), between the second premolar and first molar 25 times (32%), and below the mesial root of the molar 1 time (1.3%). Therefore the average foramen of white people was below or in front of the second premolar (89.3%) and the average foramen in blacks was below or distal to the second premolar (85.9%).

The mental foramen vertical position is usually found more coronal and facial than the mandibular canal (Figure 31-33). Agthong et al. stated the foramen was 14 to 15 mm from the inferior border.[66] Neiva stated the position was 12 mm (range, 9 to 15 mm) from the lower cortex of the mandible.[36] Fishel et al. noted in a white population, the foramen was coronal to the apex of the first premolars 38.6% of the time, 15.4% at the apex, and 46% apical to the apex position. The position of the foramen in relation to the second premolars was 24.5% coronal, 13.9% at the apex and 61.6% apical.[29] Therefore the vertical position of the foramen is variable. On occasion, more than one mental foramen may be present. However, this appeared to occur less than 2% of the time in whites and 5.7% in blacks.[67]

Jacobs et al. evaluated panoramic radiographs and could observe the foramen 94% of the time, but only 49% were clearly detectable.[68] Fishel et al. found that

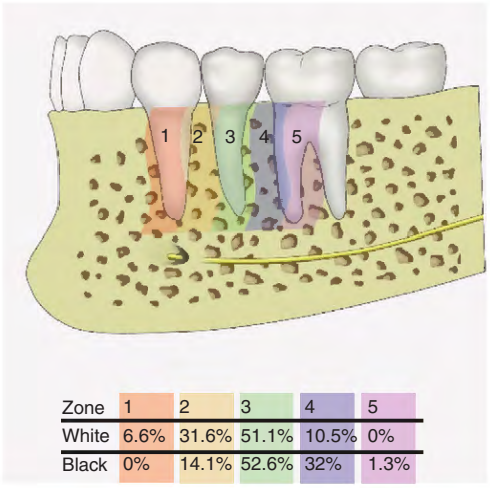

Figure 31-32 The mandibular foramen may extend as far forward as the first premolar to as far distal as between the second premolar and first molar roots. It is often correlated to sex and race.

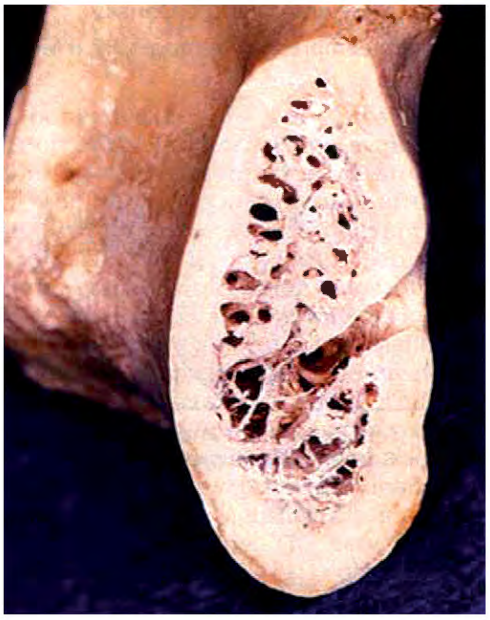

Figure 31-33 The mandibular foramen is usually coronal and facial to the position of the mandibular canal. The foramen is cone shaped, with the outer rim larger than the inner dimension of the foramen.

even the mental foramen was only visible on approximately 50% of periapical radiographs.[29] On the other hand, Yosue and Brooks[69] showed that the mental foramen could be identified on a panoramic radiograph 87.5% of the time. However, only 64% of the radiographs evaluated clearly showed the accurate position of the foramen. These same authors evaluated a panoramic x-ray and the actual skull in four subjects. The panoramic radiographs illustrated the mental foramen in the correct position less than 50% of the time, and often it was significantly closer to the inferior border of the mandible than its actual position. In addition, the appearance of the foramen varied with the positioning

WWW.HIGHDENT.IR

of the mandible in relationship to the focal length used while obtaining the radiograph.[69] Conventional tomography and CT are usually more diagnostic as to the position of the mental foramen.[28,70,71,72]

Procedures to Identify the Mandibular Canal

The available bone height over the mandibular canal is critical to determine whether adequate bone is present to place root form implants. The most common methods to assess this dimension are periapical radiographs, panoramic radiography and CT images with or without reformatted images.

Several clinical approaches to the posterior mandible have been proposed using radiographic techniques. Usually the inferior alveolar nerve proceeds anteriorly, inferiorly, then horizontally and laterally below the apices of posterior teeth and curves superiorly to exit at the mental foramen. It is reported to never transverse lower than 6 mm below the height of the foramen.[73] In the region of the first mandibular molar, the mandibular canal is often difficult to identify on a periapical or panoramic radiograph. A cortical lining of the canal is not always present in the molar region.

The angulation of the bone in the posterior mandible progressively evolves from almost vertical in the premolar region to 15 degrees in the first molar and 25 degrees in the third molar region. A periapical radiograph cannot be parallel to all three of these planes. In addition, the floor of the mouth prevents the periapical x-ray from being ideally positioned in relation to the edentulous ridge. As such, foreshortening or elongation of the image is expected.

Because the x-ray beam of a panoramic radiograph originates from below the patient's mandible, the location of the canal in reference to the crest of the ridge is dependent on the buccolingual position of the mandibular canal. If the nerve canal proceeds along the lingual aspect of the mandibular body, the canal will be projected more superior toward the crest. When the nerve canal proceeds toward the foramen on the buccal of the mandibular body, it will be projected more inferior in relationship to the crest. In other words, the distance from the crest to the mandibular canal may be the same in two different patients, but appear on the panoramic films as two different positions (Figure 31-34).

Despite obvious limitations, a panoramic radiograph is often used as the initial method to determine the height of the bone available over the mandibular canal. Most often, a panoramic radiograph can identify the entry of the mandibular inferior alveolar nerve into the ramus, because the lingula is cortical bone and the canal has a cortical lining, surrounded by softer trabecular bone. The mental foramen is also able to be identified on most films. Although a bifid canal has been observed, its occurrence is less than 1%.[74]

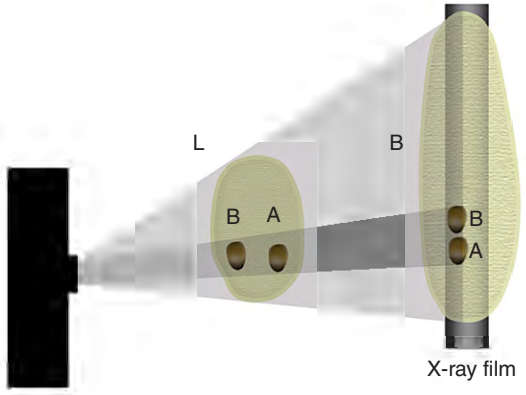

Figure 31-34 Although the distance from the crest of the ridge is similar in both of these nerve locations, when the canal resides more buccal in the mandibular body, it appears more apical on the x-ray film.

When present, the canal that exits the mental foramen is the opposing landmark, because sensory nerves that do not innovate soft tissue are of little concern for paresthesia.

After the panoramic radiograph is observed and the bone height over the radiographic canal directly measured on the radiograph, the patient may be placed in one of three categories: (1) there is obviously enough radiographic bone height over the canal and foramen (>15 mm), (2) there is obviously not enough height over the landmarks (<9 mm), or (3) the adequate bone height is questionable. The magnification of the radiograph is initially ignored to determine in which of the three categories the available bone height is placed.

A 25% manufacturer-supplied magnified image of the implant body may be placed over the radiograph to help select the desired size of implant to be inserted in the abutment positions. This magnified image is not accurate, but may help to determine whether the patient obviously has enough bone. These magnified images often prove imprecise in marginal cases because panoramic radiographs do not have a uniform magnification rate. Additional variables such as the patient's head position may significantly alter magnification by as much as 55%. In addition, at the time of surgery, the crest of the edentulous ridge is often modified by osteoplasty to increase the width of crestal bone. The premeasured bone height is reduced by a dimension that may be difficult to assess.

A study by Sonick et al. compared the location of the mandibular canal with panoramic and CT radiographs of a cadaver mandible.[72] The average distortion of the panoramic image was 3.0 mm (range, 0.5 to 7.5 mm) and the CT average was 0.2 mm (range, 0 to 0.5 mm). Therefore the panoramic method of mandibular nerve location would be limited to obvious extremes of abundant or inadequate bone.

The cortical lining of the mandibular canal is often absent in the first molar region and even when present may be confused with a vascular region surrounded by

WWW.HIGHDENT.IR

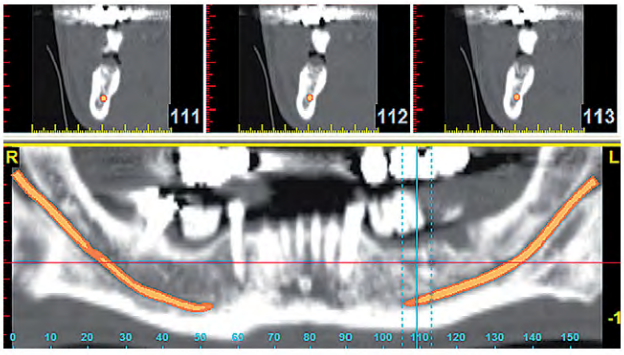

Figure 31-35 A computed tomography–reformatted image of a mandible allows the identification of the mandibular canal in several planes. Therefore the width of available bone above the nerve, the height of available bone, and the angulation of the bone may be determined.

trabecular bone. As such, tomograms or an individual CT image may not easily determine the position of the mandibular canal. A computer-generated tomogram series of reformatted images represents an improved diagnostic tool for identifying bone width, height, and mandibular canal location (Figure 31-35). Therefore when the diagnosis is unclear, the use of a CT scan and the reformatted images into a computer software package (i.e., Materialise, Implant Logics) is a considerable advancement in diagnostics for the location of the mandibular canal. Using a CT scan is most indicated when the panoramic radiograph gives an uncertain answer relative to the available bone in the region. When questionable bone height is present, the CT scan is indicated to determine a more exact canal position and whether an implant may be inserted above the mandibular canal.

A surgical approach without block anesthesia has been suggested to allow implants placement above the canal in questionable ridges.[75] In this technique, local anesthesia is achieved by infiltration into the surrounding soft tissues. The bone is then prepared without anesthesia, because few sensory nerve fibers exist in this region, except those of the mandibular canal. The patient is instructed to notify the surgeon if sensation or discomfort is experienced, which theoretically correlates to the rotary instrument approaching the mandibular nerve. However, the infiltration surgical approach presents several disadvantages. With this approach, sedation must be minimal to enable the patient to communicate intelligently during the procedure. The misinterpretation of a pressure phenomenon or bur vibration raises the patient's and doctor's anxiety regarding nerve encroachment. Additional sensory mandibular nerve pathways are often present within the bone. These nerves innervate teeth but little or no soft tissue of the face. Apprehension or misinterpretation by the doctor or patient with this technique can result in the selection of a short endosteal implant of lesser bone-implant surface area. This condition may lead to greater bone loss and failure and is not recommended.

The placement of endosteal implants medial to the mandibular canal has been reported.[76] However, the position of the canal in a transverse plane is not reliable. The inferior alveolar nerve enters the medial aspect of the ramus above the lingula and exits on the lateral aspect of the mandibular body at the mental foramen. The crossover from medial to lateral aspects usually occurs in the third to second molar region, but this is highly variable. Attempting to place an implant medial or lateral to the canal as a result of an average anatomic location or, more recently, with information from the CT image has been suggested.[76-78] This technique requires precise control of the angulation of penetration at the crest of the edentulous ridge. Surgical error of a few degrees may result in perforation of the canal. Visualization of a few degrees is most difficult in the posterior regions of the mouth when observing the mandible from the lateral aspect of the patient. As a result, the general rule is to place the implant above the mandibular canal.

ZONE OF SAFETY

The zone of safety is defined as an area within the bone that can safely support implants without fear of impingement on the mandibular neurovascular bundle. A zone of safety for the placement of posterior mandibular endosteal implants was established by Misch in 1980 by the evaluation of 530 panoramic radiographs of partially edentulous patients. In 1989 this evaluation was confirmed by Misch and Crawford with an additional 324 consecutive panoramic radiographs.[32]

The zone of safety is a clinical method to assess a safe zone to insert endosteal implants. It is used when a CT image does not confirm the presence of adequate available bone height. Therefore when periapical or panoramic images are the only diagnostic tool to assess available height and abundant height seems present (>15 mm), two treatment methods may be used:

1. A 2-mm pilot drill prepares an implant site 9 mm deep. A 9-mm-long force direction indicator is positioned in the osteotomy, and a periapical radiograph is made. The indicator is evaluated in light of the opposing landmark, and a decision is made to remain at 9 mm or reprepare the site to 12 mm deep.
2. The mental foramen is reflected and the safe zone is established before drilling the initial osteotomy depth.

The zone of safety is determined either on panoramic radiographs or clinically during surgery as follows. Line A is drawn parallel to the posterior plane of occlusion, at the level of the residual crestal ridge and at the sites of implant placement. Line B is drawn at the most superior aspect of the mental foramen parallel to line

WWW.HIGHDENT.IR

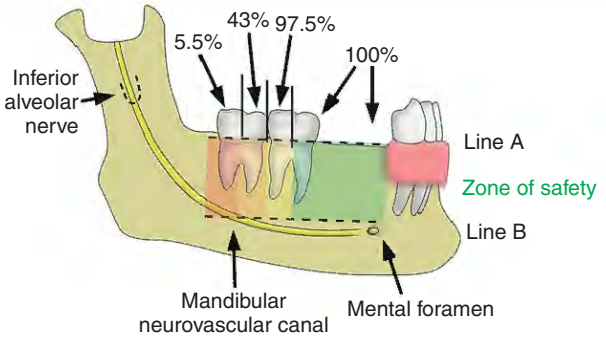

Figure 31-36 Mandibular zone of safety. Draw an imaginary line parallel to the plane of occlusion at crest of the posterior ridge **(A)** and another parallel line at the top of the foramen **(B).** The height of bone between these lines is the zone of safety to the mid first molar region.

A. Lines A and B are joined with a perpendicular line C. The length of line C is the safe zone measurement to the mesial half of the first molar (Figure 31-36).

The results of studies by Misch and Crawford[32] indicated the prevalence of the mandibular canal below the second line (B) on radiographs, using the landmark of the mental foramen. A zone of safety was observed 100% of the time mesial to the middle of the mandibular first molar. The most common position of the mandibular canal was 2 mm or more inferior to line B (drawn from the top of the foramen). Therefore the area within the zone of safety is above the mandibular canal and allows a surgical safety zone that most often approximates 2 mm. In the region of the distal half of the first molar, the mandibular canal was below line B (within the safe zone) in 97.5% of radiographs. In the region of the mesial half of the second molar, the mandibular canal was below line B in 43% of the radiographs; in the distal half of the second molar, it was only 5.5% (Table 31-3). Because implants are not often placed in the second molar area, the zone of safety has proven a useful clinical tool.

The position of the foramen is also an anatomical landmark for mandibular implant placement in the premolar region. Because the foramen is most often found distal to the first premolar, implants are often considered safe to place in the first premolar region, just anterior to the foramen. An anterior loop of the mandibular canal occurs when the mandibular nerve proceeds inferior and anterior to the position of the foramen, then loops superior and distal to reach the foramen. An anterior loop was observed in 12% of the panoramic radiographs and up to 3 mm in length anterior to the foramen.[32] Therefore when this condition exists, first premolar implants should usually be placed above the mental foramen position.

Safe Zone Procedure

The zone-of-safety technique is used before and during surgery for endosteal implant placement in the posterior mandible, when a CT scan was not used to determine the height of available bone and when a panoramic radiograph clearly indicates enough bone is present above the canal (>15 mm). First, radiographic estimates of vertical bone height are made by measuring the distance between lines A and B in the safe zone. Correction of this measurement (from magnification) may be accomplished by using calibrated balls or wires and using ratios of magnification or an arbitrary 25% magnification. The approximation of the available bone height is used to develop the treatment plan. An implant height may be initially determined, with the understanding that the safe zone is actually measured at the time of surgery and may be different because of osteoplasty or incorrect magnification allowance. If the final estimates of available bone height are less than 15 mm to the canal, it is suggested a CT scan be obtained before surgery to determine precise mandibular nerve position in this region.

Bone Preparation

If the edentulous ridge is narrower than 6 mm, an osteoplasty is performed under copious irrigation, as long as the remaining height of bone is greater than 12 mm above the foramen position. As a result of the osteoplasty, the crest width is increased, but the anatomic landmark of the mandibular canal is now closer to the remaining crest of bone.

The ideal implant position is level with both cortical plates. Bone remodels to the height of the lowest cortical plate. The height of the available bone is then determined, forward of the mesial half of the first molar. An imaginary line A is drawn parallel to the

Table 31-3 Mandibular Canal Location: Posterior Mandible*

LOCATION	MESIAL FIRST MOLAR	DISTAL FIRST MOLAR	MESIAL SECOND MOLAR	DISTAL SECOND MOLAR
+	324 (100%)	316 (97.5%)	149 (43%)	18 (5.5%)

WWW.HIGHDENT.IR

occlusal plane on the crest of the residual ridge after osteoplasty. Another parallel imaginary line B is established at the superior aspect of the mental foramen. The height of the available bone in the second premolar and mid-first molar region corresponds to the distance between these lines and represents the maximum height of the endosteal implant in this region (Figure 31-37).

The radiograph is then evaluated to confirm and extend the zone of safety beyond the mid-first molar region. If the canal appears to remain at the same distance as the zone of safety in the distal of the first molar region (97.5% of the time), the safe zone measurement is expanded to the distal root region. If the canal appears to rise 2 mm or more in the mesial of the second molar region (about 60%), the safe zone measurement is reduced accordingly in this region. The distal half of the second molar region is almost always reduced from the safe zone measurement (94% of the time) and usually is at least 4 mm less than the safe zone height. The osteotomy preparation may be started if adequate bone height is present. It is recommended to err on the side of safety in the region past the mesial half of the first molar, using the panoramic radiograph as a guide. This clinical approach has been used successfully over two decades in thousands of surgical procedures without paresthesia.

The premolar site implant osteotomy may proceed directly over the foramen to the same safe zone measurement without the implant osteotomy impinging on the nerve, based on three anatomical considerations. Although the crossover position of the mandibular canal from the medial aspect of the ramus to the lateral area of the body of the mandible is variable and may occur anterior to the second molar region, the mandibular nerve always exits the mandible facially at the foramen. Therefore the implant osteotomy is lingual to the canal and its contents in the foramen region. In addition, the mandibular foramen is cone shaped, with the base of the cone oriented facially and its summit lingually (see Figure 31-33). Therefore, when the height measurement is made from the top of the external portion of the foramen, this represents the more superior portion of the cone-shaped foramen. In addition, the nerve exits from a path inferior to the foramen, so the nerve approaches below the height of the external measurement. Thus the nerve is apical and lateral to the area of the implant osteotomy, when it is directly over the foramen and at the height of the mental foramen.

After the measurement is made for available bone height, the implant osteotomy locations may be established every 7 mm (for 4-mm-diameter implants), starting 3.5 to 4 mm distal from the last abutment tooth (Figure 31-38). An abutment location point is made on the midcrestal bone of the ridge with a round No. 6 or pilot bur (Figure 31-39). A measuring tool may be used to measure the interimplant distance on one side and the tooth-to-implant position on the other side. If the pilot holes for the implant osteotomies are positioned too close to each other, it may be separated by an

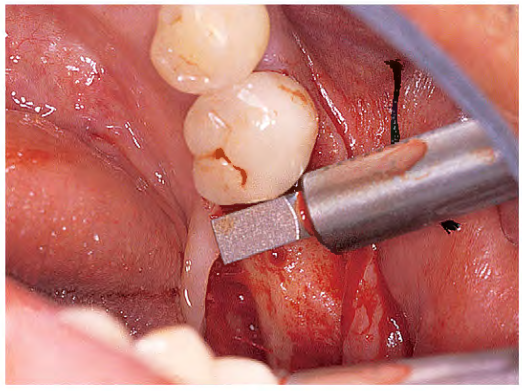

Figure 31-38 A measuring tool is placed on the distal of the tooth, so that the center of the implant site is 3.5 to 4 mm distal to the tooth. In this way, the 4-mm diameter implant will be 1.5 to 2 mm distal to the tooth.

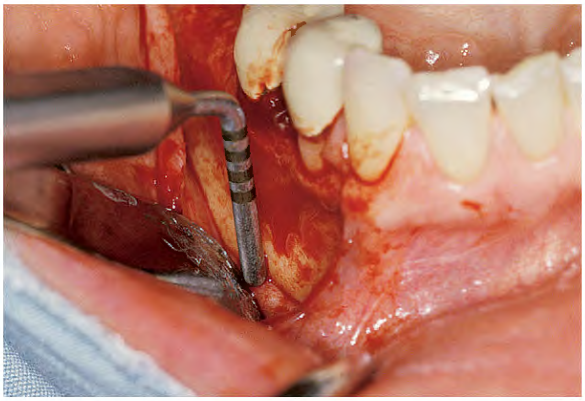

Figure 31-37 A probe is positioned over the mental foramen and measures the vertical distance to the crest of the edentulous ridge. This measurement is compared with the preoperative x-ray and determines the zone of safety for posterior implant length.

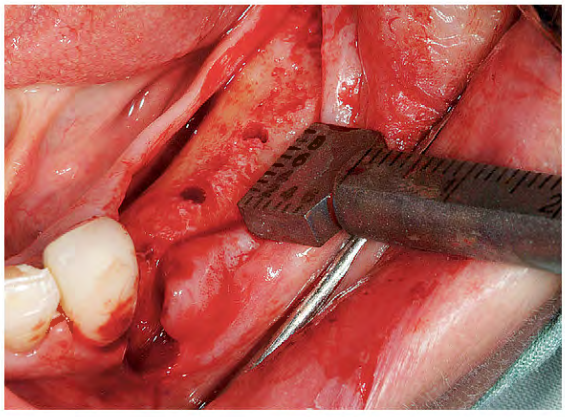

Figure 31-39 The implant sites are at least 7 mm apart in the posterior mandible so that the implants will have 3 mm of bone between them.

WWW.HIGHDENT.IR

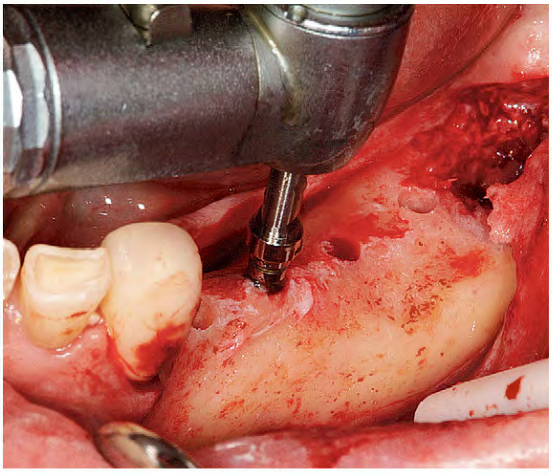

Figure 31-40 A 2-mm end-cutting drill used with copious amounts of saline prepares the osteotomies to 9 mm (when more than this height is available).

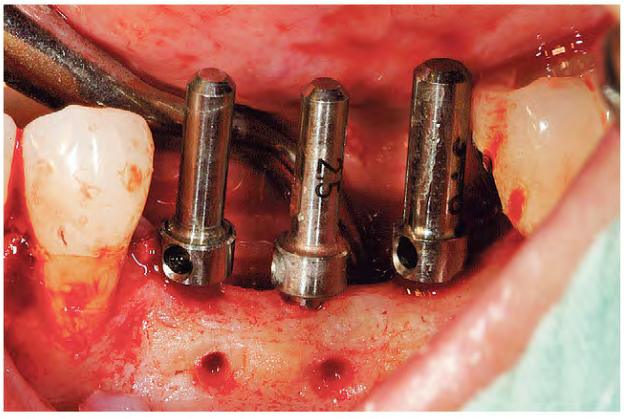

Figure 31-41 The force direction indicator is positioned into the osteotomy and evaluates implant position.

additional 1 mm by "stretching" the hole away from the problematic implant or tooth with a side-cutting Lindemann drill. This same technique is used if the osteotomy is too facial or lingual.

A 2-mm end-cutting drill with copious amounts of saline then prepares the initial osteotomy at 9 mm deep (when more than this height is available) (Figure 31-40). After the implant osteotomy is 2 mm in diameter, a force direction indicator (parallel pin) is inserted (Figure 31-41). The patient gently closes into occlusion, and the direction of force is noted. The indicator should be positioned between the central fossa and palatal cusp of the maxillary teeth. This permits the occlusal loads to be ideally directed onto the implant body.

The surgical template is fitted over the remaining teeth and compared with the pilot hole positions. A periapical radiograph may be made at this time to verify the position away from the adjacent roots and confirm the available bone height (Figure 31-42). If the preselected implant length needs to be modified from

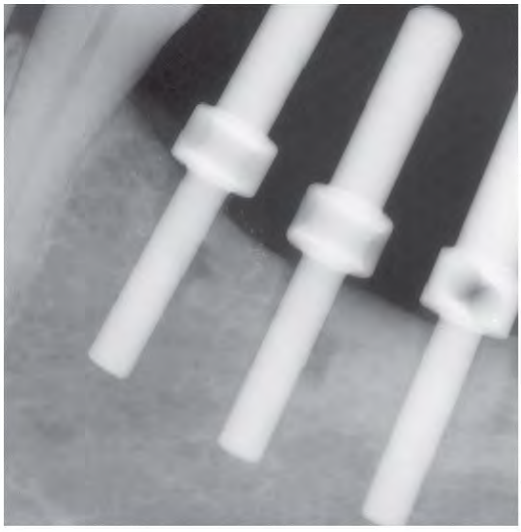

Figure 31-42 A periapical radiograph is taken with the direction indicator in place to confirm the implant position in relation to the adjacent roots and mandibular canal.

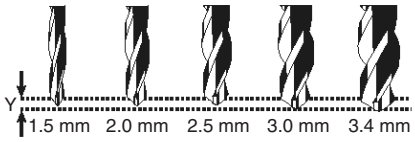
that planned on the basis of discrepancy between the initial radiographic estimations and present clinical measurements, a different-length implant is selected at this time. The available bone and implant should be at least 9 to 10 mm in height from the crest of the ridge to the inferior portion of the implant body. Larger-diameter implants (or two regular size implants) are used in the molar regions when possible to account for the greater force magnitude in the posterior regions of the mouth.

The depth of the millimeter gauge lines inscribed on the shank of the drills most often do not include the cutting edge of the drill and are not to the actual depth of the drill. Most drills have a sharp V-shaped apical portion to improve their cutting efficiency. The V-shaped apical portion of the drill (called a *Y dimension* in engineering) is often not included in the depth measurements of the commercial drills and may measure as much as 1.5 mm on larger drill diameters. As a result, implant companies often provide a caution statement included in the implant company surgical manual (drills prepare sites deeper than the depth gauge lines indicate) (Figure 31-43).[79-81] In addition, some companies include the healing cap height along with the implant depth gauge lines. Some systems make the drill depth gauge 1 mm longer than the implant (a 13-mm implant has a corresponding line at 14 mm on the drill). Other systems make the actual implant 1 mm shorter than the corresponding drill gauge (a 13-mm implant is really 12 mm, and the drill line is 13 mm). Some manufacturers make the depth line of the drill the same as the implant length. This variance in corresponding depths becomes critical when preparing bone sites over the mandibular canal or when exact measurements are required. Therefore it is necessary to evaluate the manufacture's drills and compare them

WWW.HIGHDENT.IR



Drill diameter	Y dimension
1.5 mm	0.43 mm
2.0 mm	0.58 mm
2.5 mm	0.74 mm
3.0 mm	0.86 mm
3.2 mm	0.94 mm
3.4 mm	0.99 mm
3.7 mm	1.07 mm
4.0 mm	1.17 mm
4.2 mm	1.22 mm
4.4 mm	1.27 mm
4.7 mm	1.35 mm

Figure 31-43 The Y dimension or cutting edge of a drill is often not included on the depth lines of a drill. Therefore the 9-mm depth line on a 4.7-mm-wide drill may actually represent 10.35 mm of cutting depth.

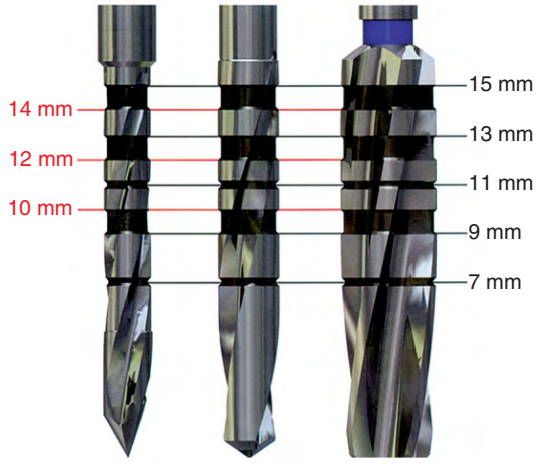


Figure 31-44 The depth lines on these drills include the Y dimension. The larger-diameter drills have no V-shaped end and therefore no Y dimension (BioHorizons Dental Implants, Birmingham, Ala.).

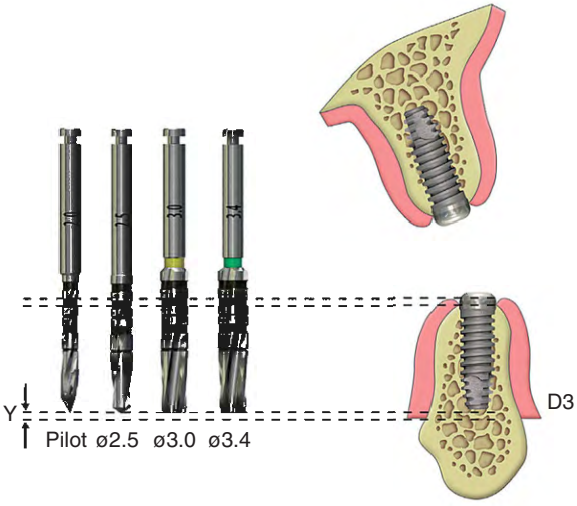

Figure 31-45 The drill sequence protocol is related to the bone density. The 2.0-mm pilot drill is most often followed by the 2.5- and 3.0-mm intermediate drills. The 3.4-mm final drill may be followed by implant insertion in D3 bone.

with the length of the implant before preparing a posterior osteotomy above the mandibular canal.

The apex drill design was modified by Strong et al.[82] to eliminate the Y dimension of a drill (Figure 31-44). The flat end in the larger-diameter drills also acts as a stop, because it does not proceed deeper than the osteotomy depth of the pilot drill. This drill design is of most benefit in the posterior mandible, when the implant approaches the mandibular nerve location.

Osteotomy preparation proceeds following the surgical protocol adapted to the bone density (Figure 31-45). A 2.5-mm end-cutting drill is followed by a 3-mm drill and the final drill dimension for the system employed. A countersink drill and a bone tap are only used for D1 bone. In the posterior mandible, D2 bone most often uses a countersink drill for a larger crest module, but does not use a bone tap. D3 bone does not use a crest module drill or a bone tap. A posterior mandible that has been edentulous for several years may present a fine trabecular pattern under a thin crestal cortical plate. The less dense trabecular bone does not require the entire osteotomy depth to be prepared before implant placement. When the available bone height is marginal and the trabecular bone is less dense, the drill may be stopped 2 mm shorter than the full osteotomy depth. In this way, the risk of nerve injury is significantly reduced. A countersink drill is not indicated under these conditions. The implant is inserted to the complete depth by compression of the trabecular bone around the apical 2 mm of the implant. The crest module of the implant compresses the thin cortical plate and increases initial fixation. When the trabecular bone is fine, countersinking the implant may place it below the crestal cortical bone, causing decreased stability during healing. The posterior mandible may exhibit greater flexure and torsion compared with the anterior mandible as a result of parafunction, and the crestal bone may be required to stabilize the implant during healing. On occasion, the lingual cortical plate at the end of the osteotomy may prevent complete seating of the implant, as a result of the submandibular fossa in the region. In these cases, the depth of the osteotomy must be completely prepared, as in the anterior mandible.

The surgical sites are thoroughly rinsed to remove any debris or contaminants before inserting the implant. Otherwise, the implant may compress the contents of the site beyond the apex and place pressure against the mandibular nerve. This may cause a transitional paresthesia. The bone tap (in D1 bone) and implant insertion is performed at a reduced speed of less than 30 rpm with a high-torque, slow-speed hand piece (Figure 31-46). Implant insertion most often occurs without irrigation. The crest module is often placed

WWW.HIGHDENT.IR

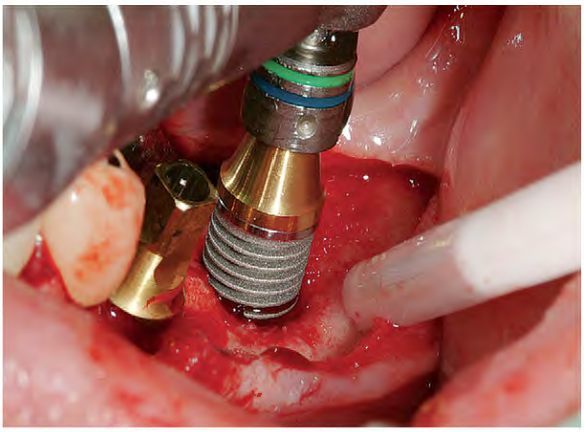

Figure 31-46 A low-speed hand piece threads the implant into position, usually without irrigation.

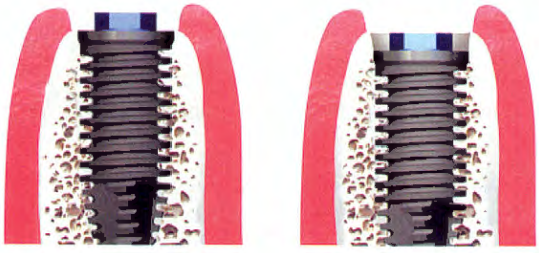

Figure 31-47 **A,** For external hex designs, the implant platform may be placed even with the crest of bone as suggested for D2 bone and when the implant is less at risk of movement during healing. **B,** In D4 bone, the implant is more at risk of movement during healing. As a result, it is countersunk below the crest of bone, so the implant cover screw is level with the crestal bone. The location of the implant platform determines the depth of implant osteotomy.

level with the crest of the ridge in soft bone and slightly above the crest in good-quality bone (Figure 31-47).

The first-stage cover screw is inserted for a two-stage surgical approach, or a permucosal healing extension (PME) is inserted for a one-stage surgical approach. A one-stage approach is used when the patient does not wear a soft tissue–borne partial denture. This approach eliminates the second-stage surgery and allows the tissue to be mature at the time of prosthetic fabrication (Figures 31-48 and 31-49).

The tissues are approximated and sutured with 3-0 or 4-0 polyglycolic acid PGA or Vicryl suture. The accessory anterior incisions are approximated first to ensure proper tissue placement after reflection. Most often, the suture is positioned within the mid-papilla in the distal of the canine from the facial. The suture then picks up the lingual aspect of the papilla and proceeds to the medial of the canine. After it is looped around the canine, it is tied to the suture end and the distal papilla is pulled medial up against the distal of the canine. An interrupted suture is placed below in the vertical release incision to allow primary closure of the soft tissue in the correct position. A continuous nonlocking suture or interrupted sutures may be placed

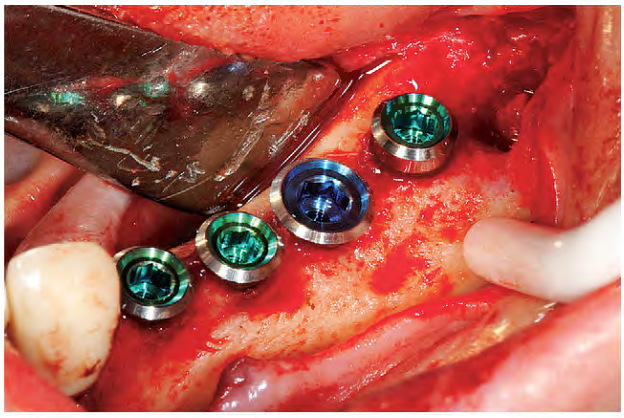

Figure 31-48 A one-stage implant surgical approach is often used in good-quality bone and when the patient does not wear a soft tissue–borne transitional prosthesis.

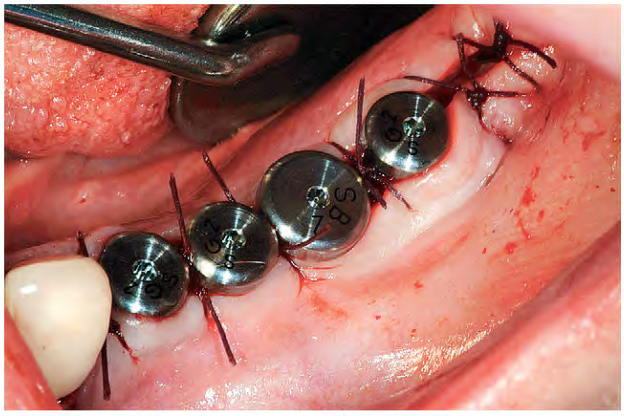

Figure 31-49 The cover screw or permucosal extensions are exposed in the one-stage surgical approach. The tissues are approximated with a resorbable suture (PGA or Vicryl).

along the crest of the ridge. Pressure is then applied to the soft tissue over the surgical site for 4 minutes to arrest any bleeding and help adapt the periosteum to the bone.

IMMEDIATE POSTOPERATIVE PROCEDURES AND INSTRUCTIONS

After surgery for the anterior mandible, the patient's mouth is rinsed with saline, and moist gauge sponges are rolled and inserted over the surgical site. Several other 4 × 4-inch gauze sponges are rolled together and placed intraorally between the arches. The patient bites on the gauze packs for approximately 1 hour. A panoramic radiograph is taken at the conclusion of surgery while the transitional prosthesis is modified (Figure 31-50). The radiograph is closely evaluated to ensure proper implant placement in relationship to the opposing landmarks or surrounding structures. If inadequate placement is observed or infringement on the mandibular canal is evident, the implant

WWW.HIGHDENT.IR

Figure 31-50 A panoramic radiograph is taken at the conclusion of the surgery to confirm the implant position away from the mandibular nerve and adjacent teeth.

placement should be corrected at this surgical visit. On rare occasions it has been necessary to remove the sutures and reposition an implant after analysis of the panoramic radiograph. The threaded implant may be unthreaded one to two revolutions to lift an implant away from a neurovascular canal when necessary. Decompression of the nerve complex decreases the risk of paresthesia. It is far better to perform this correction surgery while the patient is still anesthetized and the soft tissue is not healed than to wait for a future appointment.

In the posterior partially edentulous patient, the posterior region most often is out of the esthetic zone and does not require a transitional prosthesis during hard and soft tissue healing. The usual course of events after the surgical procedure is uneventful. If the patient needs to wear a removable partial denture with a metal framework, it is recommended to make holes through the metal mesh in the saddle area corresponding to implant placement before relining with a soft tissue conditioner. Removing only the acrylic under the metal framework on the saddle area does not provide adequate relief for the surgical site, because the acrylic is usually 0.8 mm thick.

Occasionally edema develops in the floor of the mouth, accompanied by minor hematoma formation. However, the edema may extend extraorally and include the chin, especially if the inferior cortical plates were perforated. An occasional short-term paresthesia of the lip is possible because of the edema. Analgesics and corticosteroids are recommended the first few days following the surgery, and the protocol outlined in Chapter 21 is implemented.

The patient is provided with written postoperative instructions highlighting areas such as rest, application of ice and pressure with gauze packs, and steps to follow in case of bleeding, suture line opening, and pain. Prescription of chlorhexidine gluconate rinses and the use of salt water rinses are also recommended. Usual postoperative instructions similar to those after oral surgery procedures are implemented. The patient returns in 10 to 14 days for suture removal and observation, even though resorbable sutures are used. Polyglycolic resorbable sutures require 6 to 8 weeks to resorb, and on rare occasion small fistulae form in this time frame. Any fistula, regardless of cause, affects the pH in the area and can cause bone loss; therefore the sutures are removed at the postoperative visit.

Tissue conditioners are selected for the immediate postoperative period because they are able to change dimension during the first 24 to 36 hours under pressure. As a result, excess force from swelling or occlusion on the tissue in any region will cause modification of the material. However, tissue conditioners become more rigid faster than the soft tissue liners. In addition, silicone-based products harbor more bacteria and promote yeast formation; therefore the tissue conditioner is removed at the suture removal appointment. The internal surface of the denture is then relieved, and a soft tissue liner is placed, which is also relieved over the implants in the surgical region. The patient is scheduled for an additional soft tissue checkup in 3 weeks to confirm full maturation of the soft tissue.

COMPLICATIONS

Nerve Injury

One of the most troublesome complications—short and long term—of bone harvesting (i.e., ramus block graft), third molar extractions, and implant surgery in the posterior mandible is nerve injury (Figure 31-51). The two most common nerves of concern are the inferior alveolar nerve (IAN) and the lingual nerve. The trauma from surgery or administration of local anesthetic to branches of the fifth cranial nerve may lead to loss or altered sensation (paresthesia) or, worse, to painful symptoms (dysesthesia). A thorough presentation of this topic is beyond the scope of this text; however, the clinician should know how to evaluate and refer when appropriate when associated symptoms

Figure 31-51 Implant surgery in the posterior mandible is a primary cause of mandibular nerve injury.

WWW.HIGHDENT.IR

present, or when a patient complains of the subjective or objective difference in feeling after an implant surgery.

It is beneficial to examine the patient as soon as practical as to the extent of the symptoms and to determine the classification of nerve injury (Table 31-4) (Figure 31-52). The goal of the examination is to ascertain (1) the character of the sensory disturbance, (2) the subjective degree and changes to the sensory loss, (3) the objective consequences, and (4) the start and duration. There are two steps to this process: the patient interview and sensory testing.

Character of Altered Sensation

The character of the sensory disturbance may be described in many ways. When the patient is first examined, the subjective chief complaints are identified in the patient's own words. Numerous unpleasant sensations may be described by the patient, including: (1) numbness, (2) a crawling feeling, (3) sharp and constant or periodic pain, (4) itching, (5) tingling, (6) hypersensitivity, (7) burning, (8) throbbing, (9) pins and needles, (10) prickling, and (11) warm or cold. In implant dentistry, these sensations more often affect the mandibular lip, chin, and lower anterior gingiva. Less often, the tongue may also have altered sensations. Patients with tongue symptoms may also experience loss of taste. As a consequence of these symptoms, lip or tongue biting and difficulty in shaving or applying lipstick, drinking, kissing, and even speaking have been reported. Patients affected with any of these sensory disorders of the face may complain of depression and difficulty in personal relationships.

The goal of the interview is to ascertain (1) the character of the sensory disturbance, (2) the start and duration, (3) the subjective degree and change to the sensory loss, and (4) the objective consequences (Box 31-4).

Degree and Changes of Altered Sensation Forms

The degree of subjective sensory loss and changes at subsequent appointments is noted at the patient interviews and examinations. The sensations may worsen over the following months (i.e., paresthesia evolving into dysesthesia), but most often the symptoms begin to resolve over the next few months. It is unusual for the character of the altered feeling to change during this time frame. For example, before the myelin sheath (which acts as a coating on an electrical wire) grows over the new axons, a hyperesthetic state may be present.

The second part of the patient examination at each appointment includes sensory tests. There are several

Table 31-4 Neurosensory Examination and Treatment

POSTSURGERY PERIOD	DOCUMENTATION	PHARMACOLOGIC INTERVENTION	TREATMENT	REFERRAL
48 hours	Radiographic examination Neurosensory examination	Corticosteroids	Implant evaluation: removal or reposition if impingement within the mandibular canal	None, unless unfamiliar with neurosensory testing
1 week	Neurosensory examination (testing should be continued every 2 weeks)	High-dose nonsteroidal anti-inflammatory drugs (600-800 mg TID) for 3 weeks	Palliative	Refer to microneurosurgeon if: known nerve transaction, dysesthesia, or complete anesthesia
8 weeks	Neurosensory examination	As needed	Palliative	If no sign of improvement, refer to microneurosurgeon

- Blunt cotton swab test (tingle or painful or none)
- Pulp testing teeth
- Temperatures test (cold, warmth) optional

simple tests that may be conducted within the office (Box 31-5).

1. A sharp needle test with the end of a 27-gauge needle indents the skin and mucosal surfaces (but should not penetrate) while the patient describes the sensation with their eyes closed (i.e., tingling, painful).
2. The shortest distance the patient can determine between two indentation points with the needle should also be identified. A normal distance between two indention points varies from 5 to 15 mm from one person to another. The same two procedures are performed on the unaffected side of the mouth/face.
3. An eyeliner pencil is used to map out the area of altered feeling and a photograph or a drawing is made of the region.
4. After the sharp needle test, the blunt end of a cotton swab may be used over the affected and unaffected regions while the patient describes the sensation.
5. Pulp testing of the teeth is an effective method to test sensory function of the inferior alveolar nerve.
6. When temperature complaints have been rendered by the patient, another sensory test may be the application of cold (e.g., ice) or warmth to the area and have the patient describe the sensation.

Painful stimuli are often the first function of the nerve to return after altered nerve sensation. However, when painful stimuli are an initial finding and continue for more than 1 month, the painful stimuli should be reevaluated after block anesthesia. Failure to relieve pain after a mandibular block indicates a central-sympathetic or psychologic problem rather than a peripheral cause.

Duration of Altered Sensation

The start of the sensory disturbance may be immediately after surgery (and the local anesthetic failed to "wear off"), or it may have begun several days after the surgical procedure. The former case most likely is from the surgery or local anesthetic injection, whereas the latter is usually related to postoperative swelling. On rare occasions, a fractured jaw may occur even weeks after a ramus block harvest or implant surgery, especially if the inferior border of the mandible was perforated. This is more likely in a patient with parafunction, and the flexure or torsion of the mandible may fracture the jaw through the unhealed implant site or block bone harvest, because the mandible is initially weakest at these sites. The presence and duration of the altered nerve sensations are noted at each patient evaluation, during the first month and every 4 weeks after the initial evaluation during the next few months. After 3 months, a decision should be made as to referral of the patient.

5. Most common

Classification of Nerve Injury

The goal of the patient examination is to determine the classification of nerve injury and therefore the chance of recovery. There are several nerve injury classifications, and each has particular advantages, especially for practitioners treating this disorder. The Seddon classification is user friendly for the occasional problem encountered by most dentists and will be presented in this text.[83]

Three types of nerve injury are described in the Seddon classification: neurapraxia, axonotmesis, and neurotmesis. Neurapraxia (Box 31-6) is a mild injury caused by compression injury to the nerve or retraction of the nerve. Examples of compression injuries include: pressure from a retractor over the mental foramen, hydraulic pressure from saline or blood from the implant site while the implant was threaded into position, postoperative bleeding within the bone or around the mental foramen, an implant inserted into the mandibular canal, a piece of bone that invaded the canal during the site preparation or implant insertion, or even a tie-back suture on the facial or lingual flap. Retraction injury of a nerve is usually from reflection of

WWW.HIGHDENT.IR

the soft tissue flap and the use of a retractor to maintain visibility or protect the flap from trauma during the use of rotary drills.

In neurapraxia, there is no axonal degeneration distal to the point of nerve injury, but there is a temporary conduction block while nerve recovery occurs. Spontaneous recovery of the altered sensations most often occurs within 1 to 4 weeks from this injury type. Fortunately this is the most common type of nerve injury observed, when there is no obvious violation of the nerve trunk.

When the patient is seen within 2 days of surgery with symptoms of nerve injury, an oral dose of corticosteroid (i.e., Decadron 8 mg) decreases inflammation and swelling in the region. If, during surgery, the nerve trunk is compressed or retracted beyond usual protocol, the intravenous form of corticosteroid (i.e., 1 to 2 mL of Decadron 4 mg/mL may be applied (not injected) to the injured area for 1 to 2 minutes. This direct application will decrease the risk of the formation of Nissl body disintegration, which causes the paresthesia.[84]

Axonotmesis describes a nerve injury with a loss of axonal continuity; however, the general structure of the nerve remains intact (the endoneurium is preserved) (Box 31-7). These injuries are more significant and may result in dysesthesia or less than normal nerve recovery. A stretch nerve injury from reflection of a soft tissue flap may result in this type of disorder. A nerve has a 20% elongation for the elastic limit to remain normal and 30% elongation causes structural failure. When the nerve complex is small in diameter as it exits the mental foramen, this injury is more prevalent. A slower stretching of the nerve as the flap is retracted is better tolerated by the axons of the nerve trunk. An implant drill may proceed through the top of the neurovascular canal and also cause this condition. When a postoperative radiograph reveals an implant may have slightly violated the canal space, it is prudent to unthread the implant and introduce Decadron 4 mg/mL into the osteotomy. Corticosteroids have been used with success in neurosurgery after trauma to a nerve. The decrease in inflammation increases the rate of recovery. No infection risks have been demonstrated with this protocol. After a 2- to 3-minute wait, it is prudent to place a shorter implant into the site. In addition, a corticosteroid (Decadron) is given orally for 3 to 5 days. The usual dosage is 8 to 12 mg in the morning of the first day, 4 to 6 mg the morning of the second day, and 2 to 3 mg the morning of the third day. Initial signs or symptoms of nerve recovery in this type of injury do not occur until 1 to 3 months after the injury. This injury type has symptoms and signs of nerve injury immediately after the surgery and is rarely due to swelling of the soft tissue, unless excessive.

It is possible that an anesthetic needle which penetrates the nerve trunk may cause this type of injury, although more often, neuropraxis results. Injury to the lingual nerve during inspection is more frequent than is the alveolar nerve. Women seem to be more frequently affected than men, in a 2:1 ratio. When the lingual nerve is affected, 80% of patients have an altered gustatory perception and the vast majority did not show improvement 9 to 19 months after the injury. Because the lingual nerve is smaller in diameter than the IAN, the penetration with a needle may cause more damage. In 1995, Haas et al. reported the risk of paresthesia after local anesthesia administration was 1:783,000 cases. The risk was slightly higher for drugs in greater concentration (i.e., septocaine 4% versus lidocaine 2%). An injection of anesthetic fluid into the nerve trunk may cause axonotmesis.[85,86]

Neurotmesis describes nerve injury a complete severance of the nerve trunk. When this occurs, all axons distal to the injury undergo Wallerian degeneration; anesthesia of the soft tissue that is innervated by the affected nerve is a consequence of this condition. When a discontinuity or gap is present between the nerve ends, scar tissue forms between the structures and axonal sprouts from the proximal aspect of the nerve are prevented from penetrating the endoneurial tubules (Box 31-8). Therefore no recovery of nerve sensations is expected without neurosurgical procedures. Neurotmesis is suspected when anesthesia is present or hypesthesia has lasted more than 3 months. A triggering sign that gives an electrical sensation from the injured site with palpation is suspect. A 200% increase in sensation to sharp stimuli 3 months after injury may also be a sign of neurotmesis. Fortunately most nerve injuries are not of this category, and recovery within 3 to 4 months is expected in most patients.

Box 31-7 Axonotmesis

1. Nerve injury with loss of axon continuity, but general structure intact
2. Wallerian degeneration
3. "Stretch" nerve injury from reflection
   Implant drill to top of canal
   Implant violating the canal
   Anesthetic needle
4. Management: remove offending element
   Corticosteroids
   Recovery:1 to 3 months

Box 31-8 Neurotmesis

1. Complete severance of nerve trunk
2. Wallerian degeneration
3. Complete anesthesia for more than 3 months; may have triggering signs or increase in sensation to sharp stimuli

WWW.HIGHDENT.IR

The lingual nerve may be severed during the reflection or incision to soft tissue lingual to the retromolar pad.[87] The usual location of this structure is 2 ± 1 mm medial to the lingual plate and 3 ± 0.4 mm below the crest of the lingual plate. However, according to Behnia et al., in 14% of mandibles the lingual nerve was in the soft tissue above the lingual crest of the mandible, and in 0.15% the nerve was actually residing in the retromolar pad. Therefore all incisions in the posterior mandible should be lateral to the retromolar pad. A careful reflection of the periosteum and gentle retraction of the lingual tissue, when necessary, is warranted to maintain the integrity of the lingual nerve within the lingual flap of tissue.

Lingual nerve damage is reported more often than IAN damage in third molar extraction reports when the tooth is removed through the lingual plate. However, in the usual surgical approach, the incidence of IAN injury is 2% to 7%, whereas lingual nerve involvement is less than 1% of impacted third molar extractions. In implant dentistry, the more common complication of altered nerve sensation is related to the inferior alveolar nerve.

According to Girard et al., the inferior alveolar nerve may have the potential for recovery after an injury for as long as 2 years.[88] On the other hand, Sunderland estimates 75% to 90% of the distal nerve atrophies and is irreparable after 1 year of altered feeling.[89]

Rather than waiting and decreasing the chance microsurgery may correct or improve the condition,[90] referral to a neurosurgical repair team is suggested when (1) transection or complete compression of the nerve is observed at surgery or on a CT scan, (2) painful dysesthesia exists, (3) anesthesia or unacceptable hypoesthesia from a patient's perspective has lasted for 3 months, and (4) triggering or radiating pain over the suspected site of injury is present.

It should be noted that a panoramic or periapical radiograph may not be diagnostic for an implant impingement on the mandibular canal. The implant may be buccal or lingual to the nerve location. A CT scan is warranted before diagnosis of nerve encroachment.

Life-Threatening Hemorrhage

The surgical insertion of dental implants has been shown to be a relatively safe procedure. However, since 1984 there have been at least 11 case reports of life-threatening hemorrhagic episodes as a consequence of placing implants in the mandible.[59,91-102] Although it may be considered rare and most dentists will never observe such a significant complication, it is prudent to be aware the risk exists and knowledgeable about treatment.

The cause of life-threatening hemorrhage is from significant internal bleeding in the floor of the mouth, usually caused by a perforation of the lingual cortical plate and a related swelling of the floor of the mouth and tongue, which causes respiratory obstruction (Figure 31-53). The significant hemorrhage usually begins during the surgery related to insult to the blood vessels, but may even occur 1 to 6 hours after the initial bleeding has been arrested. The hematomas that form in the lingual, sublingual, submandibular, and submental spaces displace or enlarge the tongue and the floor of the mouth, which may completely obstruct the airway. This complication has been reported secondary to several surgical procedures, including tooth extraction, local lingual anesthesia, use of sharp rotary instrument, periodontal procedures, and vestibuloplasties.

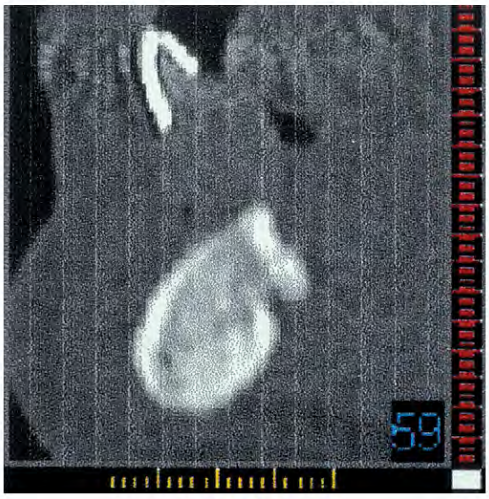

Figure 31-53 Lingual hemorrhage may be the result of implant osteotomy preparation and perforation of the lingual cortex in the anterior mandible. Careful evaluation of the symphyseal anatomy may avoid this serious complication.

There are primarily two major arteries that supply the floor of the mouth and are related to life-threatening hemorrhage: the lingual artery and the facial artery. It is important to determine the original source of the bleeding to establish a method to control the situation.

The lingual artery is usually the second anterior branch (third overall) of the external carotid artery, which crosses over the hyoid bone and is the major vessel to the tongue. This is important to know, because when the bleeding is suspected from this source, pulling out the tongue compresses the lingual artery against the hyoid bone and decreases the flow of blood to this vessel.

The lingual artery also has a significant branch, 2 mm in diameter, called the *sublingual artery*. It supplies blood to the lingual gingiva and the lingual aspect of the anterior cortical plate of the mandible, as well as other structures. Smaller branches of this vessel enter the lingual cortical plate through the lingual foramina. Typically, the largest foramina is found in the midline of the lingual cortical plate, just below the geniotubercles, with a mean distance of 6 mm from the inferior border of the mandible; however, accessory foramina in the premolar regions are also often observed.

WWW.HIGHDENT.IR

The facial artery is usually the third anterior branch (fourth overall) of the external carotid artery. This artery loops under the bottom of the mandible (in the region of the second molar), then laterally near the anterior border of the masseter muscle (antegonial notch) to supply portions of the face. The submental artery (also 2 mm in diameter) branches from the facial artery just before it crosses over the inferior border and courses along the interior and inferior aspect of the mandible. If this artery is suspected in the hemorrhage event, pressure against the interior and lingual aspect of the mandibular notch, just in front of the masseter muscle attachment, will significantly reduce the blood flow to this vessel. Bavitz et al. observed the sublingual artery was absent or small and unimportant in 53% of mandibles.[37] However, it has also been reported to be a significant or principal source of blood supply to the floor of the mouth in 29% to 59% of cases.[37,93,94]

The sublingual fossa on the lingual aspect of the mandible extends above the mylohyoid muscle attachment from the lateral incisor to the first premolar region, and is highly variable in depth from one patient to another.

In addition, the anterior mandible is often angled to the lingual, after the initial labial resorption of the bone or, even more often, after resorption of the residual ridge in a C–h mandible. An attempt to place implants in the long axis of the missing teeth often results in a lingual perforation of the mandible, especially in the canine region. In a review of the literature by Kalpidis and Setayesh, the most common site for life-threatening hemorrhage was during implant osteotomy or insertion in the canine position after the perforation of the lingual plate. Other causes included a tear in the lingual periosteum during elevation or handling of the flap.[102]

The signs or symptoms of life-threatening hemorrhage of the floor of the mouth include: (1) swelling and elevation of the floor of the mouth; (2) an increase in tongue size, which may even protrude from the mouth; (3) difficulty in swallowing or speech; and (4) pulsating or profuse bleeding from the osteotomy site or floor of the mouth.

The suggested methods to treat life-threatening hemorrhage, when suspected, may include:

1. Bimanual compression, with one finger intraorally over the site and one finger extraorally, compressing the two fingers together.
2. Pull out the tongue and observe whether a decrease in bleeding occurs (lingual artery blood flow reduced). Place deep pressure along the inner and inferior aspect of the body of the mandible at the antegonial notch region and observe whether the bleeding is reduced (facial artery blood flow reduced).
3. Elevate the head. This may decrease blood flow to the region by almost 30%.
4. Place an oropharyngeal airway behind the tongue before it enlarges and makes the insertion of this device almost impossible.
5. Place hemostatic agents in the osteotomy on or in the lingual periosteal tissues.
6. Push with firm pressure against the transverse process of the fourth cervical vertebra in the neck, on the side of the bleeding. (This reduces the blood flow to the external carotid artery.)
7. Transport the patient to the hospital if these attempts to halt the signs and symptoms of life-threatening hemorrhage are not received or if these problems develop after several hours. Do not hesitate to transport the patient to the hospital. NOTE: If complete airway obstruction prevents a patient from breathing, an emergency cricothyroidotomy may be a last resort until intubation may be performed.

Procedures in the hospital to treat this condition have included: (1) ligation of the afflicted vessels, (2) endotracheal intubation (oral or nasal), or (3) emergency tracheotomy. The duration of hospitalization in the cases reported in the literature has ranged from 1 to 11 days.

Although less reported in the literature, there are cases in which the site of life-threatening hemorrhage is the preparation of an implant site in the second molar region. The perforation of the lingual plate occurs because of the significant undercut under the mylohyoid muscle. In addition to the sublingual fossa, a submandibular fossa, which is of more significance, is found below the mylohyoid muscle attachment in the first molar to the third molar region. This facial artery and its lateral loop are found in this depression. The residual bone may be wide enough for an implant, but the angulation of the implant for proper prosthetic abutment support places the implant directly over the submandibular fossa and facial artery. When the dentist drills into the bone, the dense lingual plate is encountered. A firm pressure on the drill may result in penetration of the lingual plate, and because a firm pressure is required for the osteotomy, after it penetrates, the drill proceeds quickly several millimeters beyond the lingual cortex. When an artery is partially cut, rather than constricting and forming a platelet plug, the bleeding may continue and fill the submandibular space. A bulging area may be observed below the mandible extraorally because it is below the mylohyoid muscle. Pressure on the antegonial notch is not effective in this situation, because the artery laceration is before the bony landmark.

Pressure against the transverse process of the fourth vertebra and elevation of the head to reduce blood flow are primary methods to reduce blood flow from the site. Firm external pressure to the posterior floor and intraoral pressure with a finger over the site is also of benefit. If the borders of the surrounding region continue

WWW.HIGHDENT.IR

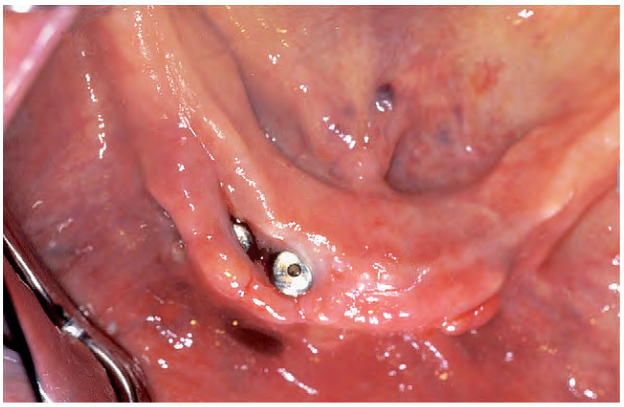

Figure 31-54 Implant premature exposure should not be resutured again to approximate the tissues. Instead, the implant should be completely uncovered and the permucosal extension inserted.

to expand, a nasotracheal or orotracheal airway and transportation to the hospital are appropriate.

Prevention is the key to handling life-threatening hemorrhage. The awareness of bone undercuts may be appreciated by a CT scan and reformatted images or by palpation of the lingual plate of the mandible at the time of surgery. A *stop* on the dental drill at the desired depth, so it does not penetrate several millimeters after the lingual plate is perforated, is also of benefit A shorter implant that reduces the need to engage the opposing cortical plate is often appropriate.

Incision Line Opening

The most common postoperative complication is incision line opening. If a minor opening in the incision line is observed, the cause of the incision opening should be determined. If the design of the removable interim prosthesis is involved, it is corrected. The patient is instructed to rinse three to three times daily with chlorhexidine and gently debride the incision line with a moist sponge or soft toothbrush. Within a few days to weeks, the soft tissue will granulate into the opening without compromise to the implants. Resuturing the area should not be attempted because it would further increase the problem.

If the granulation process to close the incision line extends more than 2 weeks, it may be encouraged by trimming the epithelial margins of the wound with a high-speed hand piece and coarse diamonds. This will cause minor bleeding and allow the granulation process to continue. This minor debridement is generally performed with only topical anesthetic.

Implant Exposure

If the implants become exposed during the healing period of a two-stage surgery, no attempt should be made to cover them with tissue. Implant exposure alone does not alter the success of rigid fixation. The soft tissue over the top of the implant has little to do with the bone forming on the surface of the implant (Figure 31-54). However, if the cause of the exposure was pressure necrosis of the soft tissue over the implant from the prosthesis, this is a problem that may cause micromovement of the implant. Therefore, whenever an implant becomes exposed through the tissue, external forces over the implant should be eliminated. The denture is relieved aggressively over the area with implant exposure.

Barboza et al.[103] and Tal et al.[104] have observed that partial exposure of a dental implant is more detrimental than complete exposure. Pinpoint to three-quarter exposures of the implant are more often associated with exudate or chronic inflammatory tissue around the crestal region and marginal bone loss. The incidence of anaerobic bacteria also increases. As a consequence, it is highly recommended the partial exposure of the implant not be ignored or treated lightly.

The protocol of partial exposure, unassociated with exudate, includes the following: (1) complete exposure of the implant cover screw, removal of the healing cover, flushing the implant with chlorhexidine and insertion of a permucosal extension (PME); (2) oral hygiene with a soft toothbrush morning and evening; and (3) chlorhexidine application over the area twice each day.

An implant with a partial exposure or exudate requires more aggressive therapy. The implant should be completely uncovered. The cover screw should be removed and the implant irrigated with chlorhexidine. In addition, the amount of marginal bone loss should be ascertained. Reflection of the tissue and exposure of the implant is in order. The granulation tissue should be curetted from the surrounding bone. The implant surface area may be mechanically cleaned with a diamond bur or air abrasion with baking soda and the implant surface may be treated with tetracycline or citric acid. A bone graft and a membrane may also be necessary when the bone loss is several millimeters. When a bone graft is placed, the tissue should completely cover the membrane.

In regions of limited bone loss, a PME may be inserted and the tissue approximated around the extension. When a membrane is used, usually primary closure is in order to increase the success rate. Antibiotics for 5 days and daily rinses of chlorhexidine are also indicated. The same regimen is implemented for nonsubmerged or a one-stage healing protocol.

Implant Failure

Mobility of the implant during healing is unusual but may occur. This complication is rarely accompanied by pain or infection, but it is often accompanied by a radiolucent zone around the implant. Whatever the cause (bone necrosis, implant movement, or infection), the implant should be removed, followed

8 to 10 weeks later by a graft with autogenous or bone substitutes, and allowed to regenerate bone before the next implant placement. On rare occasion, an early implant failure may be replaced with a larger-diameter implant. This is contraindicated in the presence of infection.

SUMMARY

Root form implants placed in an anterior mandible are the most common indication of the completely edentulous patient. It is an excellent region to begin a learning curve in implant surgery because the landmarks are clear, access is good, and bone density often permits more flexibility in technique. The step-by-step approach described in this chapter allows excellent results for implant-supported prostheses. The placement of root form implants in the posterior mandible is also a common procedure in the partially edentulous patient and is described with a clinical technique to assess the zone of safety after the placement of implants safely above the mandibular canal. Figure 31-55 illustrates the surgical tray and basic armamentarium.

Chapter 32

Stage II Surgery: Uncovery and Treatment of Healing Complications

Carl E. Misch

The loss of implants from initial surgery to prosthetic loading has gradually decreased over the last decade and is often less than 5%.[1,2] These failures may be explained to the patient as caused by local conditions or intraoral healing responses, and they are usually well accepted by the patient. Failures from stage II uncovery until prosthesis connection have also been identified and range from 2.5% to 5.9%.[1-6] These early loading or "late failures" are more of a problem because the restoring dentist has begun the restoration, accompanied by laboratory and chair time costs. The patient often blames the restoring dentist for this complication, relating it to some clinical event such as the final impression or removal of the transitional prosthesis.

NOMENCLATURE FOR IMPLANT FAILURES

With the development of many different implant systems and the advent of such techniques as single-stage surgery, immediate loading, and direct implant placement of the prosthesis, implant failure terminology can be confusing. A review of the literature shows inconsistency in its classification of implant failures relative to time. In particular, the terms *late failure* or *later failure* have not been precisely defined in regard to the timing of the failure. *Late failure* may be used to describe early loading failures after stage II uncovery or complications after several years to decades after implant loading.

Misch and Jividen have published a classification for implant failure, based on the unusual events of an implant history.[7] The suggested terminology of failures relative to time includes *surgical failure*, which may be used to describe the inability to place the implant at the time of surgery (e.g., from fracture of bone, failure to obtain initial rigid fixation)(Table 32-1).

Osseous healing failure may describe the period from implant placement to abutment connection of the implant and is related to the healing ability of bone. *Early loading failure* describes the period from the abutment placement to the first year the implant serves as a prosthetic abutment. When immediate loading is performed, the osseous healing period and early loading time frame are similar. Early implant failure is more likely caused by inadequate surface area of the implant for the magnitude of the load or quality of bone that is not sufficient to support the load. *Intermediate implant failure* is the period after the first year of loading and includes up to the subsequent 5 years of function. *Late implant failure* is used to describe the condition after the implant and prosthesis have been loaded for longer than 5 years and shorter than 10 years. *Long-term failure* may be used to describe failures after 10 years. Peri-implant disease and fatigue fracture are more common causes of long-term failures. This nomenclature is therefore proposed to facilitate future research efforts and interpretation.

The initial surgery and healing process ideally result in a rigidly fixated implant, absence of crestal bone loss around the implant, adequate zones of nonmobile keratinized tissue (>2 mm), soft tissue thickness less than 4 mm, and an absence of tenderness or discomfort under vertical or lateral forces (Box 32-1). A second-stage implant (uncovery) surgery permits the direct evaluation of these criteria and the corrections necessary to lay

Table 32-1 Implant Failure Terminology

TYPE OF FAILURE	TIMING
Surgical	At surgery
Osseous healing failure	Between stages I and II
Early loading	Abutment placement to first year
Intermediate	First-year loading to 5 years
Late	5 to 10 years
Long term	>10 years

the groundwork for long-term success. An opportunity exists at the stage II surgery to correct poor implant placement, inadequate crestal bone healing, soft tissue defects, or poor soft tissue relationships. The final restoration should not be placed in long-term jeopardy at the expense of compromised initial healing conditions.

A second-stage surgery most often is used by the profession for an implant that is completely covered by soft tissue during the initial healing period. However, even when the implant was inserted with a one-stage surgical approach or became exposed during the healing process, a second-stage surgery may be of benefit to evaluate the surrounding bone and soft tissue conditions.

The goal of a two-stage surgical approach, as presented by Brånemark in 1977, is to have the implant covered with soft tissue for 3 to 6 months while the bone remodels around the implant.[8] The primary reasons cited were to reduce the risk of infection and prevent the apical migration of tissue around the implant. In addition, the implant was countersunk below the bone to reduce the risk of loading or movement during initial healing. If the implant became prematurely exposed during the first 6 weeks, the soft tissue would be surgically repositioned to recover the implant once again.

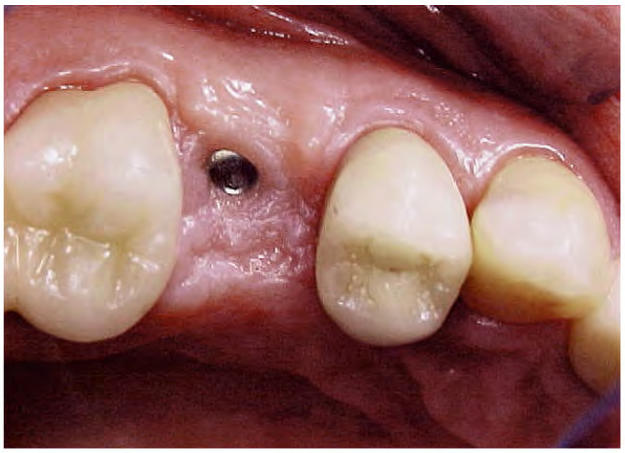

Figure 32-2 The epithelium over the implants of a spontaneous exposure, on occasion may be associated with chronic inflammatory cells.

SPONTANEOUS EARLY EXPOSURE

The implant covered with soft tissue may spontaneously become partially or completely exposed prior to stage II uncovery (Figure 32-1). The spontaneous early exposure of submerged implants has been found, on occasion, to be accompanied by early exudate, inflammation, and crestal bone loss. In a 15-year report by Adell et al., 4.6% of 2768 implants presented early perforations.[9] These implants had an external hex and were countersunk, level with the bone.

When Rosenquist and Grenthe[10] placed implants into extraction sockets, 11% of the implants had early exposures. Tal et al.[11-14] observed early exposure in 16.1% of external hex implants and 11% with internal hex implants. Therefore it appears the risks of early exposure occurs approximately 5% to 15% of the time and is dependent on the profile of the implant at surgery and the hard and soft tissue conditions.

When the implant has an early exposure, the epithelium may become hyperplastic, with cells exhibiting hyperparakeratosis and acanthosis (Figures 32-2, 32-3). The connective tissue may also be infiltrated by chronic inflammatory cells, mainly lymphocytes and plasma cells.[13] Toljanic reported 3.9 times more bone loss in premature exposures, with a mean bone loss of 2.71 mm (standard deviation [SD] ±1.78 mm) for prematurely exposed implants versus 0.43 mm (SD ±1.08 mm) for nonexposed implants. It may be argued that the exposure of the implant triggers the "biological width" phenomenon, which would occur regardless after stage II uncovery. In 1996, Ericsson et al. found in a dog study the amount of marginal bone loss initially was similar, but after 6 months of exposure, both the one-stage and two-stage implant bone levels were similar (Figures 32-4, 32-5).[16]

WWW.HIGHDENT.IR

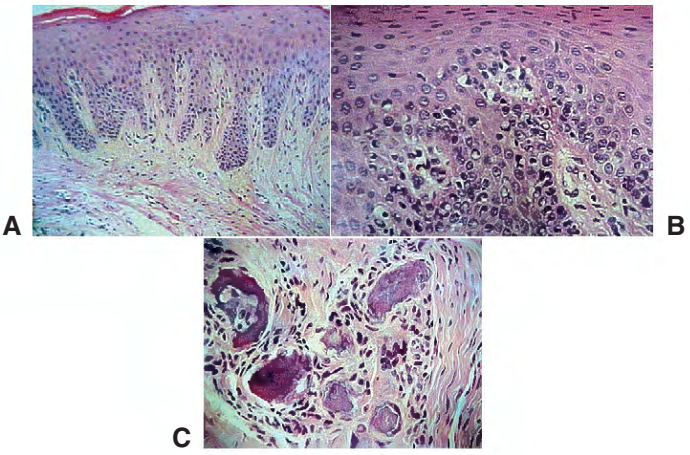

Figure 32-3 Histologic evaluation of the patient in Figure 32-2 **(A)** revealed connective tissue with infiltrated chronic inflammatory cells **(B,C).**

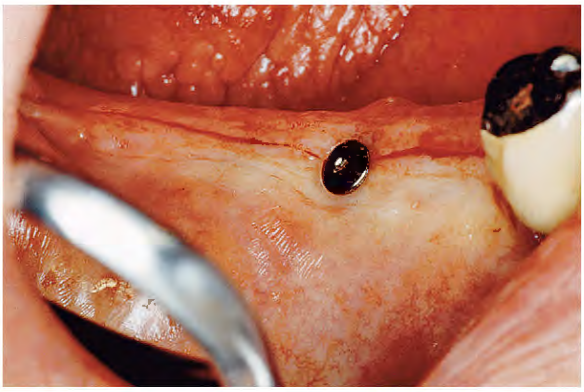

Figure 32-4 Spontaneous exposure during healing may occur to only one implant of multiple sites.

Tal et al. evaluated 115 early exposures of submerged endosteal implants.[14] Of this group, 11% had significant bone loss, with 2 implants >4 mm; 2 implants, 3 to 4 mm; and 10 implants, 2 mm of bone loss. Although most often premature exposure was not a complication, on occasion the condition may lead to significant bone loss. Barboza et al. compared crestal bone loss for one-stage surgery versus a two-stage surgery in 10 patients with 56 implants.[17] She found more crestal bone loss around exposed implants and also found a higher incidence of *Prevotella intermedia*, *Streptococcus* beta hemolysin, and *Fusobacterium* sp. The exposure of the implant cover screw seems to create a potential focus for bacterial plaque which may contribute to crestal bone loss (Figures 32-6, 32-7). Therefore it is indicated to monitor patients from stage I surgery to stage II surgery every 4 to 8 weeks to access and treat appropriately premature exposure of implants.

It has been observed by several authors that the risk of exudate or inflammation is increased when the implant is only partially exposed (Figure 32-8).[11-16] The

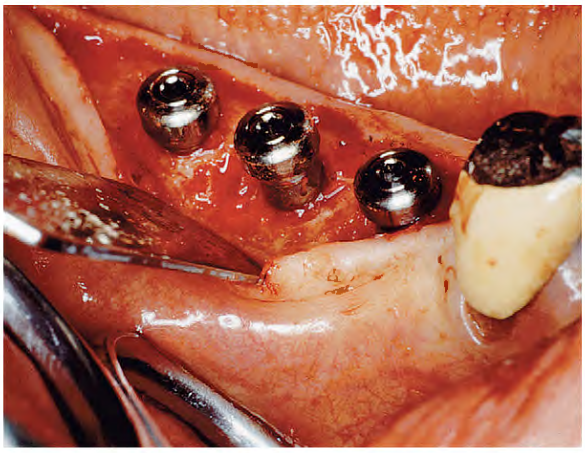

Figure 32-5 At the uncovery, the implant with premature exposure has more crestal bone loss than the implants completely covered during initial healing. This initial difference may be related to the "biological width" after the implant becomes exposed. Most often the overall crestal bone is similar during the next 6 months.

Figure 32-6 In approximately 10% of implants with spontaneous premature exposure, the implant has exudate or significant bone loss.

Figure 32-7 The periapical radiograph of the previous implant at implant placement **(A)** and 3 months later after spontaneous premature exposure **(B).** Note the 4 mm of marginal bone loss. *(Courtesy E. Barboza, São Paulo, Brazil.)*

contaminated crevice of the cover screw is more likely to be in a septic environment under these conditions. Therefore whenever the implant cover screw is partially exposed, the first action is to completely expose the implant (Figure 32-9). The cover screw is then removed

WWW.HIGHDENT.IR

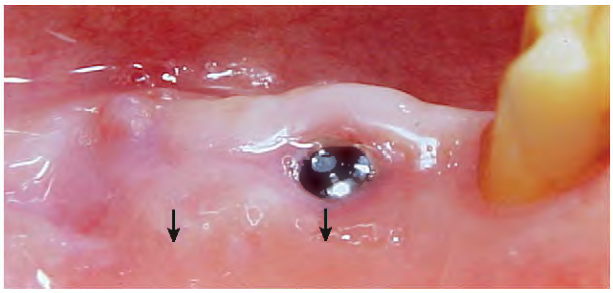

Figure 32-8 The two implants have become partially exposed during the initial healing process. The smaller the exposure (implant on left has pain point exposure), the greater the risk of marginal bone loss. *(Courtesy E. Barboza, São Paulo, Brazil.)*

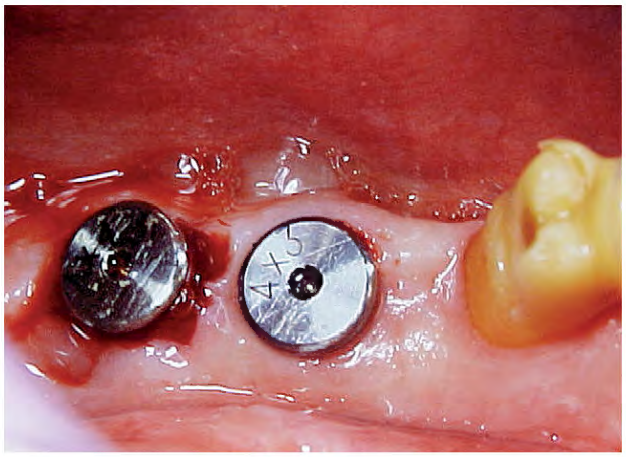

Figure 32-9 The implants in the previous picture have been completely exposed and flushed with chlorhexidine 0.12%, and the permucosal extension has been inserted. *(Courtesy E. Barboza, São Paulo, Brazil.)*

and the implant body irrigated with chlorhexidine 0.12%. A permucosal extension (PME) is then inserted into the implant. After the implant is completely exposed in the oral environment, a daily oral hygiene regimen is in order. This consists of twice-daily plaque removal with a soft toothbrush and the direct application of chlorhexidine 0.12%. If the patient is wearing an overlaying removable prosthesis, it should be modified so that no direct force is applied to the implant until after the bone interface is ready for occlusal loading.

There are most likely three reasons to explain the greater crestal bone loss around a prematurely exposed implant. The first is related to the microgap. Bone is able to grow over the cover screw crevice when covered by soft tissue. However, after the cover screw (or PME) is exposed in the oral environment, the oral epithelium most often repositions itself 0.5 to 1.0 mm below the crevice of the cover screw, usually within a few weeks. A second cause of marginal bone loss is related to the crest module design. When smooth metal is placed below the bone and the implant is exposed to the oral environment, the marginal bone loss extends apically until it reaches a rough surface or a groove (or thread) on the implant body. This process also occurs within the first month. As a consequence, submerged healing implants have less bone loss than implants, which becomes prematurely exposed.

It should be mentioned that after the implant is uncovered and used for prosthetic support, the phenomena described occur and bone loss becomes evident. Although submerged implants exhibit less marginal bone loss after initial healing, the overall marginal bone loss of two-stage and one-stage implants may be similar by the time the prosthesis is delivered to the patient.[17]

In addition to marginal bone loss from the microgap and the biological width, additional bone loss may occur from bacterial plaque. Rams and Link noted the bacterial environment becomes at greater risk of an anaerobic component when the probing depth is greater than 5 mm.[18] The anaerobic condition may be established around a prematurely exposed implant in two ways: A partial exposure of the implant has a greater risk of an anaerobic environment, and the cover screw is not tightened to 10 to 30 N-cm and may be loose, making the implant internal structure more likely anaerobic. Either of these conditions increases the risk of exudate or inflammation with greater marginal bone loss. It should be noted this cause of marginal bone loss could be corrected by uncovering the implant completely and flushing the region with chlorhexidine 0.12%. However, the bone loss that occurred before this event would not be corrected at this point.

Another factor to contribute greater marginal bone loss is that the implant may have become prematurely loaded through the soft tissue, causing tissue dehiscence. The premature load may cause the cover screw to loosen (increasing the anaerobic environment) and overload the developing crestal bone-implant interface.

UNCOVERY PROCEDURE

When more than three implants are uncovered, the patient is prepared for surgery in a manner similar to the original stage I procedure. In general, discomfort, swelling, and risk of infection occur to a lesser degree than at the original surgery. However, if corrective procedures are indicated during surgery, they should not be compromised by poor patient preparation. This chapter primarily addresses uncovery of multiple implants out of the primary esthetic zones. Maxillary anterior implants in patients with high lip lines are treated similar to anterior single tooth replacements, which are discussed in Chapter 33.

Soft Tissue Incision

The initial incision for stage II surgery is as important as in the first stage. When a one-stage surgical approach is used, attention to the soft tissue is similar to the following procedure. The incision is designed to place

WWW.HIGHDENT.IR

Figure 32-10 At stage II uncovery, the crestal incision bisects the keratinized tissue, ensuring that the facial tissue has more than 1.5 mm of attached tissue.

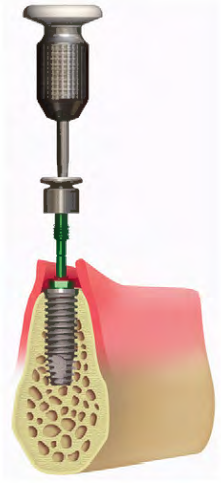

Figure 32-11 The soft tissue reflection is extensive enough to reposition the keratinized tissue around the permucosal extension of the implants or to correct any bone defect around the implants.

keratinized tissue on each side of the permucosal abutment. Therefore the full-thickness incision bisects the attached tissue on the crest of the ridge (Figure 32-10). The attached tissue and incision are usually more lingual than the actual implant site. As a result, a tissue punch is rarely used, because it usually eliminates the facial attached tissue around the implant site. The incision continues at least 5 to 10 mm distal to the last implant placed. A full-thickness envelope flap design permits reflection of the periosteum for direct implant-bone interface observation. A tissue punch may be used to uncover the implant when there is 1.5 mm or more of attached keratinized tissue facial to the implant site. This occurs more often in the posterior maxilla or when an implant was immediately inserted after the tooth was extracted.

The periosteal elevators should not be levered against the endosteal implant body or first-stage cover screw during this procedure. Instead, the lingual or palatal bone is used for leverage, and the facial tissues are

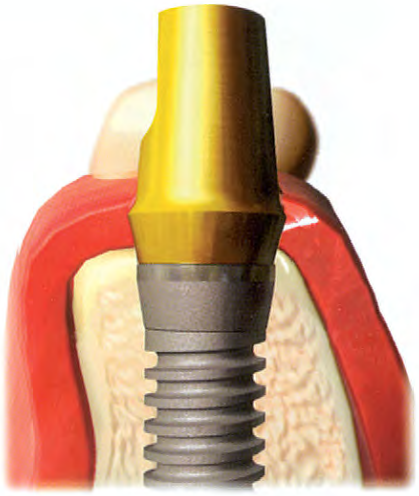

Figure 32-12 The abutment or permucosal extension may be larger in diameter than the crest module of the implant. As such, when bone is over or adjacent to the cover screw, the marginal bone must be recontoured to allow complete seating of the abutment.

gently pulled off the healed implant sites. Adequate reflection of the soft tissue completely exposes the crestal bone around the implant site and allows repositioning of the attached tissue at the conclusion of the procedure (Figure 32-11). If the healing cover screw became exposed during the healing phase, the primary crestal incision is made along the lingual aspect of the healing cover, and a sulcular incision is placed around the rest of the implant. A mucoperiosteal flap is then reflected in a fashion similar to that previously described. A lack of attached tissue is common on the facial aspect of the implant when it becomes exposed during initial healing and may require a tissue graft or acellular tissue graft on the facial to restore attached or immobile tissue.

Bone-to-Implant Interface Evaluation

After the soft tissues are reflected, the first-stage cover screws are identified and the surrounding area is closely evaluated. Many implant abutments are wider than the first-stage cover screw and may require as much as 1 mm of horizontal space around the implant platform on the crest module (Figure 32-12). Any bone growth on the cover screws or over the surrounding region is removed with surgical curettes or low-speed rotary uncovery burs designed to remove excess bone, accompanied by cooled sterile saline irrigation (Figure 32-13).

Bony Defects

On occasion, a vertical or horizontal defect may be revealed around the uncovered implant. The causes for this defect are often similar to those of premature implant exposure and include crestal bone trauma during surgery, excess torque from implant insertion (especially with wider crest modules), bone flexure

WWW.HIGHDENT.IR

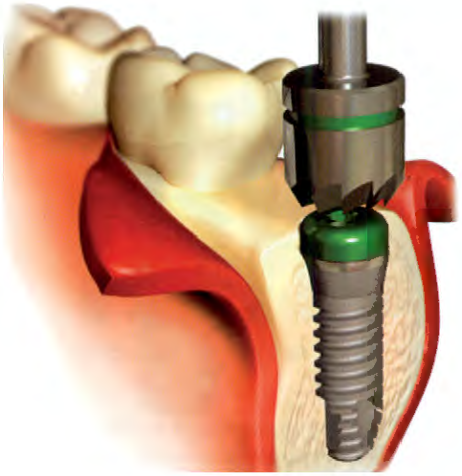

Figure 32-13 A bone profile drill in a low-speed hand piece, with copious irrigation, may remove the bone over or adjacent to the crest module and permit the abutment to be seated completely on the implants.

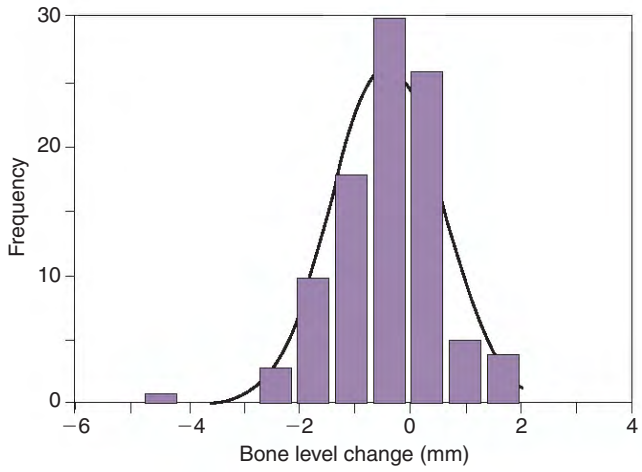

Figure 32-14 The range of bone loss in the Kline et al. study at stage II uncovery was from −5 mm to +2 mm. The average bone loss was 0.2 mm. (*Kline R, Hoar JE, Beck GH et al: A prospective multicenter clinical investigation of a bone quality-based dental implant system*, Implant Dent 11:332-334, 2002.)

or torsion in the posterior mandible, local patient habits that load the implants during healing, incision line opening, postoperative infection, implant surface contamination, idiopathic bone loss, or healing factors related to systemic disease. In a study by Kline et al., the average crestal bone loss was 0.2 mm at stage II uncovery, but the range was −5 mm to +2 mm (Figure 32-14) (Box 32-2).[2]

Vertical Defects

If a vertical defect filled with soft tissue is identified anywhere around the implant, a curette is used to eliminate it (Figure 32-15). When soft tissue is removed from around a tooth, the root is scraped because the tissue attaches to the cementum. The fibrous tissue in a vertical defect around an implant is not attached to the

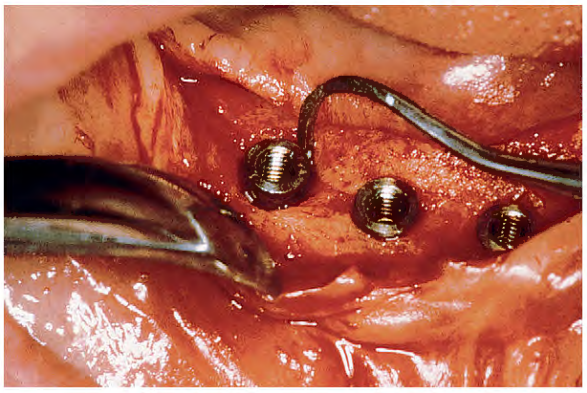

Figure 32-15 A soft tissue in a vertical defect is removed by using a curette that scrapes the surrounding bone, not the implants.

Box 32-2 Causes for Bone Loss at Stage II Uncovery

- Premature implant exposure
- Crestal bone trauma at surgery
- Excess torque at implant insertion
- Bone flexure/torsion in posterior mandible

implant. Therefore the bone is scraped, not the implant. This loosely bound and unorganized tissue is relatively easy to remove at this time. The implant surface should not be scratched or contaminated during this procedure. The extent of bone loss is assessed and should be less than 3 mm if the implant is to be uncovered at this appointment (Table 32-2).

If the vertical defect around the implant is of moderate depth (greater than 3 mm) for more than 25% of the circumference, a barrier membrane is placed over the grafted defect and the soft tissue is reapproximated. This prevents soft tissue ingrowth into the defect and provides an improved environment for the bone graft healing time against the implant surface. In this scenario, the second-stage uncovery is delayed for approximately 2 to 4 months, depending on the size of the defect.

When bone loss exposes the threads of the implant body, the ability to reform bone in the defect when the implant is uncovered and loaded is reduced. When the implant has not been exposed before the uncovery procedure, the implant body is usually not contaminated by microorganisms because it has been under soft tissue. The full-thickness reflection of the region has exposed areas of vital bone not involved in the implant support. This bone may be harvested and packed into the vertical defect (after the soft tissue in the defect has been thoroughly removed). The defect and surrounding area are overpacked. When the implant defect is larger than 3 mm, the most predictable method to correct the condition is with a particulate autologous bone graft covered by a resorbable membrane (i.e., Alloderm, Biomend), and the soft tissue is reapproximated over

WWW.HIGHDENT.IR

Table 32-2 Resolution of Bone Loss at Uncovery

DEFECT	MANAGEMENT	OPTIONS
Vertical <3 mm	Osteoplasty	Convert into horizontal defect by leveling off bone
Vertical >3 mm	Less than half of implant height	Graft with autogenous bone wedge or membrane if deep defect
	More than half of implant height	Remove implant
Horizontal	Less than half of implant height	Position soft tissue apically; graft autogenous bone
	More than half of implant height	Remove implant

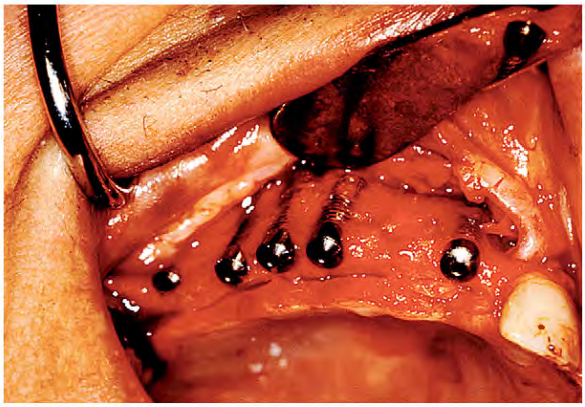

Figure 32-16 The defect at implant uncovery is greater than 3 mm and threads are exposed on the implant body. A particulate autograft covered with a membrane and primary closure is suggested.

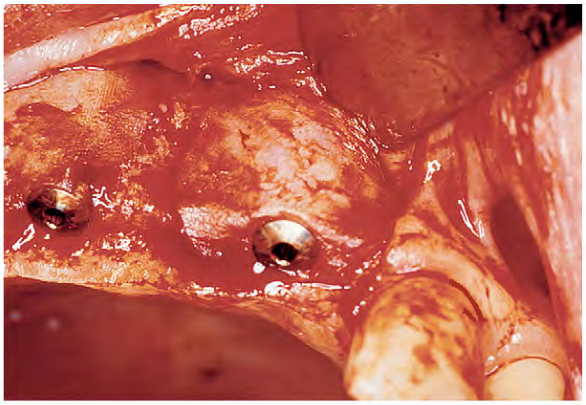

Figure 32-17 At the uncovery 8 to 12 weeks later, bone is now present over the threads of the implants.

the membrane, bone graft, and implant for an additional 8 to 12 weeks of healing (Figures 32-16, 32-17). A vertical defect greater than 3 mm is usually grafted, unless it represents half or more of the total implant height, in which case the implant should be removed (see Table 32-2).

When the vertical bone defect around an implant is less than 3 mm, the implant may be uncovered and used in the current condition for the prosthetic abutment. After the soft tissue is removed from a defect, the surrounding bone is again evaluated. In the case of a vertical bone defect of less than 3 mm, there are three surgical options. An osteoplasty may eliminate

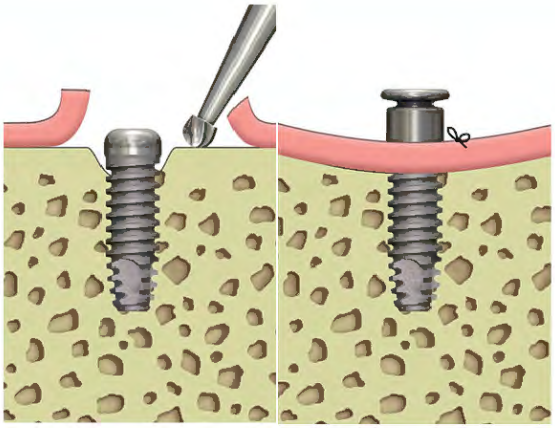

Figure 32-18 When the defect is less than 3 mm **(A)**, the implant may be uncovered. An osteoplasty to eliminate the defect **(B)** is the most predictable method, but modifies it into a horizontal defect. This may be inappropriate in the esthetic zone.

the vertical defect when the reduced bone-implant interface does not compromise the prosthetic support or esthetics. The PME is placed at the same appointment (Figure 32-18). A second method to correct a vertical defect less than 3 mm is to curette the defect and overfill the region with an autograft (Figure 32-19). The PME may be added at the same appointment and the tissue approximated around the site (Figure 32-20). When there is a desire to have thicker soft tissue around the site, a barrier membrane (e.g., Alloderm) may be used over the implant site and covered with soft tissue.

A third alternative to correct a vertical defect on the mesial and distal region is to drive a wedge into the bone several millimeters away from the implant body. Tapping a wedge-shaped osteotome into the distal bone compresses vital bone up against the implant body (Figures 32-21, 32-22). The wedge-shaped defect created in the ridge as a result of the osteotome is several millimeters away from the implant and surrounded by bone; therefore this defect will heal without consequence. A facial or lingual vertical defect may be corrected by taking a blunt instrument with a mallet and compressing the facial or lingual bone against the implant body. This technique also places living bone adjacent to the implant body (Figure 32-23). The PME is placed at this appointment.

WWW.HIGHDENT.IR

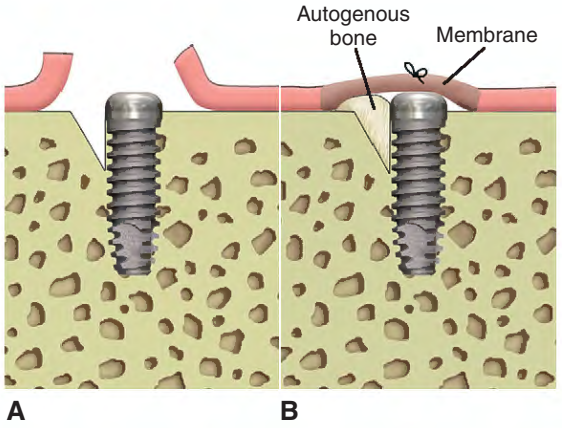

Figure 32-19 A second method to correct a vertical defect less than 3 mm **(A)** is to curette the defect and fill the region with an autograft **(B).** The implant may be exposed with a permucosal extension or covered by a membrane when additional soft tissue thickness is desired.

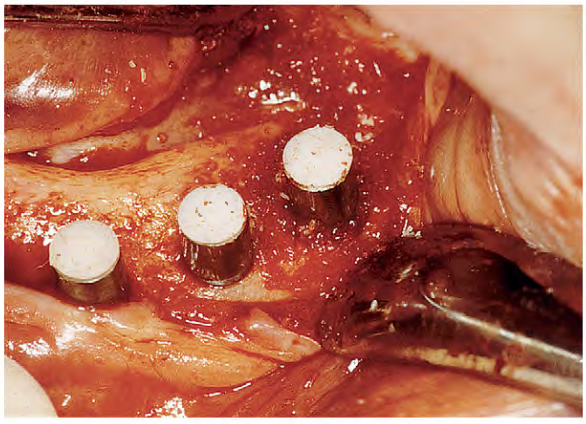

Figure 32-20 The implant on the right has a vertical defect less than 3 mm. The permucosal extension is added to the implant; autograft is collected from the surrounding area and overfills the defect. The implant may then be uncovered.

Horizontal Defects

A horizontal bony defect of bone around the implant body may also be treated in several ways. When horizontal bone loss around an implant is more than half of the implant body, the implant should be surgically removed and the site grafted at the uncovery.

The most predictable method to treat horizontal bone loss that is less than 50% of the implant body is to reduce the soft tissue thickness to decrease the probing depth around the implant. The soft tissue may be apically repositioned, exposing a portion of the implant body into the oral cavity. If threads or a rough surface are present above the bone, an aluminum oxide ("white") stone and rubber wheel are used under copious irrigation to smooth the region and limit plaque accumulation. Cement-retained prosthesis on an implant with horizontal bone loss may be placed on the implant body in esthetic regions.

Another option to address horizontal bone loss is to grow bone above the defect, and this method is

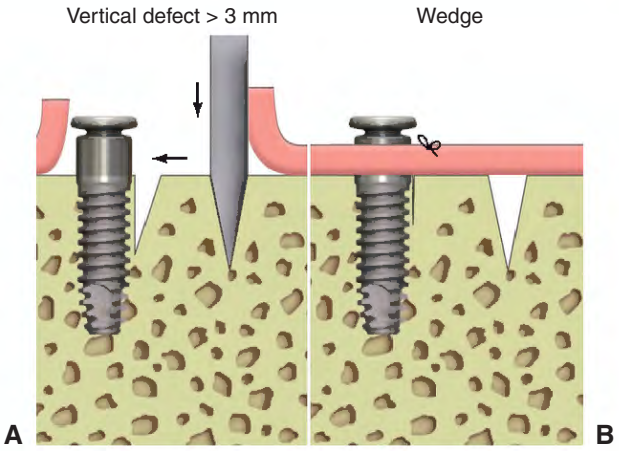

Figure 32-21 **A,** The implant on the left has a vertical defect less than 3 mm deep. **B,** A wedge is driven into the bone in the appropriate side, and vital bone is pushed up against the implant.

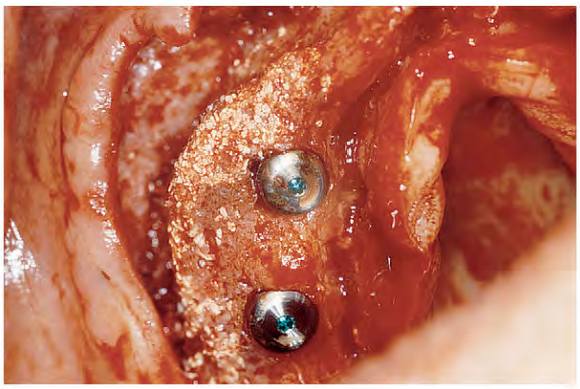

Figure 32-22 An implant in the canine region has a defect on the facial and distal aspects.

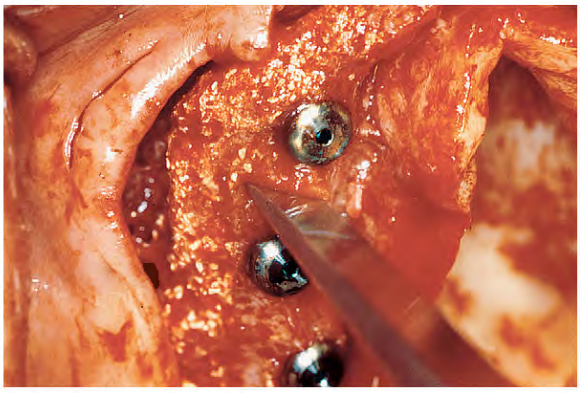
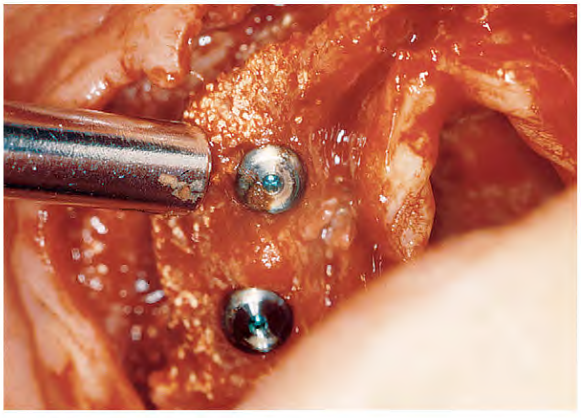
used when the final prosthesis is FP-1 or additional bone-implant interface is required to withstand the forces exerted on the prosthesis. To improve the amount of bone formation, several steps may be taken. The first is to use autogenous bone for the graft. In most cases, bone is harvested and placed on the crest, after the region has been curetted to increase blood supply and increase the regional acceleratory phenomenon. A barrier membrane is also placed over the site to prevent fibrous tissue ingrowth into the region. Anaerobic bacteria are often growing on the implant body when bone loss is present and should be mechanically removed. In addition, before grafting, the first-stage cover screws are removed, and the internal cavity of the implant body is thoroughly flushed with chlorhexidine 0.12% before replacing the screws into the implant body. The tissues are reapproximated over the bone graft and membrane with primary closure. The second-stage uncovery is delayed for approximately 3 to 4 months, depending on the size of the horizontal defect and bone graft.

On occasion, the facial aspect of the implant is exposed for several millimeters. This more often occurs when the implant was placed in the maxilla and the

WWW.HIGHDENT.IR



A



B

Figure 32-23 **A,** A wedge is created on the distal aspect of the implant and tapped into place. The distal wedge bone is pressed against the distal defect of the implant. **B,** A blunt instrument placed on the facial aspect is tapped with a mallet and compresses the facial bone against the implant, which eliminates the defect.

ridge was less than 5 mm in width or bone expansion was performed to insert the implant. Although the implant has rigid fixation, the lack of facial bone places the implant at an increased risk. The implant site may be improved at the uncovery surgery by performing an onlay graft. Most often, the easier method to accomplish the augmentation is the layered, particulate, membrane graft technique described in Chapter 37. The ridge is decorticated on the facial, mesial and distal aspects to the implant. Autologous bone is harvested with a trephine bur from above and lateral to the implant site. The autograph is particulated in 3 × 3-mm pieces and laid over the facial aspect of the implant. A mixture of 30% demineralized, freeze-dried bone cortical fibers (Grafton) and 70% mineralized, freeze-dried bone allograft (MinerOss) is mixed with the platelet-rich plasma from 10 to 20 mL of whole blood. A resorbable membrane (i.e., Biomend) or acellular tissue (AlloDerm) covers the graft.

Because the implant is already integrated, a PME may be placed into the implant body and the tissue approximated around the implant. Before soft tissue closure, the labial flap should be expanded with tissue

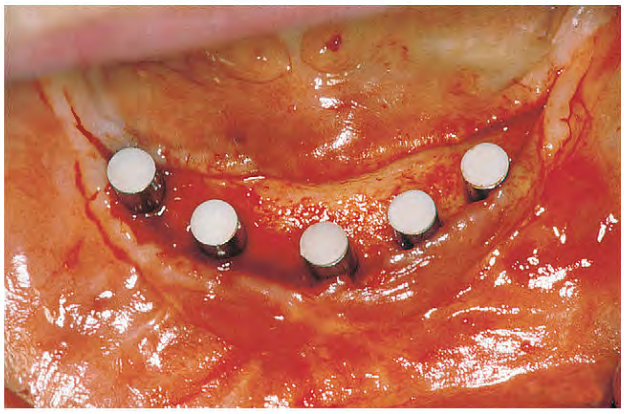


Figure 32-24 If the bone levels are acceptable, a 3- to 5-mm-high permucosal extension is threaded into the implant body.

scissors (i.e., Metzenbaum scissors). The final prosthesis should be delayed for more than 3 months when this procedure was performed at the uncovery appointment to allow maturation of the tissues.

RIGID FIXATION DETERMINATION

If the bone level is acceptable around the crest module of the implant, the first-stage cover screws are removed, the internal chamber of the implant body is thoroughly flushed, and the top of the crest module is closely evaluated to make sure it is free of any bone or soft tissue over the edges. A 3- to 5-mm-high, second-stage PME is then seated with finger pressure into the implant body (Figure 32-24).

The rigid fixation of the implant body is then tested for resistance to the torque required to place the permucosal extension with 10 N-cm torque (less than half the final force for the abutment). This may be accomplished by freehand pressure and a short insertion tool. The clinician must use caution when tightening the PME because the torque force required to remove the permucosal extension at the next appointment is similar to the force needed to tighten it. Reverse torquing is more critical when applied to the implant body in D4 bone at this stage of healing, because it may traumatize the bone-implant interface.

REVERSE TORQUE TESTING

Reports in the literature have suggested reverse torque testing (RTT) at stage II surgery or to assess an implant suitability for immediate loading.[19] Two alleged advantages are its use as a biomechanical measure of initial stability and its use as a definitive verification of initial osteointegration.

RTT has been used as a research tool for many years. Several research studies have been performed to ascertain the nature and strength of the bone-implant interface

WWW.HIGHDENT.IR

using both push-out and RTT techniques.[20-28] These findings have been useful for the development of implant body designs and surface coatings. A strong and stable bone-implant interface has always been intuitively desirable. Interest in resistance of bone-implant interface to torsional forces has been heightened as a result of the increased awareness that specific (and higher than previously believed necessary) torquing preload forces are needed to reduce the incidence of abutment screw loosening. From a clinical standpoint, it is desirable to determine whether the bone-implant interface can withstand the preload torque forces needed to tighten abutment screws.

Several reports[3-5,29] have reported on the phenomenon of early loading or late failures, whose incidence ranges from 2.5% to 5.9%. The term *late failure* in these reports refers to implants that have failed in the time between an apparently successful stage II surgery and before the completion of prosthetic restoration. In the Misch and Jividen classification, this is an *early loading failure.* The rationale for RTT is based on the premise that most, if not all, late failures are the result of an inconspicuous nonintegration, which is a condition whereby an implant passes current assessments for the evaluation of rigid fixation (manual mobility, radiographs) at uncovery, yet it is insufficiently integrated to indefinitely remain in that state. These implants are said to have a subclinical micromovement that is not visible or detectable with existing techniques. RTT was suggested to subject implants to early objective testing before undergoing prosthetic reconstruction.

RTT, used as verification for rigid fixation, involves placing a defined reverse torque (counterclockwise) to the implant (via mount) at stage II uncovery surgery. The level of applied torque ranges from 10 to 20 N-cm. In a study using a primate model, Carr et al.[24] found that 5.4% of the metallic implants could not withstand a reverse torque level of 35 N-cm. Implants failing such testing are presumed to be nonintegrated, likely to become early loading failures, and are therefore not recommended for use as prosthetic abutments.

It has been suggested that RTT is not advisable or necessary in D1 or D2 bone.[19] Concerns of stripping of the external hex in implants made of grade I titanium, because of the higher bone strength and presumed lower incidence of early failures lessen or obviate the need for RTT for these bone types. However, a multicenter clinical trial involving 2131 implants in 707 patients found the highest stage II failure rate was actually for the most dense bone.[30] As a result, it appears that implants in all quality bone would also have high enough incidence of early failures to justify the evaluation of every implant. In addition, if the same N-cm torque is used in all bone densities, the hex components are at similar risk.

The strength of trabecular bone before fracture in the jaws is directly related to its density. The densest bone (D1) is 10 times stronger than the least dense (D4). The RTT is suggested to be most beneficial in less dense bone, yet this density bone is most at risk of failure during the RTT evaluation. In addition, bone is often only 60% mineralized at stage II uncovery after the surgical trauma from stage I surgery. According to computer densitometry reports, bone may be more dense and the bone interface stronger on the day of surgery, compared with the stage II uncovery date.[8,31,32] It takes 52 weeks after initial surgery for bone to be completely mineralized. The mineralization of bone is related to its strength. Therefore using RTT at stage II uncovery evaluates the interface when it is weak and more at risk to fracture from overload. In addition, at 4 months, the bone is often still histologically woven bone, rather than lamellar bone. Woven bone is unorganized and weaker than the load-bearing lamellar bone, which is more desirable at the implant interface.[33] An RTT at uncovery does not permit this improved interface to develop before testing. RTT of implants too early in the healing process (relative to bone density) is more likely to lead to the removal of implants that would otherwise be integrated.

RTT protocol requires a clinician to detect even small micromovements that would indicate failure. Sullivan states that "on initial activation of the electronic torque control unit, the illusion of movement can be ascertained when slack is taken out of the system."[6,19] This movement is subtle enough that the use of magnifying loops is recommended. The amount of implant movement of successful rigid fixated implants is variable[21] and dependent on bone density.[35] An implant in D4 bone may move 60 to 80 µm. In comparison, a lateral incisor tooth in health moves 97 µm, which can be seen with the naked eye. The illusion of movement may be attributed to bone density, not to a lack of rigid fixation or fibrous encapsulation.

Torque-to-failure trials in human dental applications have been limited to only two studies. Tjellstrom[21] measured the removal torque of osseointegrated titanium implants placed in the mastoid bone and found a range from 26 to 60 N-cm. The mastoid bone is cortical externally and coarse trabecular internally. This corresponds to a D2 bone description. Sullivan et al.[19] recorded that removal torque values for three implants in a human volunteer were between 45 and 58 N-cm. However, the implants for Sullivan were surrounded by "extremely dense marble-like bone quality." Therefore the RTT values to failure of these implants cannot be used to simulate the RTT of implants in D3 or D4 bone, which is not surrounded by a marble-like structure.

Bone, as a structure, exhibits significant variations in strength depending on the types of forces acting on it. These forces may take the form of compression, tension, or shear. Research has shown that cortical bone is strongest in compression, 70% as strong in tension, and only 35% as strong in shear.[36,37] An RTT places primary shear forces on root form implants with a round

WWW.HIGHDENT.IR

cross-section design. The only region of compression for RTT would be the bone grown into the apical hole at the bottom of the healed site. Therefore the force type (shear) is the weakest to the RTT method of testing.

The RTT may also be affected by implant design. Implant bodies, such as hollow basket designs or those with flat sides to resist shear forces, may exhibit greater RTT values to failure. An RTT on a threaded implant uses the mechanical advantage of a screw to break the implant-bone adhesion. The screw would also convert the shear force to some tensile force. An RTT attempts to lift the implant from the crypt, using the screw design to assist this aim.

Occlusal loads aim at being primarily compressive in origin. Implant bodies are not designed for pure shear loads; therefore RTT applies forces that do not correspond to clinical loads. Failure of an implant during RTT does not necessarily mean that it could not have functioned as a successful implant under (primarily) compressive loads.

The stated need for RTT is to help reduce the number of early loading failures, with the assumed cause being a subclinical nonintegration at stage II surgery. A more likely cause of these failures is early implant loading beyond the bone strength present around the implant. Progressive bone loading studies have demonstrated the density (and related strength) of bone increases after loading.[38,39] Early implant failures may be reduced to less than 1% when progressive loading is performed on implants of adequate size, design, and number. Reverse torque testing has been represented as a possible means to predict early implant failure that most likely has a fibrous tissue interface. However, these failures are more likely from excessive stress at the bone-implant interface and excessive occlusal loading.

The criteria suggested for a clinical verification standard are that it be objective, be easy to administer, use available armamentaria, be as definitive as possible within the available knowledge base, and possess an adequate level of safety so that damage to the implant-bone interface does not occur. This is not found in RTT evaluation.

In the author's opinion, RTT presents too many subjective variables. Misjudgment can damage the bone-implant interface and prolong treatment and increase costs associated with the extra reparative treatment. The desire for objective standards for clinical verification of osteointegration is understandable. The most common methods of clinical verification used today, radiographs and manual mobility testing, have an admittedly subjective component. However, they do not place the implant at risk and have stood the test of time.

When the root form implant has a fibrous tissue interface, there is little resistance to rotation in either a clockwise or counterclockwise direction. Therefore if fibrous tissue surrounds the implant, and a permucosal extension is threaded into the implant body with a 10 N-cm force, the implant will visibly turn and the insertion and tightening of the healing cap can be used to evaluate the complete lack of integration with the bone. In addition, a 10 N-cm force on the permucosal healing cap places a screw implant under shear tension and compression on the bone. The clockwise turn on a screw will more likely resist these forces, even in very soft bone.

A vertical force places more compressive forces on the implant-bone interface. The mobility test with a lateral force applied to the side of the permucosal extension also places some compressive forces on the implant-bone interface. Therefore the implant is initially evaluated for rigid fixation with the torque test to thread the permucosal healing cap into position and then evaluated similar to a natural tooth mobility test, with a 5-lb axial and lateral load.

The Periotest (or resonance) is a nondestructive, objective, and useful test to determine implant micromovement. A study by van Steenberghe and Quirynen[40] suggests that the prognostic value of the Periotest remains unproven with regard to implants because too few failures have been studied and reported in the literature. However, several studies exist that describe the usefulness and sensitivity of this instrument.[41-45] Furthermore, a large-scale study of 1838 implants by Truhlar et al.[45] and 4-year evaluation by Misch[46] found the Periotest to be capable of assessing the status of the implant-bone interface. It is sensitive to slight differences in the implant dampening effect (mobility) and provides baseline Periotest values that can be helpful in evaluating improvement or degradation of the implant-bone complex.[47-49] However, a disadvantage is that many clinicians do not have access to these instruments.

IMPLANT POSITION

After the implant is uncovered and a PME is seated into the implant body, the prosthetic template is inserted and the implant position evaluated. An implant body in a position that compromises the prosthesis should not be maintained. The inappropriate implant may often be removed by reverse torquing with a hand ratchet. Luxation, as with a tooth, is not indicated because it places compression forces on the implant-bone interface and usually leads to the fracture of either the bone or the implant before its removal. A trephine drill may be required to remove an implant in denser bone qualities. A trephine drill can create a small space all around the implant to its base (Figure 32-25). A forcep then is used to rotate and shear the base of bone at the apex.

The implant is removed if its position places the final prosthesis at risk or if more than one half of the

WWW.HIGHDENT.IR

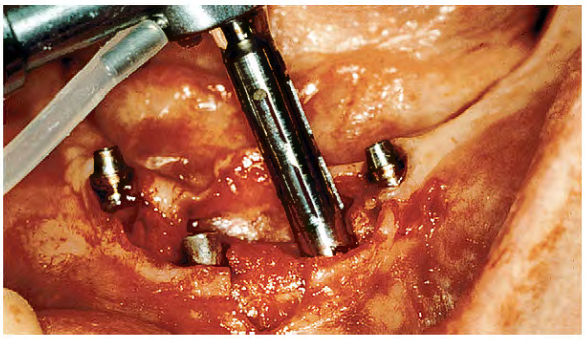

Figure 32-25 When the implant is in too poor a position to be restored or more than 50% of the bone is missing, a trephine bur may be used to remove the implant.

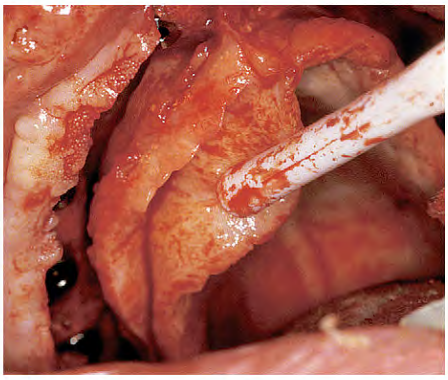

Figure 32-27 An incision is made on the periosteal side of the palatal flap, and the excessive connective tissue is excised to decrease the overall palatal tissue thickness.

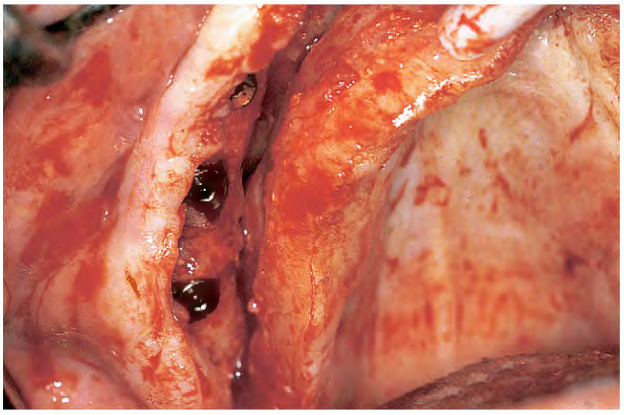

Figure 32-26 When the overlying tissue is greater than 4 mm thick, the soft tissue should be reduced in thickness, thus reducing the sulcus around an implant.

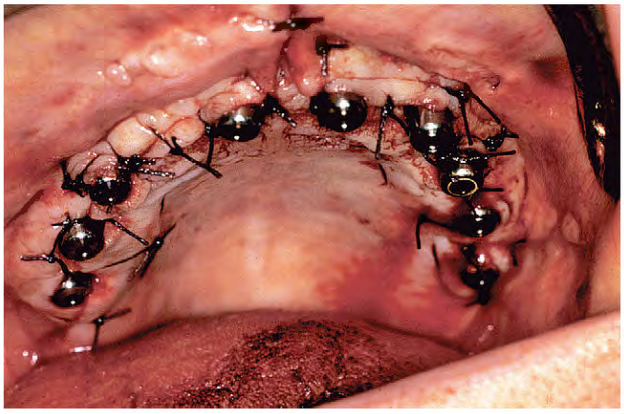

Figure 32-28 The tissue with a reduced thickness may then be approximated around permucosal extensions 3 to 5 mm in height.

implant has lost bone in a vertical dimension. Several options exist if implant removal is indicated: (1) the implant may be removed, and if enough implants remain, the prosthesis may still be fabricated; (2) the prosthesis may be converted from a fixed restoration to a removable RP-4 or RP-5 restoration to decrease forces to the superstructure in amount or duration; (3) an additional implant may be placed in an optional implant location at the same time as the implant removal; (4) the implant may be removed and a larger-diameter implant simultaneously inserted with a different angulation or deeper within the osteotomy; and (5) the implant may be removed, the site augmented, and an additional implant placed months later. The treatment of choice attempts to best satisfy the conditions for the patient and prosthesis without compromise.

TISSUE THICKNESS

The thickness of the overlaying crestal tissue is evaluated once it is reflected. Soft tissue thicker than 4 mm will result in a less than ideal pocket depth around the implant (Figure 32-26).[47,48] The tissue is relieved from the periosteal surface especially in the labial flap, until it is less than 3 mm thick (Figures 32-27 and 32-28). If abundant attached tissue is present in the palatal region of the maxillary implants, a gingivoplasty may be performed (Figure 32-29).

Permucosal Abutment Selection

The 4-mm permucosal healing cap should extend at least 1 mm above the tissue after suturing to help prevent tissue overgrowth during the next few weeks (Figure 32-30). An enlarged permucosal extension may be designed as part of the healing abutment (e.g., Maestro, BioHorizons) or attached to the healing abutment (e.g., Nobel Biocare). This larger contour helps maintain the apically positioned tissue in place, or it may support a periodontal dressing to maintain the tissue in place.

A suture groove, 3 to 5 mm above the platform connection, may be incorporated in the healing abut-

WWW.HIGHDENT.IR

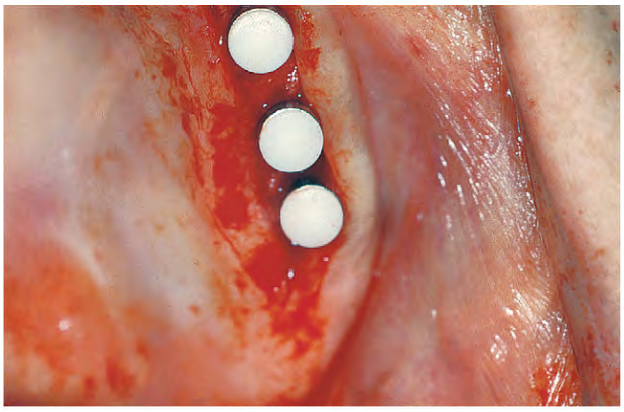

Figure 32-29 A gingivoplasty is often performed in abundant areas of keratinized, attached tissue, such as on the palate, to reduce sulcus depth around the implant.

Figure 32-30 The permucosal extension should extend at least 1 mm above the soft tissue after it is approximated around the implants.

Figure 32-31 A suture groove in the permucosal extension may be positioned 3 to 5 mm above the bone.

ment (e.g., Maestro, BioHorizons) (Figure 32-31). When the tissue requires apical repositioning or when it is 3 to 4 mm thick and may grow over the healing abutment, the suture groove may be used (Figure 32-32). A suture is placed next to the healing abutment. Tissue forceps lifts the suture from the incision line, and the suture is then rotated to form a loop. The loop is placed over the enlarged healing abutment and into the suture groove

Figure 32-32 The suture groove helps to apically reposition the tissue, so it will remain less than 3 to 5 mm thick, to reduce the sulcus depth.

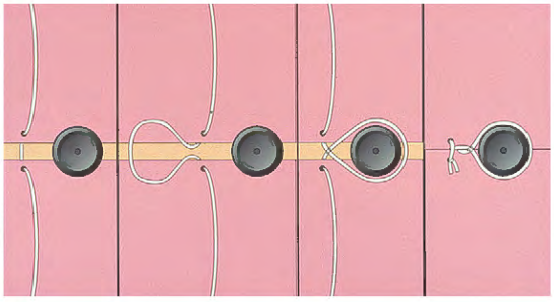

Figure 32-33 The suture groove in the permucosal extension may be used to loop the suture around the groove and tie the tissue at a more apical position.

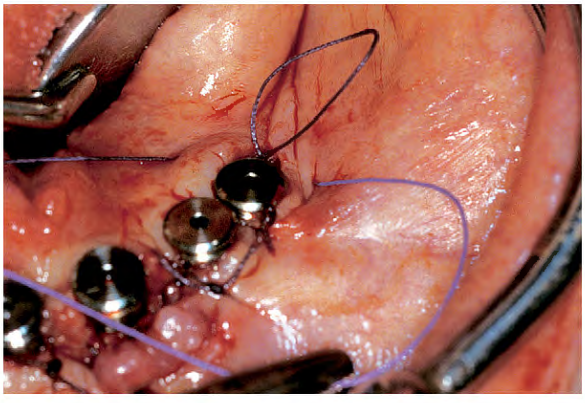

Figure 32-34 The most distal implant to the right has mobile tissue around it, which is difficult to reposition apically. The suture is placed on the distal aspect and looped over the suture groove to act as a soft tissue retainer.

or under the healing cap. The suture may then be tied, securing the tissue at the height of the suture groove (Figure 32-33). A similar technique is used on the other side of the healing abutment. These two sutures (one on each side) hold the tissue at the level of the suture groove and prevent it from lifting up and over the healing cap during soft tissue healing (Figures 32-34, 32-35).

A healing abutment wider than the implant crest module may be selected when the implant is not countersunk below the bone, with the following advantages:

WWW.HIGHDENT.IR

Figure 32-35 When the suture is tied around the permucosal extension, it apically positions the tissue around the implants.

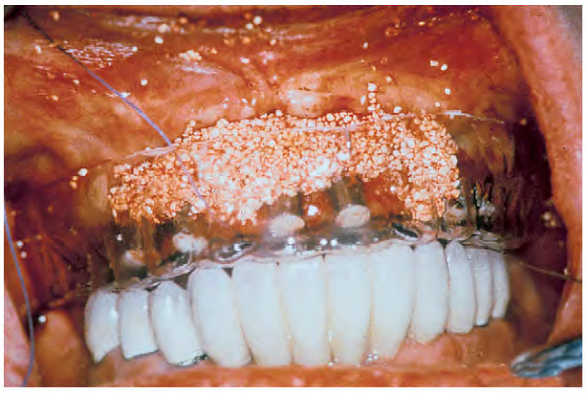

Figure 32-36 A prosthetic template of the labial flange of the denture indicates how much dense hydroxylapatite is required to support the lip above the fixed-implant prosthesis.

1. The perimucosal tissue heals with a larger diameter than the final abutment. As a result, when the final abutment is added after healing, the risk of entrapping soft tissue between the final abutment and the implant body is eliminated.
2. The wider space remains around the abutment for less than 30 minutes. Subgingival abutment preparations, impression, placement of retraction cord, and development of an emergence profile for the crown may all be facilitated when the space around the abutment is present.

The bacterial flora is similar around teeth and implants. Probing depth averages between 1.5 and 4 mm provide an environment that is conducive primarily to aerobic bacteria. As the sulcus depth increases beyond 5 mm, the incidence of anaerobic bacteria increases.[50] When 75% of the bacteria are anaerobes, an active process places the region at risk for disease. A dental probe next to a natural tooth is stopped by the connective tissue attachment zone. Unlike teeth, there is no connective tissue attachment next to an implant. In addition, the junctional epithelial attachment is less tenaciously bound to the implant compared with teeth. As a result, the same probing force used for a tooth will proceed almost to the crestal bone next to an implant. In addition, when plaque is allowed to accumulate next to an implant, the number of inflammatory cells infiltrating the connective tissue are found to be much larger and more extensive.[51] As a result, it has been suggested to maintain tissue thickness around the implant abutment less than 4 mm to decrease the risk of bacterial contributed bone loss.[52,53]

The sulcus depth next to an implant is directly related to the thickness of the tissue over the bone. The tissue thickness before implant placement is variable and may be greater than 6 mm, especially in the maxilla. During stage I implant placement surgery, excessive tissue thickness may be reduced. However, tissue thickness may be of benefit during initial healing to act as a cushion over the implant and reduce the risk of implant micromovement during healing. One of the goals of stage II uncovery surgery is to reduce the tissue thickness and therefore the final abutment sulcus depth to less than 4 mm. A 4- to 5-mm-tall PME is often selected at stage II uncovery to ensure that less than 4 mm of tissue exists. Otherwise the tissue will be higher than the healing cap. In addition, when taller healing caps are used, a soft tissue–borne transitional prosthesis must be sufficiently relieved over the abutments (to prevent excessive loads on the immature interface), and a greater moment of force is transmitted to the implant crest region under lateral loads.

Soft Tissue Support—Ridge Augmentation

When the maxillary lip or pontic position requires greater support or contour for esthetics, dense hydroxyapatite (HA) may be added to the labial bone surface for fixed prostheses. The prosthetic template is placed over the implant site and should represent the desired lip support region to determine the amount of labial HA graft required (Figure 32-36). The augmentation aims at providing an improved esthetic result and should not be attempted to increase the bone volume. Another alternative is the use of connective tissue or acellular tissue grafts (Alloderm, Lifecell, Branchburg, NJ), which may have the same goal. The advantage of HA for this intent is that limited long-term tissue shrinkage is observed. In addition, an increase in bone density is often observed in regions where the particulate HA attaches to the bone.

KERATINIZED TISSUE

Keratinized Tissue Concerns

The absence or presence of a zone of keratinized gingiva around a natural tooth or an oral implant is controversial. No direct evidence confirms or denies

WWW.HIGHDENT.IR

the need for nonmobile keratinized tissue next to natural teeth. Lang and Loe[54] advocate a minimum 2 mm of keratinized gingiva and 1 mm of attached gingiva to maintain gingival health. In longitudinal studies, however, Wennstrom[55] and Kennedy et al.[56] demonstrated that the lack of adequate keratinized and attached tissue does not compromise the long-term health of soft and hard tissue as long as patients maintain good oral hygiene. Moreover, Stetler and Bissada[57] concluded that if subgingival restorations were to be placed in areas of minimally keratinized gingiva and less than optimal plaque control, augmentation to widen the zone of keratinized tissue may be warranted. They also noted that in unrestored teeth, the difference in the inflammatory status of sites with or without a wide zone of keratinized tissue was not significant. The tooth with the least amount of keratinized tissue is often the mandibular first premolar. Yet this tooth is rarely the first tooth lost from periodontal disease. If all other periodontal indexes are normal, the amount or absence of keratinized gingiva has little to do with the expected longevity of the tooth.

The need for keratinized tissue around dental implants seems more controversial than around teeth.[58-64] Several reports demonstrate the long-term implant survival in the absence of keratinized tissue. Although reports are more cautious with mobile mucosa next to an implant, nonmobile tissue appears to be the primary criterion relative to tissue type.

Although keratinized tissue around a tooth may not be mandatory for long-term health, a number of benefits are present with keratinized mucosa. The color, contour, and texture of the soft tissue drape should be similar around implants and teeth. The interdental papillae should ideally fill the interproximal spaces. A high smile line often exposes the free gingival margin and interdental papillae zones. The keratinized tissue is more resistant to abrasion. Hygiene aids are more comfortable to use. The degree of gingival recession appears related to the absence of keratinized gingiva. Root sensitivity and esthetic concerns may be associated with gingival recession. From a restorative dental aspect, keratinized mucosa is more manageable during the retraction and impression-making process. Subgingival margin placement is more precise, as is long-term stability, in the presence of keratinized tissue.

The presence of keratinized tissue next to an oral implant may present even greater benefits than those with natural teeth (Figure 32-37). Some reports indicate the lack of keratinized tissue may contribute to implant failure. Kirsch and Ackermann[60] reported that the most important criterion for implant health in the posterior mandible was related to the absence or presence of keratinized gingiva. Mobile, nonkeratinized mucosa exhibits greater probing depths, which has been confirmed histologically. A study by Warrer et al.[59] in monkeys found that an absence of keratinized mucosa increases the susceptibility of peri-implant regions to plaque-induced destruction.

Keratinized gingiva has more hemidesmosomes; therefore the junctional epithelial attachment zone may be of benefit when in keratinized tissue. The orientation of collagen fibers in the connective tissue zone of an implant often appears perpendicular to the implant surface, whereas these fibers in mobile, nonkeratinized tissue run parallel to the surface of the implant. Schroeder et al.,[58] James and Schultz,[63] and Lisgarten et al.[64] have suggested that mobile mucosa may disrupt the implant-epithelial attachment zone and contribute to an increased risk of inflammation from plaque.

In addition to general advantages, keratinized tissue around implants may be beneficial in several other ways. In a two-stage protocol, the implant is less likely to become exposed during the healing process. The formation of interdental/implant papillae is completely unpredictable with mobile unkeratinized tissues. However, no clinical or histologic benefits are reported with unkeratinized nonmobile mucosa. When the unkeratinized tissue is mobile, several reports state that this is unsatisfactory.

The question relative to the need for keratinized tissue around implants should be modified to "which would you prefer?" No one has stated that the unkeratinized tissue is better than keratinized tissue for any reason. Therefore the controversy has abated. Some authors prefer keratinized mucosa more intensely than others. If one side of controversy demonstrates benefits and the other side states that keratinized tissue is not mandatory, both sides may be correct.

In specific clinical instances, attached keratinized gingiva is more often desirable. For example, an FP-1 (fixed prosthesis type 1) restoration in the esthetic zone requires keratinized mucosa to develop the soft tissue drape around the implant crowns. A second prime example is a mandibular overdenture, which benefits from a vestibule and zone of nonmobile tissue around the implant abutments.

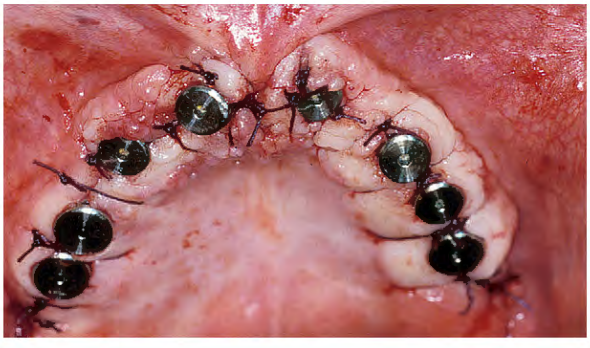

Figure 32-37 The presence of keratinized, attached tissue around implants provides even greater benefits than around natural teeth.

WWW.HIGHDENT.IR

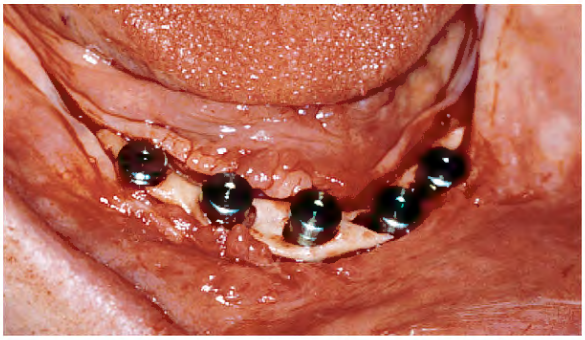

Figure 32-38 The anterior mandible was augmented with an iliac crest graft before implant placement. The crestal tissue presented little attached keratinized mucosa. An acellular tissue graft (AlloDerm) is placed around the implants.

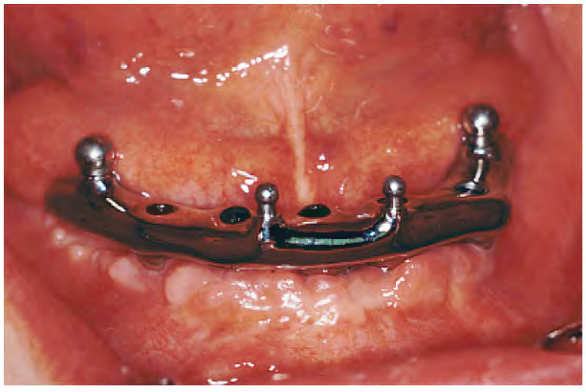

Figure 32-40 Long term, the tissue has remained attached around the implants.

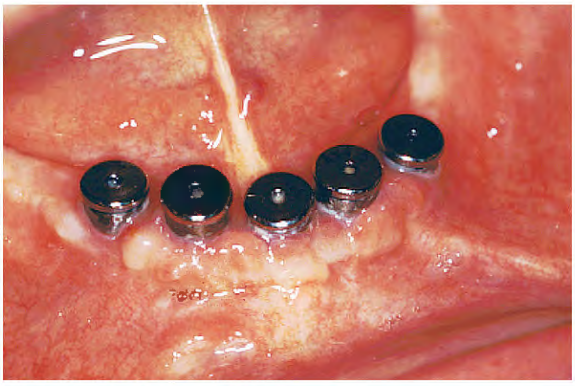

Figure 32-39 After several weeks, the tissue (although not keratinized) is not mobile around the implants.

Ono et al.[65] have proposed a classification of attached gingiva and surgical alternatives to improve soft tissue types in edentulous sites for implant placement. Meffert et al.[66] prefer to obtain keratinized tissue before implant placement.

Around natural teeth there are two main tissue types: attached, keratinized tissue and unattached, nonkeratinized tissue. These tissue types become more obscure around implants. When the tissue in a maxillary arch is thick before implant placement, the implant surgery often results with mobile, keratinized tissue that is several millimeters thick around the implant abutments. This type of tissue should be reduced in thickness to form a probing depth less than 4 mm.

When the implant is placed into a residual ridge that has lost overall width or had an iliac crest graft, the implant often has mobile, unattached nonkeratinized tissue in the facial aspect (Figure 32-38). This nonkeratinized tissue must become nonmobile, nonkeratinized tissue by placing either noncellular tissue graft (Alloderm) or hydroxyapatite below it (Figure 32-39). Although the tissue does not become keratinized with this technique, it does become nonmobile and provides a mass of tissue that may remain in health for the long term (Figure 32-40).

There are four types of oral mucosa that may be found around an implant: (1) keratinized, nonmobile tissue; (2) nonkeratinized, nonmobile tissue; (3) keratinized, mobile tissue; and (4) nonkeratinized, mobile tissue. In esthetic areas that expose the soft tissue, keratinized, nonmobile tissue is the best option. In nonesthetic regions, either keratinized, nonmobile, or nonkeratinized, nonmobile tissue is acceptable. Keratinized, mobile tissue may usually be made nonmobile by gingivoplasty techniques. Nonkeratinized, mobile tissue usually requires a soft tissue procedure to create a zone of keratinized tissue (i.e., free tissue graft) or a subdermal procedural to modify the mobile tissue base.

The width of keratinized tissue is evaluated before the initial incision and, if inadequate, is increased at the conclusion of the procedure. If less than 3 mm of keratinized gingiva is present and the crestal bone is cortical and in excellent condition around the implant bodies, the incision bisects the thin zone of attached tissue and the labial portion is approximated to the sole facial aspect of each implant. The lingual flap approximates the lingual aspect of each PME (Figure 32-41). Loose, interrupted figure-eight sutures are placed between the healing abutments. The section between the incision line is allowed to heal by secondary intention. In this manner, attached gingiva forms between the implants and the original attached tissue width is now divided between the facial and the lingual surfaces of the implants (Figure 32-42). The risk of this procedure involves the loss of crestal bone during soft tissue healing. The risk is reduced in the mandible, because the crestal bone is more cortical.

A second option to increase the zone of keratinized tissue at the stage II surgery is to use a split-thickness incision at the time of uncovery. After the implant body is evaluated (as previously addressed), a connective tissue or keratinized tissue graft harvested from the

WWW.HIGHDENT.IR

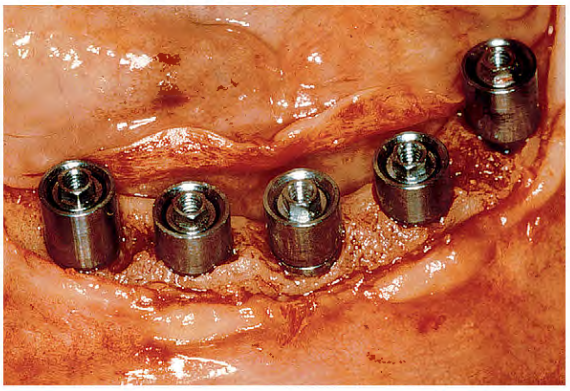

Figure 32-41 The quantity of keratinized tissue may be increased by allowing the margins of the tissue to granulate over the ridge.

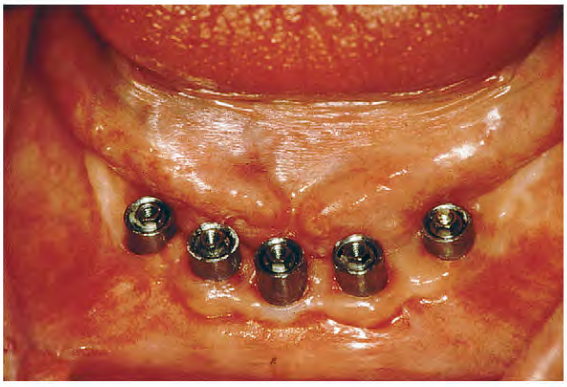

Figure 32-42 The tissue that heals by secondary intention between the margins of the original keratinized tissue creates attached, keratinized tissue around the implants.

palate may be placed and sutured around the stage II PMEs.

A third option to increase the zone of keratinized tissue is to harvest a 6- to 8-mm doughnut-shaped gingival collar from the palate. The open region of this collar is 4 mm in diameter and is inserted over the top of the PME and on top of the underlying bone or split-thickness incision.

A fourth option to increase a zone of mobile tissue is to place dense HA around the permucosal extension before approximating the tissues. This does not increase the zone of attached gingiva, but it makes the nonkeratinized tissue less mobile. However, this technique may also increase the gingival sulcus around the implant.

A fifth treatment option is to place an acellular tissue graft over the implants and directly onto the bone. The acellular tissue may be bound to the bone by tissue tacks. The overlying tissue is approximated around the implants. The tissue is then attached to acellular tissue by sutures or tissue tacks. The overlying tissue attaches to the acellular tissue, and the acellular tissue attaches to the bone. Although a keratinized tissue does not develop, the unkeratinized tissue is nonmobile. The nonmobile tissue has been observed to have benefits similar to nonmobile keratinized tissue.

TRANSITIONAL PROSTHESIS

A noneugenol periodontal dressing may be added over the top of the PMEs, but is usually not required. The complete denture or soft tissue–supported transitional prosthesis is aggressively relieved to prevent premature loading of the permucosal healing abutments. A tissue conditioner several millimeters thick is placed in the prosthesis over the implant healing abutment. The tissue conditioner is then relieved over the PMEs and in any region of desired secondary intention soft tissue healing. In nonesthetic regions of the partially edentulous patient, no transitional restoration is worn until after the sutures are removed.

The sutures are removed 2 weeks postoperatively. The soft tissue is not completely keratinized and healed at this time and may still be slightly inflamed. However, the patient may be referred to the restoring dentist for reconstruction. The final abutments will be selected by the restoring dentist after completion of the soft tissue maturation.

If the tissues appear healthy at the suture removal appointment, the first prosthetic appointment may be held at the same time. The stage II permucosal healing abutments are removed and replaced by the final abutment for screw retention or abutment for cement retention. An indirect impression transfer coping is placed into the abutment for screw retention. Vertical pressure is placed on the implants to ensure lack of tenderness. The surrounding gingiva may be recontoured by gingivoplasty with a diamond bur to shape an interdental papilla around the implant abutments for FP-1 prostheses or to reduce the depth of an implant sulcus.

A preliminary irreversible hydrocolloid or elastic impression is made of the implants. A preliminary impression made with additional silicone or polyether instead of irreversible hydrocolloid eliminates the need for the surgeon to have implant analogs or dental stone readily available. Instead, the impression is sent to the laboratory, where analogs and other materials are selected and used. The indirect impression transfer coping or abutment for cement retention is removed after the impression is made, and the stage II permucosal healing abutment is replaced.

The patient is scheduled to be seen again in 1 to 2 weeks, depending on the extent of soft tissue maturation at the suture removal. The indirect impression transfer coping or implant abutment analog (for screw or for cement) is placed into the preliminary impression, which is poured with dental stone. The purpose of this step is to permit the fabrication of the final impression tray and begin the fabrication of a transitional prosthesis if a fixed restoration is indicated.

WWW.HIGHDENT.IR

SUMMARY

Stage II surgery permits direct evaluation of the hard and soft tissues condition. The fabrication of the final prosthesis should begin with ideal abutment support. This includes an absence of crestal bone loss or defects, rigid fixation, no discomfort on loading, adequate zone of attached gingiva, pocket depths less than 5 mm, and acceptable implant body and abutment position for the intended prosthesis. Stage II surgery is an opportunity to evaluate these criteria and, if not present, restore them before prosthesis fabrication. On occasion, this requires additional time and surgeries. However, the alternative is a higher risk of future complication, which will require even more time, cost, and effort to correct or improve.

Chapter 33

Anterior Single-Tooth Replacement: Surgical Considerations

Carl E. Misch

Single-tooth replacement will most likely comprise a larger percentage of prosthetic dentistry in the future, compared with past generations. In 1960 the average American older than 55 years had just seven original teeth. Today, the baby boomers (those born between 1946 and 1964) can expect to have at least 24 teeth left when they reach 65 years of age.

Contrary to missing a posterior tooth, most patients have an emotional response regarding a maxillary anterior missing tooth. No question exists regarding the need to replace the tooth, and financial considerations are less important. When posterior teeth are extracted, little resistance to the preparation of adjacent teeth may be given to the dentist. However, when anterior, normal-looking teeth must be prepared to serve as fixed partial denture (FPD) abutments, the patient is more anxious and often looks for an alternative. In the patient's perspective, anterior FPD restorations are never as esthetic as natural teeth. This in part is because they are able to distinguish between good and poor esthetic results. More important, because patients are only able to notice the restorations that are not natural in appearance, they think anterior FPDs are not esthetic.

In younger patients with congenitally missing maxillary lateral incisors or with trauma to the maxillary central incisor (which resulted in its failure, often after endodontic therapy), the parents are eager to provide the best possible replacement option. They often perceive this option to be a single-tooth implant. As a consequence of these psychological factors, a common site for a single-tooth implant in a restorative practice is the maxillary central or lateral incisor.

Single-tooth implants are now one of the most common implant procedures performed in the United States. In the nonesthetic posterior region, the single-tooth implant is one of the simplest procedures in implant surgery and prosthetics. However, it should be noted the maxillary central incisor single-tooth replacement is often the most difficult procedure in all of implant dentistry.

The highly esthetic zone of the premaxilla often requires both hard (bone and teeth) and soft tissue restoration. The soft tissue drape is often the most difficult aspect of treatment. As a consequence, maxillary anterior single-tooth replacement is often a challenge, regardless of the experience and skill of the dentist or dentists.

ALTERNATE TREATMENT OPTIONS FOR ANTERIOR SINGLE-TOOTH REPLACEMENT

The alternatives to restore a single, maxillary anterior missing tooth include a traditional FPD; a cantilever FPD (for a missing lateral incisor); a removable partial denture (RPD); an acid-etched, resin-bonded prosthesis; or a single implant–supported restoration. These options were presented in Chapter 16. Maxillary single-tooth replacement is one of the most challenging restorations in dentistry. However, in light of all the advantages of single-implant longevity, bone maintenance, reduced abutment teeth complications, and increased survival of adjacent teeth, single-tooth implants have become the treatment of choice.

The single-tooth implant has the highest success rate compared with any other treatment option to replace missing teeth with an implant restoration (e.g., overdentures, short-span FPD, full-arch FPD, single-tooth implant).[1-11] In 2005, Misch et al.[7] reported on 276 anterior maxillary single implants used to restore missing teeth from agenesia. In 255 adolescent patients, the implants were monitored for a range of 2 to 16 years, with a 98.6% implant and crown survival rate. In the same year, Wennstrom et al.[8] reported on a 5-year prospective study with 45 single-tooth implants, with a 97.7% implant survival rate with minimal bone loss.

WWW.HIGHDENT.IR

In 2006, Zarone et al.[11] reported on lateral maxillary agenesis replacement with 34 implants, with a 97% survival rate at 39 months. A review of the literature by Goodacre et al.[6] found single-tooth implant studies had the highest survival rate of any prosthesis type and averaged 97%.

More recently, a trend toward single-stage and immediate-extraction implants has emerged, appearing especially attractive in the maxillary anterior region, where preferably the soft tissue drape is present before the tooth extraction and patients are more anxious to get a fixed replacement. Kemppainen et al.,[12] in a prospective study of 102 single-tooth implants in the anterior maxilla, reported a 99% success rate using one-stage and two-stage implants. Other studies have recommended one stage and immediate load with some success in specific situations.[13-15]

Figure 33-1 A single missing central incisor is often the most challenging implant restoration. The soft and hard tissues should be perfect to obtain an acceptable result.

Figure 33-2 The maxillary left central incisor implant crown in position. The soft tissue drape is established through both surgical and prosthetic methods.

CHALLENGING ESTHETICS

The esthetics of a maxillary anterior single crown on a natural tooth is often one of the most difficult challenges in restorative dentistry. It is even greater on an implant abutment (Figures 33-1 and 33-2). The implant is often 5 mm or less in diameter and round in cross section. A natural maxillary anterior crown cervix region is 4.5 to 7 mm in mesiodistal cross section and is never completely round. In fact, the natural central incisor and canine teeth are often larger in their faciopalatal dimension at the cement-enamel junction (CEJ) than in the mesiodistal dimension. Because the bone is lost first in the faciopalatal width, the greater width of implants in this dimension would require even greater augmentation than presently advocated. As a result, the cervical esthetics of a single-implant crown must accommodate a round-diameter implant and balance hygiene and esthetic parameters. Additional prosthetic steps and components with varied emergence profiles or customized tooth-colored abutments are often required to render the illusion of a crown on a natural abutment.

Bone Height

The available bone should be closely evaluated because it will greatly influence the soft tissue drape, implant size, implant position (angulation and depth), and ultimately the final esthetic outcome. Hard tissue topography is a prerequisite to an optimal, esthetic implant restoration. Available bone volume is necessary, and the position of the osseous crest is specific. The model midcrestal position of the edentulous site should be 2 mm below the facial CEJ of the adjacent teeth. On occasion, the bone crest may be above this position when the interproximal bone height is higher and/or a bone graft was performed at extraction. The interproximal bone should be scalloped 3 mm more incisal than the midcrestal position.

The position of the interproximal crest of bone is an important anatomical consideration, especially for the development of the interproximal soft tissue height.[16,17] Becker et al.[18] classified the range of interproximal bone height above the midfacial scallop from less than 2.1 mm (flat) to scalloped (2.8 mm) to pronounced scalloped (<4.1 mm). The flat anatomy should correspond to a square-shaped tooth, the scalloped to an ovoid-shaped tooth, and the pronounced scalloped to a triangular-shaped tooth (Figure 33-3). However, these relationships do not always exist. When a flat interdental-to-crest dimension is found on triangular teeth, the interproximal space will usually not be filled with soft tissue, because the dimension of the interproximal contact to the bone will be greater than 5 mm (Figure 33-4).[21]

Often the osseous crest may be more apical than ideal, in both the implant site and the adjacent tooth

WWW.HIGHDENT.IR

Figure 33-3 A triangular tooth form corresponds to the greatest width and height of interdental papillae and the most incisal interproximal contact position on the crown.

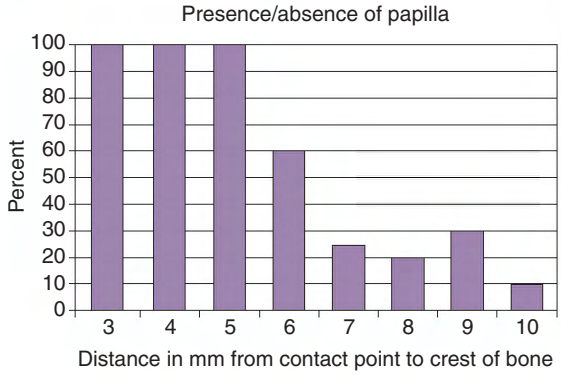

Figure 33-4 When natural teeth have an interproximal crown contact to interseptal bone distance of 5 mm or less, the interdental papilla almost always fills the interproximal space. When the distance is 6 mm, the interproximal space is not filled with soft tissue almost 40% of the time; at 7 mm the interproximal space is filled with an interproximal papilla 25% of the time.

roots. Under these conditions, ideal crown contour, soft tissue emergence, and interproximal tissue conditions are less likely (Figures 33-5 and 33-6). Bone and soft tissue changes after maxillary anterior tooth loss are rather rapid and of considerable consequence. As a result, many maxillary anterior edentulous sites require at least some bone and/or soft tissue modification before, in conjunction with, and/or at implant uncovery. Under perfect conditions, the implant body should not be inserted until the bone and soft tissue are within normal limits.

Mesiodistal Space

An adequate mesiodistal space is necessary for an esthetic outcome of an implant restoration and the interproximal soft tissue of the adjacent teeth. A traditional two-piece implant should be at least 1.5 mm from an adjacent tooth. When the implant is closer than this to an adjacent tooth, any bone loss related to

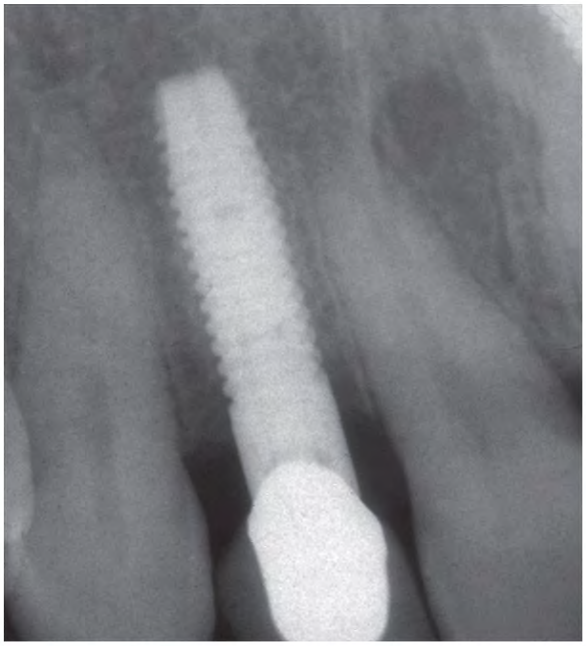

Figure 33-5 A periapical radiograph of an implant and crown placed in the maxillary right lateral incisor region. The interproximal bone adjacent to the canine is ideal; the interproximal bone on the central incisor is 4 mm below the cement-enamel junction (CEJ).

Figure 33-6 The lateral incisor implant crown from Figure 33-5. The interproximal distal papilla is acceptable as a result of the canine crestal bone level. The mesial papilla is depressed, and a "black hole" is evident. This is related to the crestal bone level on the central incisor. In addition, the triangular tooth form translates into a more incisal interproximal crown contact position, which further enhances the triangular defect. The distal bone loss on the central also increases the risk of root exposure (as shown).

the microgap, the biological width, and/or stress might cause the implant and adjacent tooth to lose bone. This may compromise interproximal esthetics and/or sulcular health of the implant and natural tooth[19-21] (Figure 33-7).

The smallest-diameter implant body offered by most commercial companies is 3.2 mm. However, the crest module of these two-piece implants is usually 3.5 mm or more. Therefore the mesiodistal edentulous space for a two-piece implant should be 6.5 mm or greater.

WWW.HIGHDENT.IR

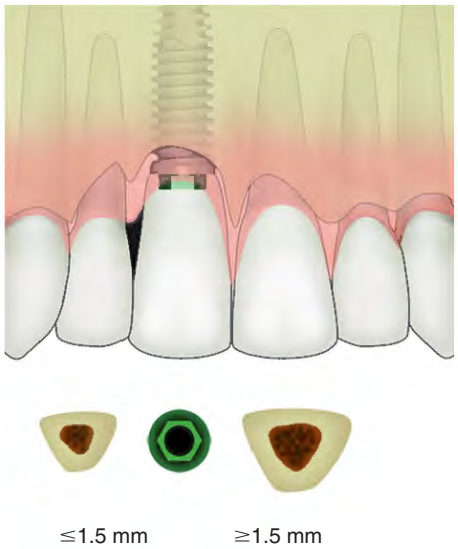

Figure 33-7 If bone loss occurs on an implant placed closer than 1.5 mm to a tooth (on the distal), then bone will also be lost on the tooth. As a result, the distance from the interproximal crown contact to the interproximal bone increases, and the risk of soft tissue shrinkage and loss of interdental papilla increases. When the implant is greater than 1.5 mm from the tooth (on the mesial); bone loss on the implants does not cause bone loss on the tooth root. The interproximal crown contact to interproximal bone relationship remains ideal, and the interdental papilla is maintained.

One-piece dental implants may be fabricated in 2.5- to 3.0-mm[22-24] diameters to accommodate a reduced mesiodistal dimension criterion. These implant designs do not have a microgap, and the vertical defect is narrower than most two-piece implant systems. As such, they may be placed as close as 1 mm from an adjacent tooth, and therefore can accommodate a 5-mm mesiodistal missing tooth space. However, because these implants have the abutment post attached to the implant body, they must be immediately restored the day of surgery. These implants are addressed in Chapter 35.

Faciopalatal Width

Most of the conditions that lead to single-tooth loss result in the loss of some or all of the facial bone in the region of the missing tooth. In addition, a 25% decrease in faciopalatal width occurs within the first year of tooth loss and rapidly evolves into a 30% to 40% decrease within 3 years. As a result, even an intact alveolus 6 to 8 mm wide is often inadequate in width after 1 year for a Division A root form implant in a central incisor position, and after 3 years it almost never presents adequate available bone for the proper-size implant. The bone width loss is primarily from the facial region, because the labial plate is very thin compared with the palatal plate, and facial undercuts are often found over the roots of the teeth (Figure 33-8). A bone graft is often necessary to restore the proper anatomy of the ridge and to avoid a compromised implant position more palatal and apical.

The amount of available bone width (faciopalatal) should be at least 2.0 mm greater than the implant diameter at implant insertion. Therefore a 3.5-mm implant requires at least 5.5 mm of bone width. Bone augmentation in width is very predictable. In many instances it is performed before implant placement; however, it may be performed at the time of implant insertion, especially when no dehiscence of the implant is visible. It should be emphasized the implant diameter measurement is at the crest module of the implant. Most 3.75-mm diameter implant bodies are 4.1 mm at the crest module. In these situations, the mesiodistal limitation is 7.1 mm and the faciolingual width limitation is 6.1 mm.

Implant Size

The first factor that influences the size of an implant is the mesiodistal dimension of the missing tooth. The average mesiodistal dimension of a central incisor is 8.6 mm for a man and 8.1 mm for a woman, a lateral

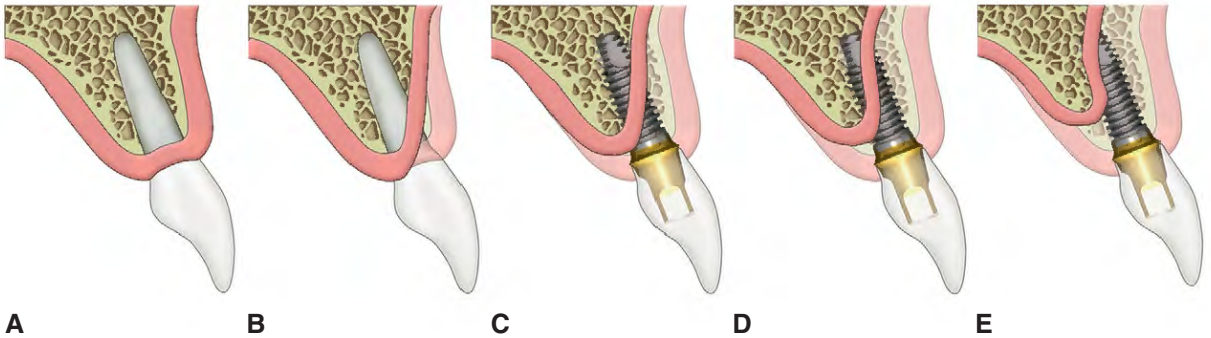

Figure 33-8 Before the loss of a maxillary anterior tooth, the bone around the roots most often is present **(A).** The cause of extraction often causes a loss of the thin labial plate of bone over the root **(B).** After extraction, the residual ridge most often is decreased in width (Division B). After 6 months to 1 year, the residual ridge continues to resorb and becomes Division B–w **(C).** Eventually, the residual ridge forms a C–w bone volume that is slightly deficient in height and less than 2.5 mm in width **(D).** This bone volume often extends almost to the floor of the nose **(E).**

WWW.HIGHDENT.IR

Table 33-1 Maxillary Teeth Dimensions

TYPE OF TOOTH	MESIODISTAL CROWN (mm)	MESIODISTAL CERVIX (mm)	FACIOLINGUAL CROWN (mm)	FACIOLINGUAL CERVIX (mm)	2 mm BELOW CEMENT-ENAMEL JUNCTION
Central incisor	8.6	6.4	7.1	6.4	5.5
Lateral Incisor	6.6	4.7	6.2	5.8	4.3
Cuspid	7.6	5.6	8.1	7.6	4.6

incisor is 6.6 mm for a man and 6.1 mm for a woman, and a canine is 7.6 mm for a man and 7.2 mm for a woman. Obviously, the implant body should not be as wide as the natural tooth or clinical crown. Otherwise, the emergence contour and interdental papillae region cannot be properly established.

The mesiodistal dimensions of the maxillary central incisor at the cervix (preferably 1 mm below the free gingival margin) averages 6.4 mm, the lateral incisor dimension is 4.7 mm, and canine natural teeth at the cervix are 5.6 mm (Table 33-1).[25,26] However, these dimensions are also too large for an implant.

The bone level on natural teeth is 2 mm below the CEJ; the natural tooth dimensions at this bone level are reduced to 5.5 mm for central incisors, 4.3 mm for lateral incisors, and 4.6 mm for canines. Therefore in theory, the latter dimensions most closely resemble the consummate implant diameter to mimic the emergence profile of a natural tooth. However, this dimension is usually too large to adequately restore the soft tissue drape of the missing anterior tooth.

The second factor that determines the mesiodistal implant diameter is the necessary distance from an adjacent tooth root.[20] Initial vertical bone loss around an implant during the first year of loading is variable and ranges from 0.5 to more than 3.0 mm.

The height of the interseptal (interimplant) bone in part determines the incidence of presence or absence of the interdental papillae between the teeth.[21] When the distance from the interseptal bone to interproximal contact is 5 mm or less, the papilla fills the space. When the distance is 6 mm, a partial absence of papilla is seen 45% of the time, and at 7 mm the risk of a compromise in the interproximal space is 75%. Therefore the intraseptal bone height is relative to the maintenance of the interdental papilla and should be preserved. As a consequence, the implant should be at least 1.5 mm from the adjacent teeth whenever possible, and the interseptal bone on the adjacent teeth should be within 5 mm of the desired interproximal crown contact position.

In summary, two mesiodistal parameters determine the preferable implant size. The suggested width of the single-tooth implant should correspond to the width of the missing natural tooth, 2 mm below the CEJ. The distance between the roots of the adjacent teeth should also be measured. The implant diameter + 3 mm (1.5 mm on each side) should be equal to or less than the distance between the adjacent roots, at the crest of the ridge (which is 2 mm below the interproximal CEJ).

The next dimension that determines the width of an anterior implant is the faciopalatal dimension of bone. The width of bone should allow at least 1.5 mm on the facial aspect of the implant so that if a vertical defect forms around the crest module, then that defect would not become horizontal and change the cervical contour of the facial gingival. Because of its initial reduced volume, facial bone tends to be labile, and its resorption is responsible for most of the compromised long-term esthetic results in the anterior maxilla.[27-29] The faciopalatal width dimension is not as critical on the palatal aspect of the implant, because it is dense cortical bone, more resistant to bone loss, and not within the esthetic zone. Facial bone grafting at the time of implant insertion is frequently needed, because the bone volume in width is often compromised (Figures 33-9 to 33-11).

The width of the implant should not only mimic the emergence of a natural tooth, but also help to preserve the bone and health of the adjacent teeth. The natural intraroot distance of the two central incisors distance is approximately 2 mm. However, the natural roots of the central to lateral and lateral to canine are usually

Figure 33-9 An implant placed in the central incisor position, with less than 1.5 mm of bone on the facial.

WWW.HIGHDENT.IR

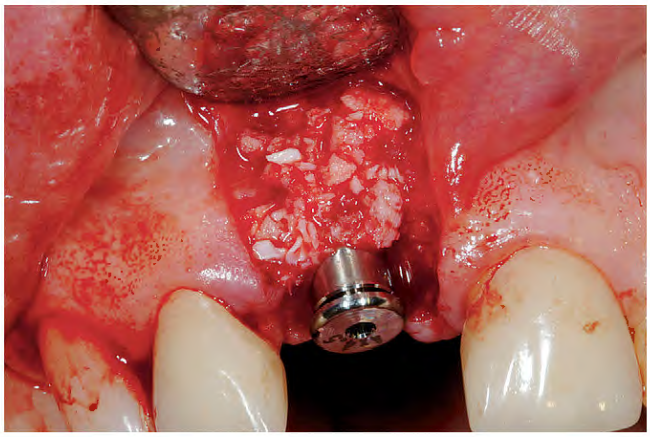

Figure 33-10 A layer of freeze-dried bone (MinerOss) is placed over the autograft on the facial bone over the implant.

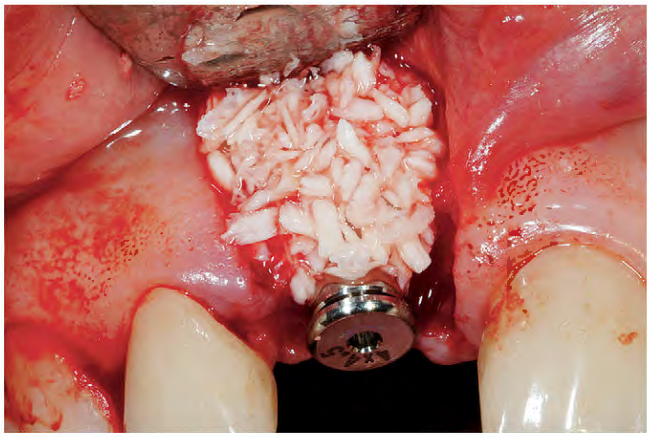

Figure 33-11 A layer of autograft, collected from the drills during osteotomy preparation, is placed on the facial bone over the implant.

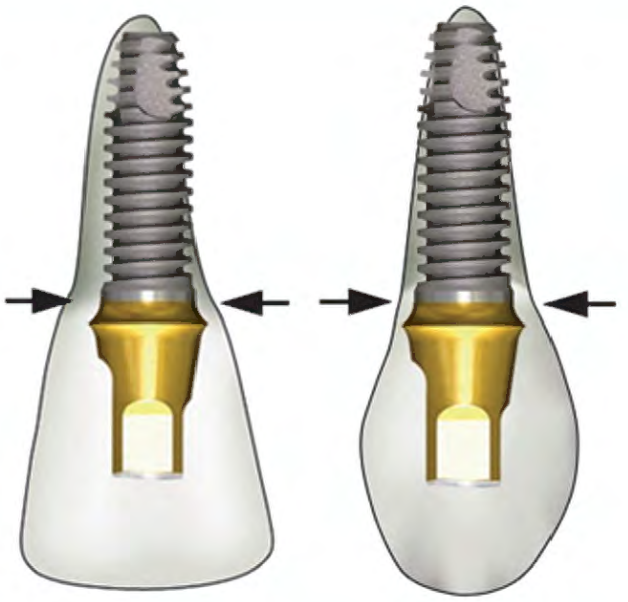
less than 1.5 mm apart and often only 0.5 mm of space exists between them. As a consequence, the archetypal size of the single-tooth implant is usually smaller in diameter than the natural tooth root.

The typical diameters of the implant used to replace the average-size tooth often results in a 4.0- to 5.2-mm implant for a central incisor, a 3.0- to 3.5-mm implant for a lateral incisor, and a 3.7- to 4.2-mm implant for a canine. The difference in the emergence profile of a 4-mm-diameter implant and a 5-mm-diameter implant is negligible and often not clinically relevant for an anterior tooth, because 0.5-mm difference occurs on each side of the implant. Therefore when in doubt, the surgeon should use a smaller-diameter implant. As such, a 4-mm-diameter implant may often be used in the central-implant position for a single-tooth replacement. Likewise, a 3.0- to 3.5-mm implant is often used for a lateral incisor single-tooth restoration.



A B

Figure 33-12 The best implant position is under the incisal edge of the final crown, or slightly more palatal **(A).** The ideal mesiodistal implant position for a central incisor is 0.5 to 1.0 mm more distal than the midtooth position. This decreases the risk of encroachment on the incisive canal **(B).** The best mesiodistal position for a cuspid is centered in the cuspid position **(C).**

IMPLANT BODY POSITION

Mesiodistal Position

The maxillary anterior single-tooth implant should be located precisely in three planes. From a mesiodistal aspect, the implant most often is placed in the middle of the space, with equal amount of interproximal bone toward each adjacent tooth. On occasion, the central incisor implant is positioned slightly to the distal of the intratooth space (Figure 33-12). The incisive foramen is variable in size and position. When a central incisor implant is planned and the foramen between the existing central incisor root and implant site is larger than usual, the remaining bone may be inadequate. The foramen may also expand off to one side of the midline within the bony canal. When the central incisor implant is placed, the implant may encroach on the canal and result in a probing pocket depth of 10 mm or greater on the mesiopalatal surface of the implant. As a precaution, the surgeon should reflect the palatal tissue when placing a maxillary central incisor implant, probe the foramen, and if necessary, place the implant in a more distal position. This usually requires a smaller-diameter implant than usual to remain 1.5 mm or more from the lateral incisor. On occasion, the contents of the foramen must be removed and a bone graft inserted, to decrease the size of the incisive canal (Figure 33-13).

WWW.HIGHDENT.IR

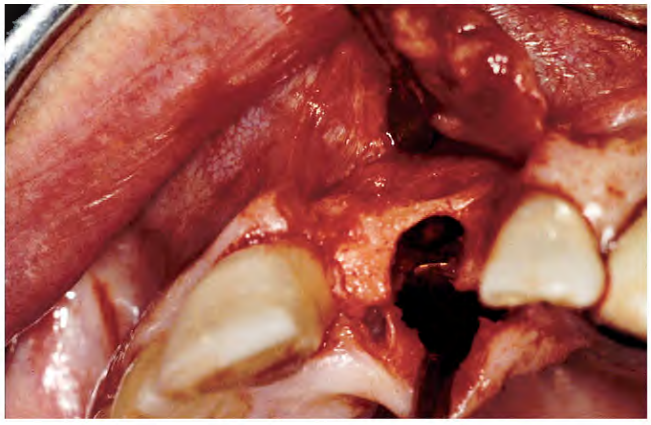


Figure 33-13 On occasion, the incisive canal extends into the site of the missing central incisor. As a result, the foramen should be enucleated and filled with a bone graft to restore the site and allow implant placement.

Faciopalatal Position

The midfaciopalatal position of the implant is in the middle to slightly palatal 0.5 mm of the edentulous ridge of adequate contour. This approach permits the use of the greatest-diameter implant. The crestal bone should be at least 1.5 mm wider on the facial aspect of the implant and 0.5 mm on the palatal aspect. Therefore for a 4-mm-diameter implant, a minimum 6-mm faciopalatal width of bone is required for the central or canine position, and 5.5 mm of bone width is required for a lateral incisor with a 3.5-mm implant. Bone spreading in conjunction with implant placement or bone grafting on the facial aspect of the edentulous site may be used when the ridge is less wide than is desirable. The thickness of bone on the facial aspect of a natural root is usually 0.5 mm thick. As a result, the implant is 1 mm or more palatal than the facial emergence of the adjacent crowns at the free gingival margin.

Implant Angulation

The implant center is positioned in the faciopalatal center of the edentulous ridge and the midmesiodistal position. The implant body angulation from this point is considered next. In the literature, three faciopalatal angulations of the implant body are suggested: (1) a facial angulation so that emergence of the final crown will be similar to adjacent teeth, (2) under the incisal edge of the final restoration, and (3) within the cingulum position of the implant crown (Figure 33-14).

Facial Implant Body Angulation

Researchers often theorize that a maxillary anterior implant body angulation be positioned at the facial emergence of the final crown. The facial implant position is predicated on the concept that the facial emergence of the implant crown at the cervical should be in the same position as a natural tooth. At first, this makes some sense. However, the crown of a natural tooth has two planes, and its incisal edge is palatal to the facial emergence of the natural tooth by 12 to 15 degrees (Figure 33-15). This is why anterior crown preparations are in two or three planes. The implant body is more palatal than a natural root, so 1.5 mm of bone exists facially. In addition, because the implant is narrower in diameter than the faciopalatal root dimension, when the implant body is oriented as a natural tooth and has a facial emergence, a straight abutment is not wide enough to permit the two or three plane reduction to bring the incisal edge of the preparation more palatal. As a result, the incisal edge of the preparation remains too facial. Therefore when the implant is angled to the facial emergence of a tooth, an angled abutment of 15 degrees must be used to bring the incisal edge more palatal.

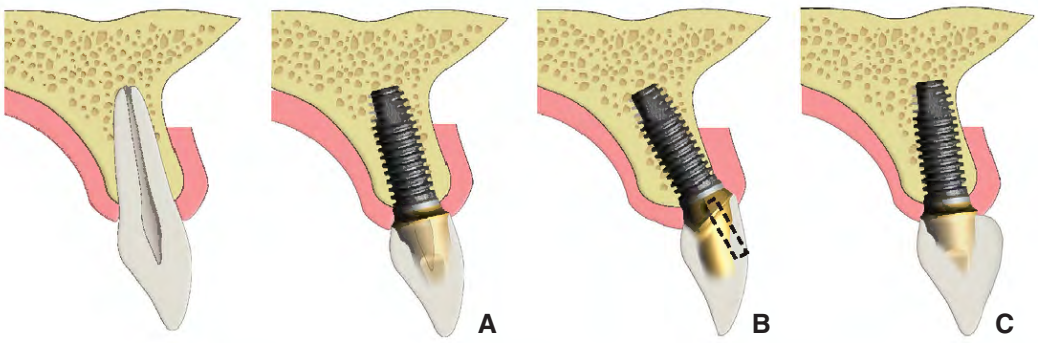

Figure 33-14 Three implant positions are found in the literature related to the final crown position. **A,** A position below the incisal edge is best used for a cemented crown in the esthetic zone. **B,** An implant is in the position of the natural root of the tooth. Although this makes sense, it places the implant too facial, and an angled abutment is usually necessary. **C,** An implant in the cingulum position that is used when a screw-retained crown is the treatment of choice. This position requires a facial ridge lap of porcelain when used for FP-1 prostheses in the esthetic zone.

WWW.HIGHDENT.IR

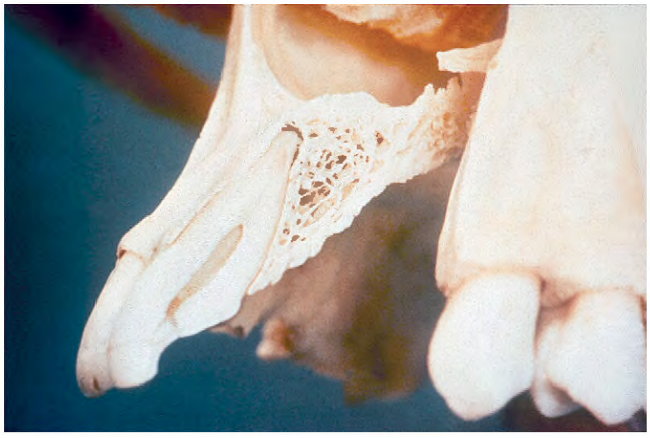

Figure 33-15 A natural tooth has very thin facial cortical bone over the root, and the incisal edge of the crown is 12 to 15 degrees palatal to the facial emergence profile. This is not an ideal position for an implant. The bone to the palatal region is better suited for an implant and allows the implant to be positioned under the incisal edge.

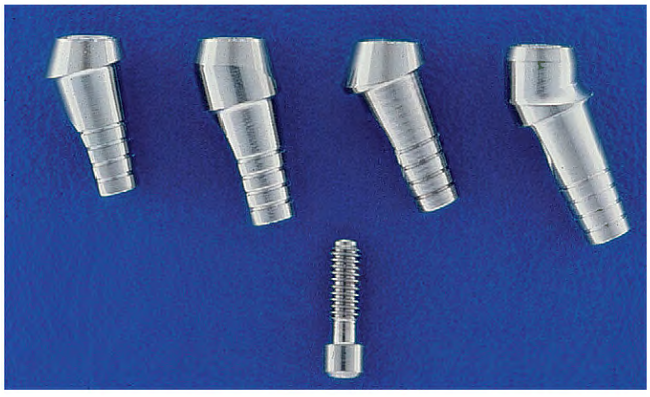

Figure 33-16 Most angled implant abutments, regardless of manufacturer, have an extra metal flange, opposite to the angled post. This increases the thickness of metal so that the component will not fracture. However, the extra metal flange is more facial than the implant body and results in increased risk of tissue shrinkage and/or metal seen through the thin facial soft tissue.

Most two-piece angled abutments have a design flaw that compromises facial cervical esthetics (Figure 33-16). The metal flange facial to the abutment screw is thinner than a straight abutment and may result in fracture (especially because angled loads are placed on the facial-positioned implant). The manufacturers thicken the profile of the abutment on the facial aspect to reduce the risk of fracture. However, this design flaw brings the cervical facial margin more facial and wider than the implant body, which is already as facial as the adjacent tooth. As a result, the implant crown margin is facially overcontoured. The restoring doctor then has to prepare the facial aspect of the abutment metal flange for esthetics, which weakens it and makes it prone to fracture. Because the doctor modified the abutment, the implant company is held harmless but, nonetheless, the patient and doctor are at risk.

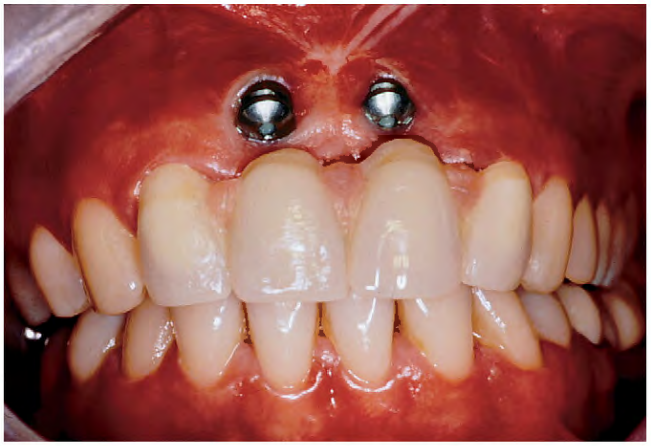

Figure 33-17 When implants are placed too facial, no prosthetic method is available to improve the poor esthetic condition.

When the surgeon attempts to align the implant body with the facial aspect of adjacent teeth, the implant may inadvertently be inserted too facial. No single method exists to restore proper esthetics when the implant abutment is located above the free gingival margin of the adjacent teeth. At best, the final crown appears too long and too facial. Soft tissue grafts and/or bone augmentation do not improve the condition once the implant is already incorrectly inserted (Figure 33-17).

The natural maxillary anterior teeth are loaded at a 12- to 15-degree angle, because of their natural angulation in comparison with the mandibular anterior teeth. This is one reason the maxillary anterior teeth are wider in diameter than mandibular anterior teeth (which are loaded in their long axis). The facial angulation of the implant body often corresponds to an implant body angulation, which leads to 15 degrees off axial loads and increases the force to the abutment screw-implant-bone complex by 25.9%, compared with a long axis load. These offset loads increase the risks of abutment screw loosening, crestal bone loss, and cervical soft tissue marginal shrinkage. As a result, implants angled too facially compromise the esthetics and increase the risk of complications (Figure 33-18).

Cingulum Implant Body Angulation

A second angulation suggested in the literature is more palatal, with an emergence under the cingulum of the crown. This may also be the result of an implant insertion in a width-deficient ridge (Division B), because the bone is lost primarily on the facial (see Figure 33-8, *C*). This position is often the goal when a screw-retained crown is used in restoration. The prosthesis fixation screw (to retain a maxillary anterior crown) cannot be located in the incisal or facial region of the crown for obvious reasons.

The cingulum implant position may cause a considerable health compromise. The implant body is round

WWW.HIGHDENT.IR

Figure 33-18 An implant that is too close to a tooth and/or too facial increases the risk of tissue shrinkage and poor cervical esthetics. The central implant crown and the natural lateral incisor have tissue recession as a result of the bone loss and improper implant position (too facial and too close to the tooth).

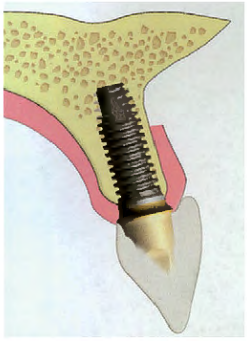

Figure 33-19 An implant placed in the cingulum position requires a ridge lap on the implant crown to restore the facial contour of the tooth.

and usually 4.0 to 5.5 mm in diameter. The labial cervical contour of the implant crown must be similar to the adjacent teeth for the ultimate esthetic effect. Because the long axis of the implant for a screw-retained crown must emerge in the cingulum position, this most often requires a facial projection of the crown or "buccal correction" facing away from the implant body. The facial ridge lap must extend 2 to 4 mm and is often similar in contour to the modified ridge lap pontic of three-unit fixed prosthesis (Figure 33-19).

The modified ridge lap crown has become a common solution to correct the esthetics of the restoration when the implant is placed in narrow bone or follows a palatal angulation position.[30,31] However, plaque control on the facial of the implant is almost impossible. Even if the toothbrush could reach the gingival sulcus, no hygiene device could be manipulated to a right angle to proceed into the facial gingival sulcus. As a result, although an acceptable esthetic restoration may be developed, especially with the additional cervical porcelain, the hygiene requirements and present implant dentistry standards render this approach unacceptable (Figure 33-20).

Some authors argue that an improved contour may be developed subgingivally with a palatal implant position. To create this contour, the implant body must be positioned more apical than desired. This position may prevent food from accumulating on the cervical "table" of the crown. However, the subgingival ridge lap does not permit access to the facial sulcus of the implant body for the elimination of plaque, as well as to evaluate the bleeding index or facial bone loss. Therefore the maintenance requirements for the implant facial sulcular region do not permit the surgeon to consider this modality as a valid primary option.

Greater interarch clearance is often needed with an implant palatal position, because the permucosal post exits the tissue in a more palatal position. Inadequate interarch space may especially hinder the restoration of Angle's Class II, division 2 patients, with the implant in this position. The bony ridge should be augmented if too narrow for the model implant diameter and position, or an alternate treatment option should be selected. The anterior single-tooth implant should use a cement-retained crown, so the cingulum screw position is not necessary.

IDEAL IMPLANT ANGULATION

The third implant angulation in the literature describes the most desirable implant angulation. A straight line is determined by connecting two points. The clinician determines the line for the best angulation by the point of the incisal edge position of the implant crown and the midfaciopalatal position on the crest of the bone. The center of the implant is located directly under the incisal edge of the crown so that a straight abutment for cement retention emerges directly below the incisal edge (Figure 33-21). Because the crown profile is in two planes, with the incisal edge more palatal than the cervical portion, the incisal edge position is perfect for implant placement and also accommodates some of the facial bone loss that often occurs before implant placement. The facial emergence of the crown mimics the adjacent teeth, proceeding from the implant body under the tissue. The angle of force to the implant is also improved, which decreases the crestal stresses to the bone and abutment screws (Figure 33-22). When in doubt, the implant surgeon should err toward the palatal aspect of the incisal edge position, not to the facial aspect, because it is easier to correct a slight palatal position in the final crown contour compared with the implant body angled too facial.

WWW.HIGHDENT.IR

Figure 33-20 **A,** The maxillary left central incisor *(right side)* with a ridge lap crown presents acceptable esthetics. **B,** However, probing on the facial aspect measures the distance to the implant but cannot evaluate facial bone loss, because it cannot be directed apically to the pocket depth. **C,** Periodically, the left central incisor implant becomes inflamed, and the bleeding index increases as a result of the inability to clean the implant sulcus on the facial.

The implant abutment selected for a maxillary anterior single-tooth implant is almost always for a cemented restoration. Single anterior crowns do not require readily retrievable restorations. In addition, a greater range of corrective options exists with a cement-retained crown for implants not well placed. The location of the cervical margin of a cemented crown can be anywhere on the abutment post or even on the body of the implant, provided it is 1 mm or more above the bone.

The implant body angulation under the incisal edge may also be used for screw-retained restorations. In these cases an angled abutment for screw retention is placed, and the coping screw for the crown may be located within the cingulum. This method does not require a facial ridge lap of the final crown, which decreases the risk of compromised hygiene.

When ideal bone volume is present, a surgical template that indicates the incisal edge and facial contour of the final prosthesis may be used. The incisal edge of the template may be notched for the drills, because the best placement of the drill is directly through the incisal edge. However, most often the surgeon does not require a template, because the adjacent teeth provide a guide for a single-tooth implant. In addition, the integrity of facial cortical plate is more readily assessed during the surgery when a template is not used.

Implant Position: Depth

Too Deep (> 4 mm)

Some authors have suggested that the implant be countersunk below the crestal bone more than 4 mm below the facial CEJ of the adjacent teeth to develop a crown emergence profile similar to a natural tooth, to prevent soft tissue recession, and to support the adjacent tissue of the adjacent natural teeth.[30,31] In concept this provides an emergence transition of about 5 mm on the facial aspect to achieve the width of the natural tooth (the ideal free gingival margin on the facial is 1 mm above the CEJ). Because the root of a natural tooth is approximately 4 mm in diameter at this point, very esthetic restorations may be fabricated with this technique. The bulk of subgingival porcelain provides

WWW.HIGHDENT.IR

A B

Figure 33-21 **A,** The perfect position for an anterior single-tooth implant is under the incisal edge to the approximate midcrest position. A central incisor should have the position slightly distal and slightly toward the palate. **B,** The implant crown has a 1.0- to 1.5-mm subgingival margin and begins a facial, mesial, and distal contour at this point to exit the tissue similarly to the contour of the adjacent tooth.

Figure 33-22 The implant crown on the left is positioned under the incisal edge. The crown on the right is for an implant in the cingulum position. The reader should note the facial emergence of the crown on the left compared with the ridge lap crown on the right.

good color and contour for the crown. However, several concerns arise regarding the long-term sulcular health around the implant (Figure 33-23, *A*).

The first year of function often corresponds to a mean bone loss range of 0.5 to 3.0 mm, dependent in part on implant design. Malevez et al.[32] noted more pronounced bone loss for conical implants that had a long, smooth, tapered crest module. The bone is lost at least 0.5 mm below the abutment to implant body connection and extends to any smooth or machined surface beyond the crest module (depending on the implant design). This may lead to facial probing depths of 7 to 8 mm or greater. Grunder[33] evaluated single-tooth implants in function for 1 year and noted the bone levels were 2 mm apical to the implant-abutment connection and sulcular probing depths were 9.0 to 10.5 mm using a Brånemark implant design. As a result, daily care devices cannot maintain the sulcus health, and anaerobic bacteria are more likely to develop. The interproximal regions of the implant crown, which correspond to the incidence or absence of interdental papillae, usually exhibit even greater probing depths. As a result, gingival shrinkage of the tissue is more likely to occur when the implant is placed more than 4 mm below the facial position of the adjacent CEJ.

The attachment mechanism of the soft tissue above the bone is less tenacious compared with a tooth, and the defense mechanism of the peri-implant tissues may be weaker than that of teeth.[34] The clinician, to err on the side of safety for the best sulcular health conditions, should limit sulcular depths adjacent to implants to less than 5 mm.[35] This may be even more relevant for single-tooth implants because of the devastating consequences of gingival shrinkage for long-term esthetics. In addition, the interproximal regions of the single-tooth implant crown are shared with the adjacent teeth, and anaerobic bacteria that form in the region next to the implant eventually may affect the adjacent natural tooth because a horizontal defect may form (especially when the implant is closer than 1.5 mm to the tooth).

When the implant is countersunk below the crestal cortical bone, the trabecular bone around the crest module is weaker against occlusal loads. In addition, when the implant is placed below the crestal bone, the resultant initial crown height is increased, as are moment forces. A further increased risk of soft tissue shrinkage occurs long term, with additional bone loss at the crest module. The result is longer clinical crowns, which also decrease gradually in width (as the narrowing dimensions approach the implant body), with resultant black triangular spacings in lieu of interdental papillae and compromised long-term esthetics.

Too Shallow (< 2 mm)

When the implant body is positioned less than 2 mm below the facial free gingival margin of the crown, the cervical esthetics of the restoration are at an increased risk (Figures 33-23, 33-24). The porcelain of the crown may not be subgingival enough to mask the titanium color of the abutment below the margin. If bone loss

WWW.HIGHDENT.IR

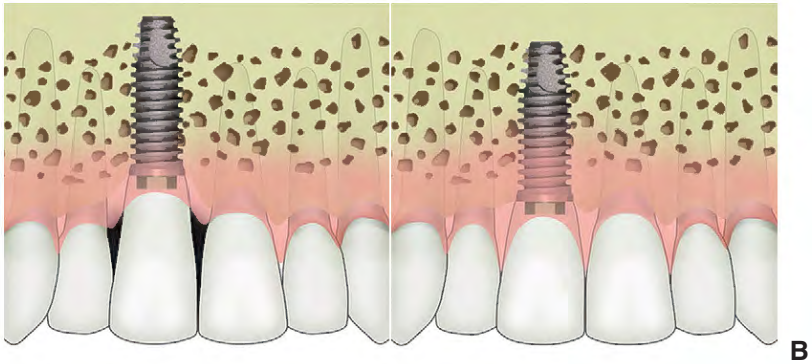

Figure 33-23 The literature usually reports two positions for the depth of the implant. The facial bone of a healthy natural tooth is about 2 mm below the cement-enamel junction (CEJ), and the soft tissue from the free gingival margin to the bone is 3 mm. An implant inserted 4 mm or more below the facial CEJ often is countersunk below the crestal bone 2 mm or more **(A).** This gives "running room" for the porcelain on the crown to create a natural-looking emergence profile. However, bone loss is likely to occur beyond the implant abutment connection and often proceeds to the first thread beyond the crest module. As a result, an increase in probing depth and growth of anaerobic bacteria are more likely. **B,** An implant placed 2 mm below the adjacent facial CEJ provides 3 mm of soft tissue drape to develop with a natural appearance and is best. An implant placed too shallowly causes severe emergence profile angles and compromises esthetics.

occurs, then the titanium implant abutment and/or body may also cast a dark shadow to the gingival tissues. If apical shrinkage of tissue occurs, then the dark titanium abutment and implant body may become directly visible. Periodontal surgical procedures to position soft tissue over the titanium roots are unpredictable.

On occasion, the crestal bone height is coronal to the perfect height. The two most common conditions that result in this finding are (1) when the adjacent teeth are closer than 6 mm (in agenesis of a lateral incisor) and (2) when a block bone graft regenerated width and height of bone. Ideally, the interproximal bone is 3 mm above the midcrestal bone. When the teeth are closer than 6 mm (i.e., a lateral incisor in the maxilla), the interproximal bone height of each adjacent tooth to the missing space is able to stimulate and maintain bone at the interproximal level. When a single-tooth implant replaces this missing tooth, an osteoplasty should be performed so that the midcrestal region is 3 mm apical to the free gingival margin of the future crown. The same conditions may occur when bone augmentation gains height to the interproximal height of bone.

To solve the problem of an implant body placed too shallow, the restoring dentist may need to prepare the implant crest module and place the margin of the crown directly on the implant body (see Figure 33-24).

Ideal Depth (3 mm)

The best platform level for a two-stage implant is similar to the most desirable bone level before the loss of a natural tooth, which is 2 mm below the adjacent tooth CEJ. This positions the platform of the implant 3 mm below the facial free gingival margin of the implant crown (see Figure 33-23). In addition, it provides 3 mm of soft tissue for the emergence of the implant

Figure 33-24 An implant platform 2 mm or less below the adjacent cement-enamel junction is too shallow and results in crown contour or increases the risk of inadequate interdental papilla.

crown on the midfacial region and more as the soft tissue measurements proceed toward the interproximal (Figure 33-25). This depth also increases the thickness of the soft tissues over the titanium implant body, which masks the darker color above the bone. It should be noted that the free gingival margin of a lateral incisor is often 1 mm more incisal than the adjacent central and canine natural tooth.

SOFT TISSUE INCISION

Once the midmesiodistal position, midfaciopalatal position, angulation under the incisal edge, and implant depth in relation to the crest and final crown have been

WWW.HIGHDENT.IR

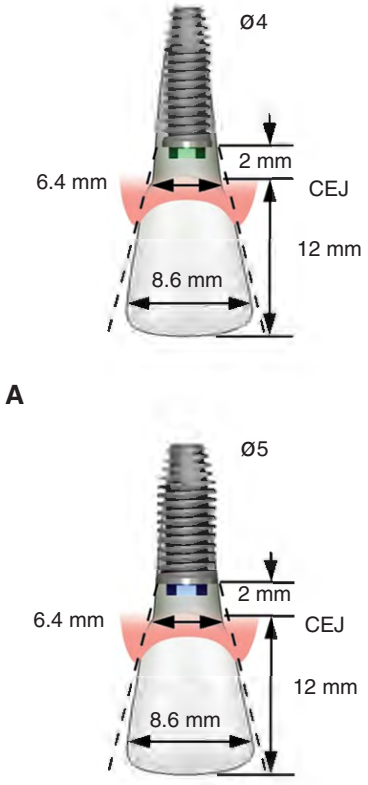

Figure 33-25 The ideal depth of the implant platform is 2 mm below the natural tooth cement-enamel junction (CEJ) or 3 mm below the free gingival margin. This provides adequate emergence profile for the implant crown and creates an environment for soft tissue health around the implant.

determined, the osteotomy preparation may be started.

The ideal tissue drape is often the most difficult aspect of maxillary anterior single-tooth replacement within the esthetic zone. Several different approaches are used to enhance the soft tissue appearance. The approaches may be surgical (addition or subtraction) or prosthetic: (1) a soft tissue graft before bone augmentation, (2) a soft tissue augmentation in conjunction with a bone graft before implant insertion, (3) soft tissue augmentation in conjunction with implant insertion, (4) soft tissue manipulation at the implant uncovery procedure, (5) a prosthetic modification of interproximal contact position, (6) creeping attachment around the implant crown, or (7) a prosthetic replacement of the soft tissue with pink-colored porcelain (Box 33-1).

Surgical additive techniques such as pouch procedures, interpositional grafts, sliding flaps, and connective tissue grafts (autogenous or acellular dermal matrix) have all been proposed. A soft tissue graft is performed as a separate procedure, before any other surgery when the patient has a high lip dynamic and the soft tissue color and/or volume is grossly deficient. Most often, a connective tissue graft to improve the soft tissue drape is indicated.

A bone graft and soft tissue augmentation is indicated when the bone on the adjacent teeth is within normal limits (2 mm below the CEJ) but deficient in width and midcrestal volume. When the interproximal bone is not within normal limits, orthodontic extrusion is considered, followed by a crown and possibly endodontic therapy. The goal of a soft tissue augmentation for either of the two previous procedures is to obtain soft tissue on the crest of the ridge at the height of the interproximal papilla height.

The interproximal soft tissue in the implant site may be classified into three categories: (1) the papillae have an acceptable height in the edentulous site, (2) the papillae have less than acceptable height, or (3) one papilla is acceptable and the other papilla is depressed and requires elevation. When the interproximal papilla has an acceptable height, "papilla-saving" incisions are made adjacent to each neighboring tooth (Figure 33-26). The vertical incisions are made on the facial aspect of the edentulous site and begin 1 mm below the macrogingival junction, within the keratinized tissue. Extending the vertical incisions beyond the macrogingival junction increases the risk of scar formation at the incision site. The full-thickness incision then approaches the crest of the edentulous site, leaving 1.0 to 1.5 mm of the interproximal papilla adjacent to each tooth. The vertical incisions are not wider at the base than the crestal width of tissue. This permits the facial flap to be advanced over the implant or short and adjacent to a permucosal extension (PME) at the conclusion of the procedure, with no voids at the incision line and primary closure (Figure 33-27).

WWW.HIGHDENT.IR

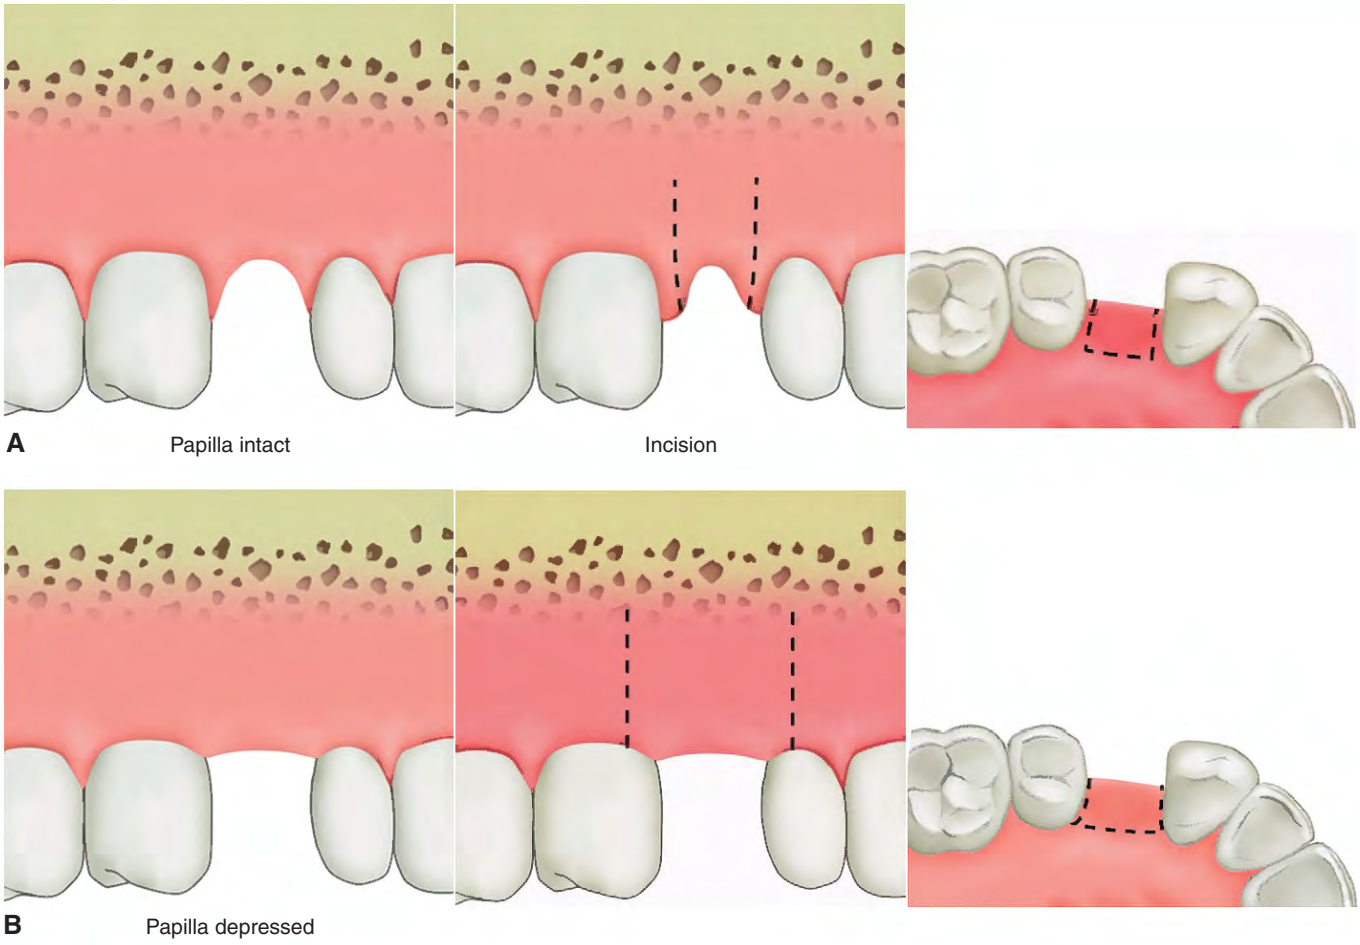

Figure 33-26 When the interdental papillae are in an acceptable position **(A),** papilla-saving incisions are made to minimize soft tissue reflection. The incisions are vertical to allow primary closure. When the papillae are depressed, the vertical release incisions include the papilla in the edentulous site. In situations with a more depressed soft tissue, facial soft tissue and papillae over each adjacent tooth are also reflected. The crestal incision is on the palatal incline on the ridge **(B).**

When the papillae are depressed in the edentulous site, vertical-release incisions are made along the root angle of each adjacent tooth, beginning 1 mm below the macrogingival junction, as well as in the sulcus of each adjacent tooth. Therefore the interproximal papilla region becomes part of the facial soft tissue flap (see Figure 33-26, *B*).

When the papillae are mixed in acceptance, a vertical-release incision is made that does not include the adequate papilla. The second vertical incision includes the depressed papilla (Figure 33-28). In either case, the crestal incision is extended to the palatal aspect on the crest of the edentulous site.

The crestal incision is made on the palatal incline of the edentulous site to provide greater thickness of keratinized tissue on the facial aspect of the flap. This also allows more interproximal tissue to be elevated to enhance the papilla height.

The soft tissue is reflected, and the crestal bone width of the ridge is evaluated. When a central incisor site is reflected, the palatal flap is reflected to the incisive foramen for identification and evaluation. On occasion, its position may require the soft tissue to be enucleated and a graft positioned in its site.

A 2-mm-diameter pilot drill is positioned in the midmesiodistal and faciopalatal aspect of the ridge and proceeds 9 mm within the bone under copious cooled sterile saline (Figure 33-29, *A*). A 9-mm-long force direction indicator is positioned into the site for evaluation (Figure 33-29, *B*). The stop on the direction indicator is often 4 mm in diameter and may be used to directly assess the amount of bone on the facial, palatal, mesial, and distal of the final implant position. A radiograph is taken, and the implant body position in relation to the adjacent roots and opposing landmark (i.e., floor of nose) is assessed. If corrections are required, then a side-cutting drill (i.e., Lindemann drill) may be used.

When the osteotomy may be extended to 12 to 15 mm, starting 3 mm below the free gingival margin of the future implant crown, the 2-mm-diameter drill is reinserted to the final depth position. Most often, the drill prepares the bone 1 to 2 mm deeper than the length of the implants (when the opposing landmark permits) (see Figure 33-29, *C*). This allows the implant

WWW.HIGHDENT.IR

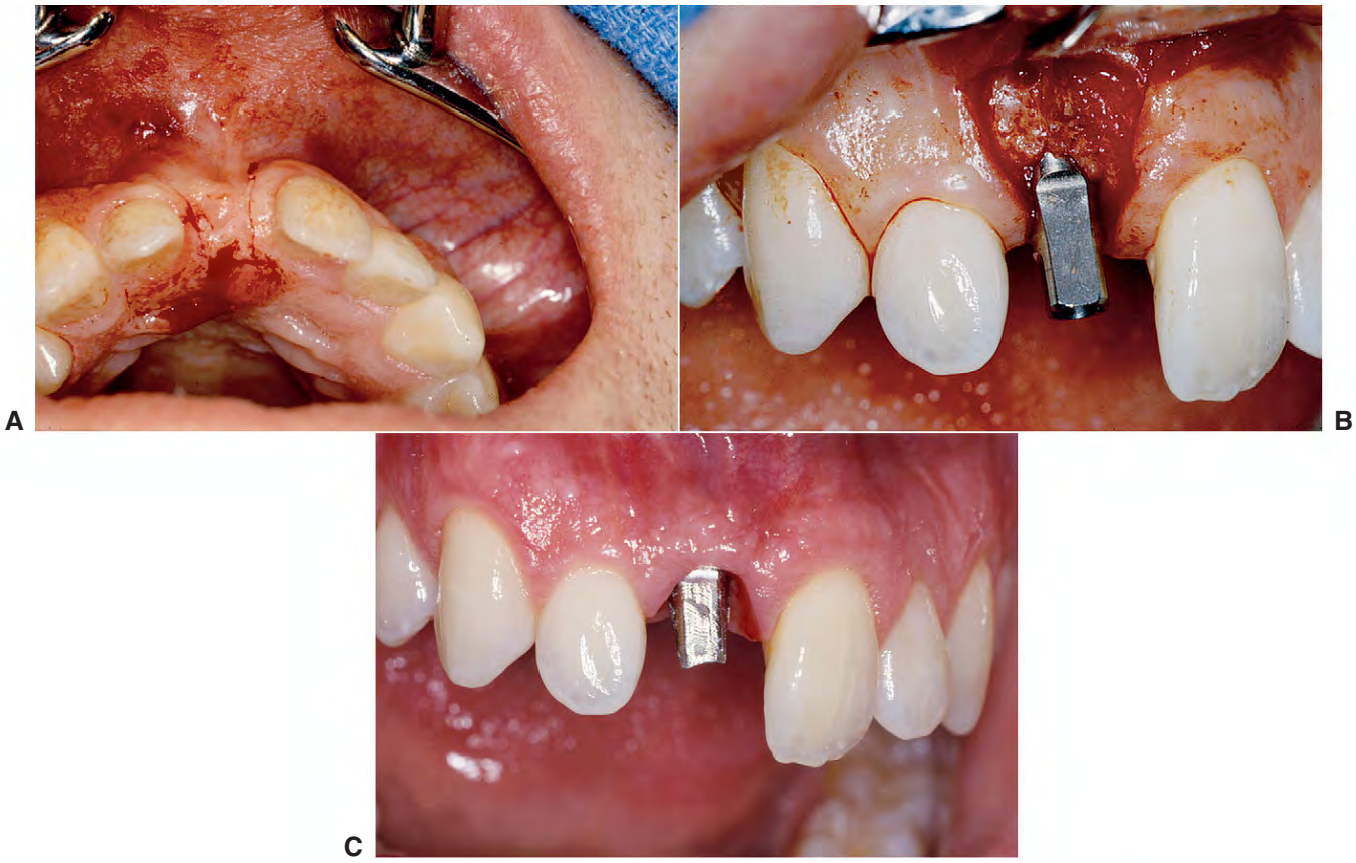

Figure 33-27 **A,** When the papillae are in an acceptable position, papilla-saving incisions are placed and the interdental papillae are not reflected for the implant surgery. **B,** The facial soft tissue is reflected to the mucogingival junction, and the central incisor implant is positioned slightly to the distal, 3 mm below the facial free gingiva margin. **C,** After initial healing and soft tissue contouring with a temporary crown, the soft tissue drape and implant components are ready for the final restoration.

to be rotated to a perfect position at the end of the procedure, without "bottoming out" at the end of the osteotomy, which may prevent the desired crestal position of the implant.

A 2.5-mm end-cutting twist drill, rotating 2500 rpm under copious amount of cooled sterile saline is then used to beyond the final depth. The drill is removed from the hand piece and reinserted into the osteotomy (see Figure 33-29, *D*). The top of the 2.5-mm drill should be directly under the incisal edge of the future implant crown. On occasion, it is slightly facial. This is because the more dense palatal bone has pushed the end-cutting drill facially to the less dense trabecular bone, rather than permitting its uniform preparation. When this occurs, the side-cutting drill is introduced into the osteotomy, and the palatal bone is removed by "shaving" up and down in the palatal aspect of the preparation.

A 3.0- and then a 3.4-mm-diameter end-cutting drill then prepare the site for a 4.0-mm diameter implant (the final drill of each implant system may be a slightly different dimension) (see Figure 33-29, *E* and *F*). Again, each drill is removed from the hand piece, inserted into the bone site, and evaluated as to position under the incisal edge. When facial, the side-cutting drill corrects its position.

A crestal bone drill is most often not used in the maxillary anterior region, because the bone is usually D2 or D3 and little to no cortical bone is found on the crest. This allows the implant to compress and slightly expand the bone in the crestal region of the implant site.

Once the final osteotomy diameter and depth is prepared, a bone tap is used in a low-speed, high-torque hand piece (i.e., 30 rpm, 70 N-cm) to form the threads within the bone for the implant (see Figure 33-29, *G*). This is an important step for all threaded implants. Because dense cortical bone is on the palatal aspect of the implant osteotomy, a self-tapping, threaded implant will tend to be pushed to the softer bone on the facial, and the implant will end up more facial (with less facial bone over the implant) than expected. In fact, even the bone tap may be pushed facially. Therefore once the tap is inserted to the final depth, it is removed from the hand piece and the angulation is evaluated relative to the incisal edge position of the future crown. When it is more facial than desired, a side-cutting drill is used to remove some of the palatal bone.

WWW.HIGHDENT.IR

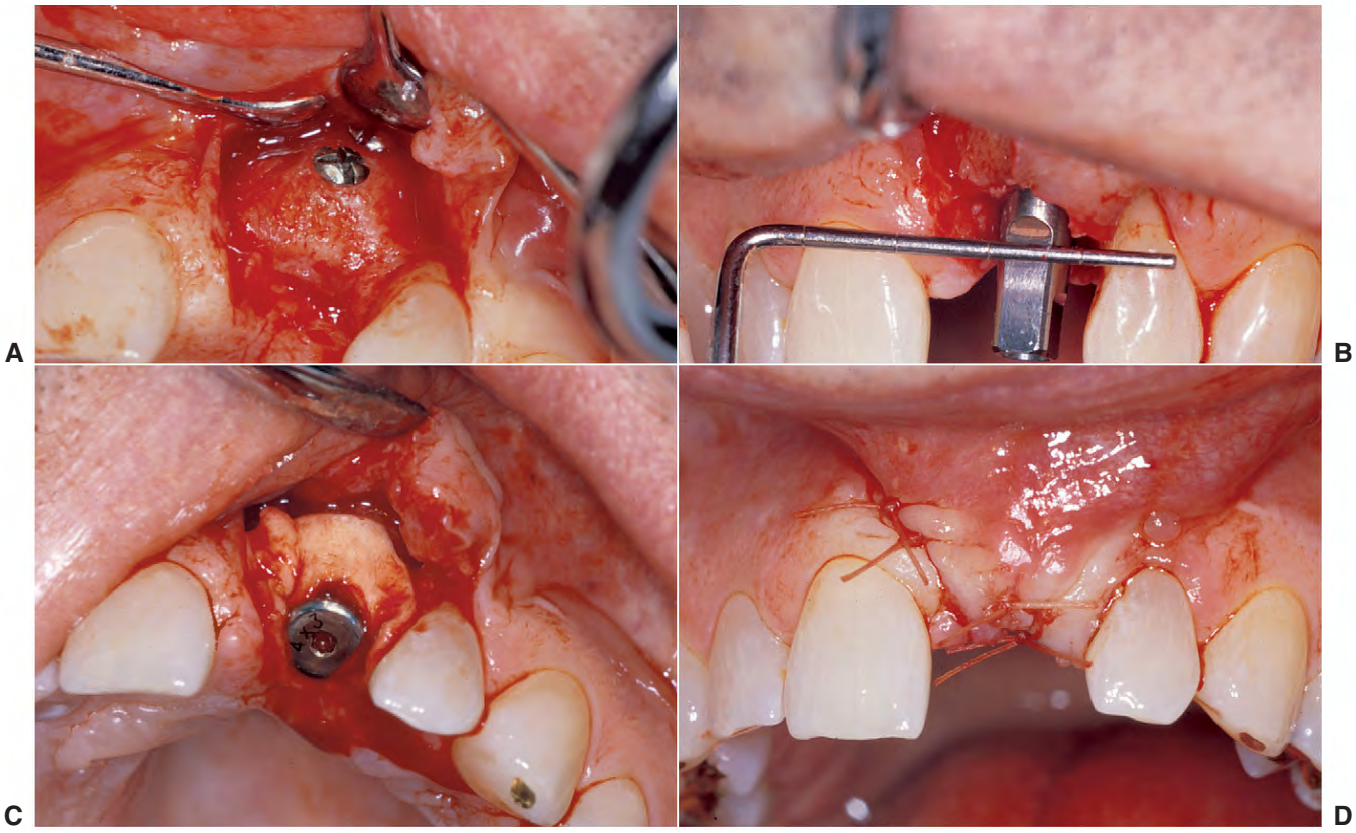

Figure 33-28 **A,** A papilla-saving incision is made to the mesial aspect. The incision to the distal included and reflected the papilla (which was depressed). **B,** The implant is positioned 3 mm below the free gingival margin of the implant crown. **C,** A 3-mm-high permucosal extension (PME) is placed into the implant body, and an acellular tissue graft (AlloDerm) is positioned around the PME to help augment the distal papilla and crest of the ridge. **D,** The tissue is elevated over the PME and membrane to increase the height of the crest and distal papilla.

The threaded implant is inserted with a hand piece at 30 rpm (see Figure 33-29, *H*). When the implant (or bone tap) is threaded by a hand wrench or with the surgeon's fingers, it is easily pushed more facial, without the awareness of the surgeon. When a hand piece is used, counterforces on the hand piece handle and the fingers of the other hand on the hand piece head may permit the implant to be inserted without compromise to angulation or position.

The implant is rotated in final position, with a flattening of the antirotational component to the facial. This position allows a greater thickness of metal on the abutment to the facial so that the restoring dentist may slightly prepare the facial aspect of the abutment when necessary, to allow a greater thickness for porcelain.

The implant mount may be removed, and the surgeon decides whether a low-profile cover screw or PME healing cap is used within the implant. When the hard and soft tissue contours are ideal and a papilla-saving incision was made, a permucosal abutment may be used. When a bone graft was placed and/or the crestal tissue elevated to increase the height of the papilla, a low-profile cover screw is more often used.

Once the cover screw is inserted, the surgeon decides whether a bone graft on the facial bone is indicated. When the facial bone over the implant is less than 1.5 mm thick, a particulate graft and a resorbable membrane may be used to augment the site (See Chapter 37). Most often the membrane is an acellular dermal matrix such as AlloDerm, because it will improve the bone graft site and also increase the tissue thickness.

SOFT TISSUE CLOSURE

As previously discussed, several different steps exist at which the soft tissue contour may be addressed. The ideal tissue height during initial implant healing is level with the height of the desired interdental papillae. A connective tissue graft or acellular dermal matrix (AlloDerm) material may be placed at the implant placement surgery under the facial and interproximal tissue to improve and/or thicken the contour of the soft tissue drape. The soft tissue is approximated and sutured with a resorbable material (4-0 or 5-0) around the PME or over the cover screw, depending on whether

WWW.HIGHDENT.IR

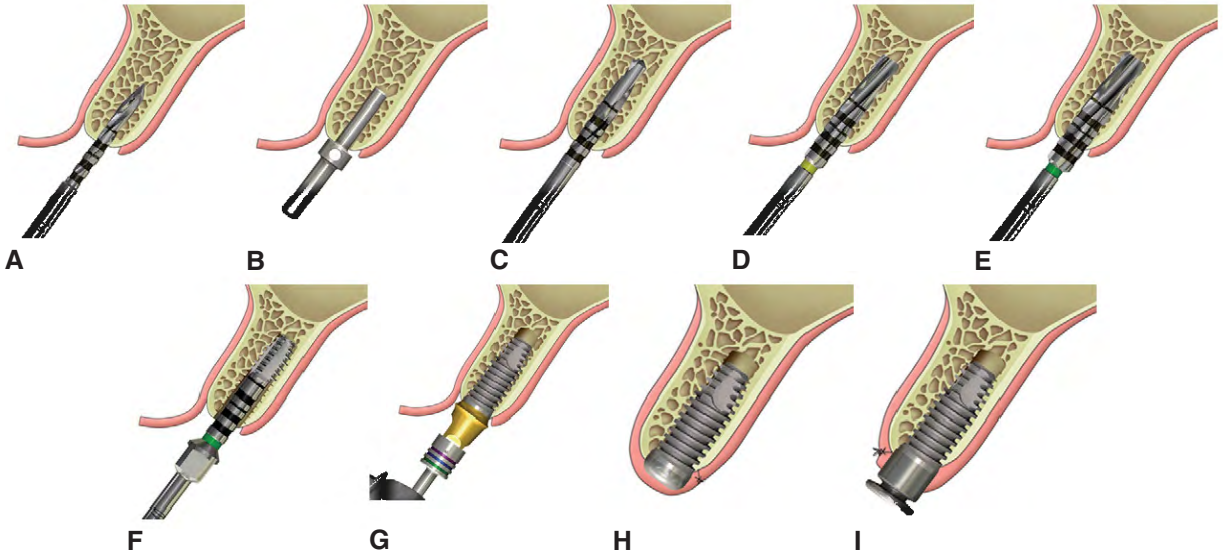

Figure 33-29 A 2-mm-diameter pilot drill is positioned in the midmesiodistal and faciopalatal aspect of the ridge and proceeds 9 mm within the bone under copious cooled sterile saline. **A,** A 9-mm-long force direction indicator is positioned into the site for evaluation. **B,** The 2-mm-diameter drill is reinserted to the final depth position. Most often, the drill prepares the bone 1 to 2 mm deeper than the length of the implants (when the opposing landmark permits). **C,** A 2.5-mm end-cutting twist drill, rotating at 2500 rpm under copious amount of cooled sterile saline, is then used to beyond the final depth. The drill is removed from the hand piece and reinserted into the osteotomy to evaluate the implant site angulation. **D,** A 3.0- and then a 3.4-mm-diameter end-cutting drill then prepare the site for a 4.0-mm-diameter implant (the final drill of each implant system may be a slightly different dimension). **E,** Once the final osteotomy diameter and depth is prepared, a bone tap is used in a low-speed, high-torque hand piece (i.e., 30 rpm 70 N-cm) to form the threads within the bone for the implant. **F,** The threaded implant is inserted with a hand piece at 30 rpm. **G,** The soft tissue is approximated and sutured with a resorbable material (4-0 or 5-0) around the permucosal extension or over the cover screw, depending on whether the tissue is at the right position or is being augmented **(H** and **I).**

the tissue is at the right position or is being augmented (see Figure 33-29, *H* and *I*). The increased tissue thickness from augmentation facilitates the sculpting of interdental papillae at stage II surgery, improves ridge contour, and prevents the grayish hue of the titanium implant body from showing through the labial mucosa in the event of crestal bone loss in the future.

The transitional prosthesis often needs to be relieved in the cervical region of the implant site during the healing period to accommodate the increased soft tissue height over the implant and to avoid pressure on the area over the implant body.

Transitional Prosthesis

It is strongly suggested that a resin-bonded fixed restoration be fabricated to provide improved speech and function, especially when crestal bone regeneration is performed. The soft tissue–borne transitional restoration enhances crestal bone loss during the graft healing, may cause bone loss around the implant during stage I healing (or even implant failure from the early loading), and may depress the interdental papillae of the adjacent teeth. As a result, a resin-bonded fixed prosthesis is fabricated for the extended healing, and a removable device may be used short term for cosmetic emergencies should the device become debonded. When a resin-bonded restoration is used, the adjacent teeth are not prepared and the device is bonded to the tooth regions below the centric occlusal contacts of the teeth.

The transitional restoration for the single-tooth implant has the benefits of being off the soft tissue drape, the developing bone augmented site, and the healing implant-bone interface. Other options exist besides the resin-bonded device that permit these goals. An Essix appliance is an acrylic shell, similar to a bleaching tray, that has a denture tooth attached to replace the missing tooth. This device is the easiest for tooth replacement after surgical procedures. When an adjacent tooth requires a crown in the overall treatment plan, the adjacent tooth may be prepared and a cantilevered transitional FPD with a pontic over the surgical site may be used. When the patient requires orthodontics, a denture tooth and an attached bracket may be added to the orthodontic wire. A cast clasp RPD with indirect rest seats to prevent rotation movements on the surgical site is also an excellent option.

IMMEDIATE IMPLANT INSERTION AFTER EXTRACTION

According to Kois,[36] five diagnostic keys exist for predictable single-tooth peri-implant esthetics when

WWW.HIGHDENT.IR

Table 33-2 Implant Placement in Extraction Site

IMMEDIATE	DELAYED
Advantages	
↓ Surgery	↑ Surgical control, position, angulation
↓ Time	↑ Hard tissue quality
↑ Maintenance of soft tissue	↑ Success, less risk of infection
Intraosseous bone graft	
Disadvantages	
↑ Facial bone loss after loading or during healing	Extended time for transitional
Implant too facial and/or angled abutment	Onlay graft may be needed at surgery

an immediate extraction and implant insertion is contemplated: (1) the tooth position relative to the free gingival margin, (2) the form of the periodontium, (3) the biotype of the periodontium, (4) the tooth shape, and (5) the position of the osseous crest before extraction. Therefore the soft tissue and bone comprise three of the five factors for predictable esthetics.

The goal of the anterior implant restoration is to simulate the appearance of a natural tooth. Adequate bone volume must be present for correct hard and soft tissue contours. Implant placement soon after initial alveolar bone healing or bone grafting is usually advantageous. As such, immediate implant placement in an extraction site has become a very popular topic[37-57] (Table 33-2).

Disadvantages

When placing an implant in an immediate-extraction site, the surgeon should consider the socket dimension and the defect between the labial plate of bone and the implant. The faciopalatal dimension of an anterior tooth is often greater than its mesiodistal dimension. When an anterior tooth requires extraction, during the extraction process the thin facial cortex often becomes compromised or lost. As a result, it is most always several millimeters apical to the palatal cortical plate, and frequently bone grafting and/or membrane placement in conjunction with the implant insertion are needed. Immediate implant placement in the anterior region using a round implant often requires that the osteotomy and implant insertion engage the lingual wall of the alveolus and penetrate halfway to two thirds of the way down the extraction site into the remaining lingual apical bone for rigid fixation. This surgical approach is more challenging than preparing the osteotomy in a homogenous bone density.

The best implant size is often 4 to 5 mm in diameter for a central incisor, and the extraction socket is often greater than 6 mm (especially in the faciopalatal dimension), so a surgical defect as large as 2 mm remains around the implant. More or less broad, oval- or kidney-shaped spaces have been described to run coronoapically along the entire surface of the socket next to the implant.[41] The natural resorption of the facial plate may not be halted by implant insertion, and bone-implant contact is reduced when the facial plate resorbs.[41a] When the facial bone is missing, the bone regenerated over the facial aspect of the implant with guided bone regeneration (GBR) is often immature woven bone, which is more prone to resorption because of occlusal overload. Typically, techniques for immediate implant placement after extraction include countersinking the implant 2 mm or more below the facial plate (which is already more apical than the palatal plate) and placing calcium phosphate ($CaPO_4$), resorbable HA, and/or autologous bone to fill the labial defect, with or without the addition of connective tissue grafts and/or membrane. Prolific literature proposing varied classifications and protocols has been published within the last 10 years.

The implant will obtain rigid fixation with nearly all of these techniques. However, the goal of the anterior single-tooth implant is not limited solely to rigid fixation. The inability to achieve proper esthetic and health parameters constitutes a compromised result and increased risk of esthetic or implant failure.[47] When the implant is countersunk below the facial bone, the implant platform may be as much as 4 mm apical to the CEJ of the adjacent teeth, which increases the anatomical crown height and the pocket depth, especially after crestal bone loss during the first year. In addition, synthetic grafts placed around the titanium implant grow less dense quality bone, which is also limited in implant contact. The capacity of this less dense bone promoted by barrier membranes around implants to withstand loading seems to be limited, and animal studies indicate as much as 85% may be lost after loading.[58] An explanation may be that no blood vessels arise from the implant; to the contrary, it reduces the number of bony walls of the defect and limits blood supply to the facial bone graft. As a result, bone is less likely to form, and when it forms it is less dense and more at risk of resorption once the implant is loaded.

Primary closure of the soft tissue provides a more predictable environment when grafting is performed on the facial aspect of the implant and may be difficult with the immediate extraction technique. Although not advocated, the labial tissue is often reflected to approximate the tissue over the socket defect. This technique further compromises the blood supply to the labial cortical bone and also decreases the amount of facial attached gingiva, because the facial tissues are placed over the extraction socket. As a consequence, a free tissue, subepithelial, or connective tissue graft may be indicated after stage I healing to restore the facial attached keratinized tissue.

WWW.HIGHDENT.IR

The labial bone usually remodels to 0.5 mm below the abutment to implant connection (which was, in most cases, already countersunk below the facial bone and several millimeters below the palatal bone). Bone loss may continue to the region of the first thread (as a result of the implant crest module design), then stabilize in a region of greater bone density. As a consequence, reports often illustrate soft tissue pocket depths greater than 7 to 8 mm at the midfacial tooth position. The presence of anaerobic microorganisms in soft tissue pockets of 5 mm or more has been documented. With good hygiene the soft tissue often recedes, with a resulting lengthened clinical crown and "black triangles" in the interproximal areas caused by the absence of properly developed interdental papillae, which compromises long-term esthetics and/or contributes to soft tissue complications.

An increased risk of postoperative infection exists around the implant with an immediate insertion, by the bacteria associated with the cause of tooth loss when judicious case selection has not been exercised. The presence of exudate lowers the pH, which causes a solution-mediated resorption of the grafted bone and contaminates the implant body with a bacterial smear layer, which in turn reduces bone contact.

An improved bone interface may be obtained if the large-diameter extraction site is grafted before implant placement. If the labial plate is compromised, then additional intraorally harvested bone and/or GBR are indicated. The delayed implant insertion method appears to enhance capillary propagation and trabecular formation before implant placement, facilitating the formation of an implant-bone interface.[59] Before grafting, the soft tissue granulates over the extraction site, thus creating an increased zone of attached gingiva. The result of the augmentation is evaluated before implant placement, rather than dealing with compromises after implant integration. In this way, the implant may be placed in an ideal position in relation to the crestal bone, and adjacent teeth and within the exact contours of the final restoration.

Advantages

The benefits of immediate implant insertion after tooth extraction are related to an improved preservation of the soft tissue drape and the bone architecture, compared with their collapse after tooth extraction. As a result, bone augmentation and soft tissue grafts may be avoided. The procedure has been described as a preservation technique aiming at maintaining the harmonious gingival architecture. The procedure also reduces the number of surgeries, which may decrease the cost to the patient. Whenever this technique is considered, the technique of orthodontic extrusion before extraction and implant insertion offers many benefits.

Teeth with a tapered crown form have a higher risk of soft tissue compromise after extraction. The tapered crown also has more interproximal bone between the teeth and more facial bone over the tapered root. As such, under perfect conditions, the tapered tooth form may be more advantageous for extraction and immediate implant insertion. Therefore under the best conditions, which include lack of pathology, thick gingival tissues, ideal bone contours, ideal soft tissue contours, and tapered tooth forms, an immediate implant insertion after tooth extraction is considered.

A square tooth form has less gingival shrinkage after extraction and exhibits less scalloping of the interproximal and facial bone with adjacent tooth roots. There is also less bone between the roots and larger spaces between the extraction site and the implant. As a result, an immediate implant insertion after extraction offers less benefit for the soft tissue and greater risk for the implant-bone interface. Therefore root extrusion before extraction, or extraction with a delayed implant insertion, is more often considered.

Technique

When ideal conditions for an extraction and immediate implant insertion are present, the following scenario may occur. First of all, the patient is informed that the procedure may be aborted and only a bone graft may occur. The surgeon does not want to compromise a 30-year prosthesis simply to avoid waiting an additional 3 to 6 months.

The tooth is removed with periotomes, a class I lever forceps (Physics Forceps, Detroit, Mich.), and/or other atraumatic procedure. The surrounding walls of bone are evaluated, and confirmation of an intact, noninfected boney socket is made (Figure 33-30).

The best position for the implant is under the incisal edge, in the midfaciopalatal and mesiodistal center. This does not coincide with the root apex position; therefore a pilot drill penetrates the palatal incline of the root, approximately two thirds of the way down from the crest, slightly more palatal than desired, to the depth of 12 mm (Figure 33-31). The drill is then repositioned under the incisal edge of the future crown. A radiograph with a force direction indicator (or the drill removed from the hand piece) in place confirms its mesiodistal position relative to the adjacent roots and the opposing landmark.

Once the correct position is confirmed, the 2-mm twist drill prepares the osteotomy to the opposing landmark, up to 18 mm (Figure 33-32, *A* and *B*). The drills overprepare the depth of the osteotomy so that the apical bone may be harvested from the drill. The side-cutting drills are used as previously indicated, to keep the osteotomy under the incisal edge. The final length implant is usually 12 to 15 mm long. The incremental drills prepare to this final length and diameter (Figure 33-32, *C*). The bone tap is used to this final depth, as previously presented (Figure 33-33).

The bone harvested from the cutting drills is then positioned within the osteotomy, primarily on the inner facial wall, where the largest defect is present (Figure 33-34). The implant is threaded into position

WWW.HIGHDENT.IR

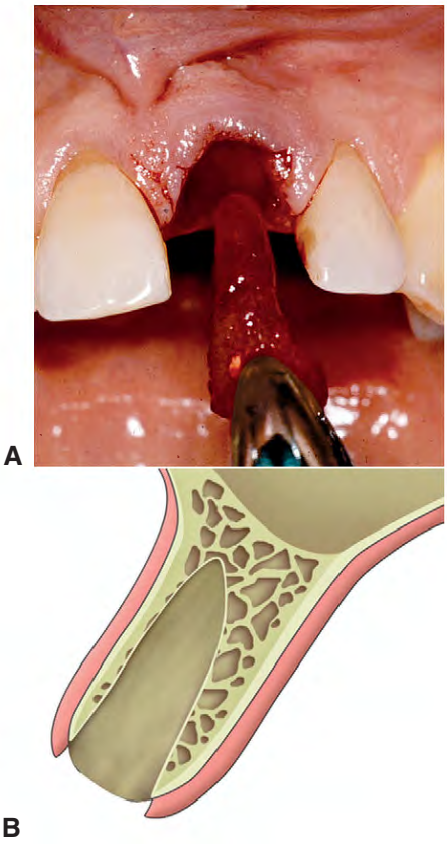

Figure 33-30 The patient's left maxillary incisor is atraumatically extracted **(A).** The surrounding walls are evaluated and confirmed to be intact and free of infection **(B).**

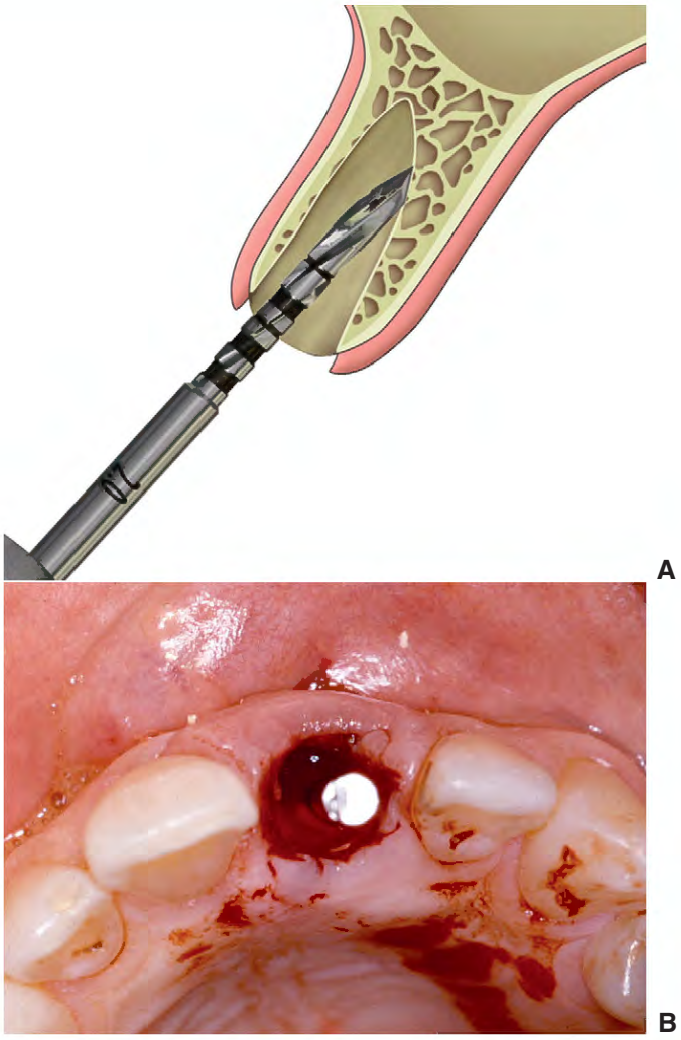

Figure 33-31 **A,** A 2-mm pilot drill first prepares the initial osteotomy two thirds of the way down from the crest and through the thick palatal cribiform plate. **B,** The drill is then rotated to prepare the site under the incisal edge of the future implant crown.

using a slow-speed, high-torque hand piece and no irrigation. Some of the bone graft will be pushed to the apex of the osteotomy (Figure 33-35). However, because it is deeper than required, it does not impede the implant seating in its final position. Therefore the implant is in the correct position, and the socket defects are filled with autologous particulate bone.

A PME has a higher profile than the cover screw. A 4.5-mm PME placed into the implant helps to support the tissue above the crest of bone (Figure 33-36). Once the PME is inserted into the implant, the transitional prosthesis is delivered. The primary motivator for immediate implant insertion after extraction is to maintain the soft tissue drape. Therefore the PME and/or the transitional device should fill the emergence contour, without voids or compression to the soft tissue (Figure 33-37).

STAGE II SURGERY AND SOFT TISSUE EMERGENCE CONTOURS

The clinician should use radiographs to closely evaluate the crestal mesial and distal bone-implant interface relative to an absence of crestal bone loss before the abutment post is added to the implant body. Probing is necessary to evaluate the facial and palatal conditions. If bone loss is suspected, then the tissue should be reflected for direct evaluation. Correction of a cervical horizontal defect includes local autogenous grafts covered with a barrier membrane and reapproximation of the soft tissue. For a vertical defect less than 2 mm, autogenous bone may be added and the uncovery of the implant may proceed, because bone growth is more probable in the presence of the lateral walls of bone.

Before the stage II uncovery procedure, the soft tissue drape may be modified: (1) before a bone graft procedure, (2) in conjunction with the bone graft in the implant site, and (3) at the time of implant insertion. The fourth time in this sequence that the tissue may be addressed is at the stage II uncovery procedure.

When the implant-bone interface is acceptable, the exposure of the implant body should be accomplished with the soft tissue final architecture in mind. To achieve

WWW.HIGHDENT.IR

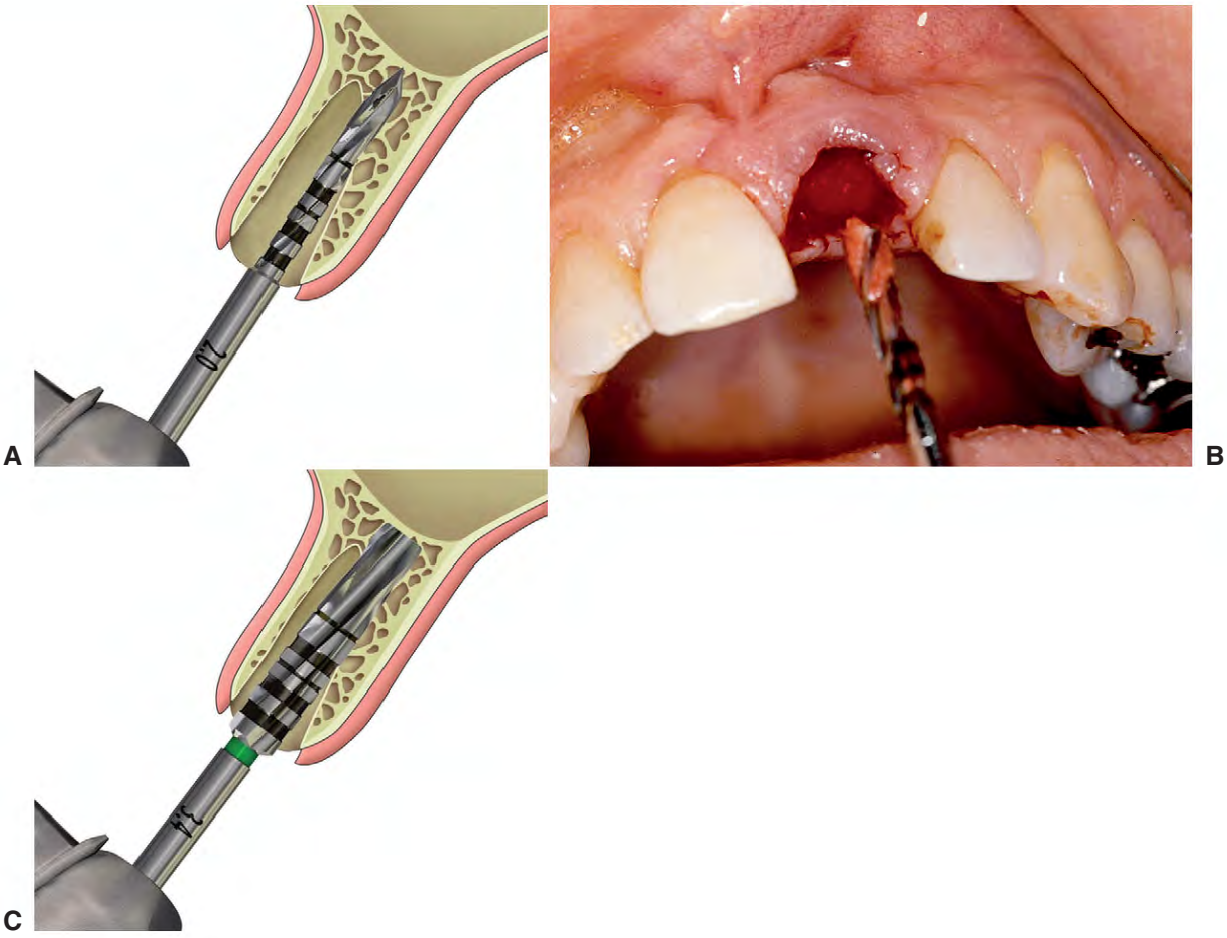

Figure 33-32 The implant drills prepare the site to the floor of the nares **(A)** and harvest bone beyond the tooth apex **(B).** The osteotomy is kept in an angulation aligned with the incisal edge of the adjacent teeth **(C).**

Figure 33-33 A bone tap is used to final depth using a hand piece.

the proper soft tissue architecture, several options are available, depending on the soft tissue appearance before stage II uncovery (Box 33-2). These soft tissue procedures may be classified as *subtractive, additive,* or *a combination of each.*

Subtractive Technique

When the soft tissue along the edentulous crest is at the level of the desired interdental papillae and is of sufficient quality and volume, a subtraction technique (e.g., gingivoplasty with a coarse diamond) sculpts the crestal gingival tissues to reproduce the cervical emergence contour of the crown, complete with interdental papillae and proper labial gingival contour (Figure 33-38). The contour of the midfacial position of the tissue is 1 mm more incisal than the contour of the adjacent teeth to allow for the gingival shrinkage commonly observed during the first year of implant loading. The interdental papilla zones are also made slightly larger than the final desired form to accommodate possible shrinkage.

Addition Technique

If the gingival contour at stage II uncovery is insufficient for the proper architecture for the interdental papillae, then an additive surgery is performed to gain tissue thickness. Several addition techniques have been proposed.[60-65] For example, an incision is made on the palatal aspect of the ridge, from the palatal angle of each adjacent tooth; a

Figure 33-37 After a 4-month healing period, the implant is ready to be restored.

release incision can also be made in the midline to the height of the facial gingival contour desired. The tissue is elevated from the crest of the ridge, and the first-stage cover screw is identified. Once removed, a low-profile healing cap of 3 mm is inserted. A connective tissue graft or AlloDerm is placed around the low-profile healing cap. The crestal tissues are then draped over the healing cap and sutured to the palatal tissue. The tissue heals by secondary intention in the palatal area, and excess tissue forms on the facial and interproximal regions. After 4 to 6 weeks, a stage II uncovery and gingivoplasty (both subtraction techniques) is performed to the contour of the desired crown emergence profile.

An alternative stage II uncovery procedure developed by the author is called the *split-finger technique*.[65] An incision is made in the gingival sulci of the adjacent teeth. The incision is started at the distolingual line angle of the adjacent teeth and forms a loop at the facial emergence location of the implant crown. This creates two "fingers" at least 2 mm in width adjacent to each natural tooth. Once elevated, these two facial fingers will become the facial aspects of the interdental papillae. A central palatally supported finger is also created. The tissues are then elevated, and the implant cover screw is exposed and replaced with an abutment. The palatal finger may then be split into two segments (i.e., the split-finger approach). Each segment is rotated to the interproximal region to support the elevated facial fingers. A 4-0 or 5-0 modified mattress suture positions the papillae in the proper location, next to a transitional crown (Figures 33-39).

When additional height is required, the split-finger technique may be used in conjunction with a connective tissue graft or AlloDerm to further augment the tissue height. This procedure may also be performed at insertion surgery, when a one-stage approach is desired.

Once the soft tissues are subtracted or added to obtain the desired emergence contour, the surgeon has primarily two options to maintain this region. The first option is that a PME abutment may be inserted. Its size and shape should be smaller than the cervical contour of the final crown and extend through the tissue 1 to 2 mm. The emergence of the PME abutment will develop the initial soft tissue form. A wide-profile PME abutment should not be used, because it may cause gingival shrinkage and limit the restoring dentist's ability to shape it into its ideal form. A transitional prosthesis is recontoured to fit over the healing cap for the next few weeks, until the patient is seen for the first prosthetic appointment. The soft tissue heals to the contour of the healing abutment or permucosal device. The patient is referred to the restoring dentist for fabrication of the final crown after 4 to 6 weeks of tissue maturation. This

Box 33-2 Flow Pattern for Maxillary Anterior Single-Tooth Replacement

I. Treatment plan
  A. Single-tooth implant FPD
    1. Mobile abutments
    2. Inadequate bone height, including adjacent teeth
    3. Inadequate mesiodistal space
    4. Fear of multiple surgeries
    5. Cost
  B. Adjacent remaining teeth
II. Transitional device
  A. Removable
    1. Essix
    2. Flipper
    3. Clasp, cast RPD with rests
  B. Resin bonded
  C. Orthodontic wire and denture teeth
  D. Transitional cantilevered prosthesis from adjacent tooth requiring crown
III. Implant site development
  A. Orthodontics
    1. Space (mesiodistal)
    2. Tooth extrusion
    3. Soft tissue enhancement
  B. Soft tissue augmentation
  C. Bone augmentation
IV. Soft tissue incisions, wire, and reflection
  A. Papillae saving
  B. Ridge elevation
V. Implant size
  A. Implant 1.5 mm from each adjacent tooth
  B. Implant 1.5 mm from facial plate and 1 mm from palatal plate
  C. Usual size 4.3 mm for centrals, 3.0 to 3.7 mm for laterals, 4.2 mm for canines
VI. Implant body position
  A. Midmesiodistal—if central incisor, then incisive foramen size and position evaluated
  B. Midfaciopalatal
  C. Angulation—one half in front, two thirds behind incisal edge of implant crown to midfaciopalatal
  D. Depth—position should be 3 mm below facial free gingival margin of future implant crown
VII. Soft tissue and implant healing approach
  A. Primary closure
  B. One stage—PME added
  C. Soft tissue crest elevated—PME added and covered with soft tissue
  D. Nonfunctional immediate restoration
    1. Abutment added
    2. Cemented crown out of occlusion
VIII. Stage II uncovery and soft tissue
  A. Subtraction technique (canine soft tissue drape)
  B. Addition technique
    1. Split-finger approach
    2. Crest elevated and PME added as "tent pole" for soft tissue
IX. Abutment selection
  A. Manufacturer straight abutment
  B. Custom abutment
    1. Laboratory prepared
    2. Porcelain on abutment
X. Final crown

FPD, Fixed partial denture; *RPD,* removable partial denture; *PME,* permucosal extension.

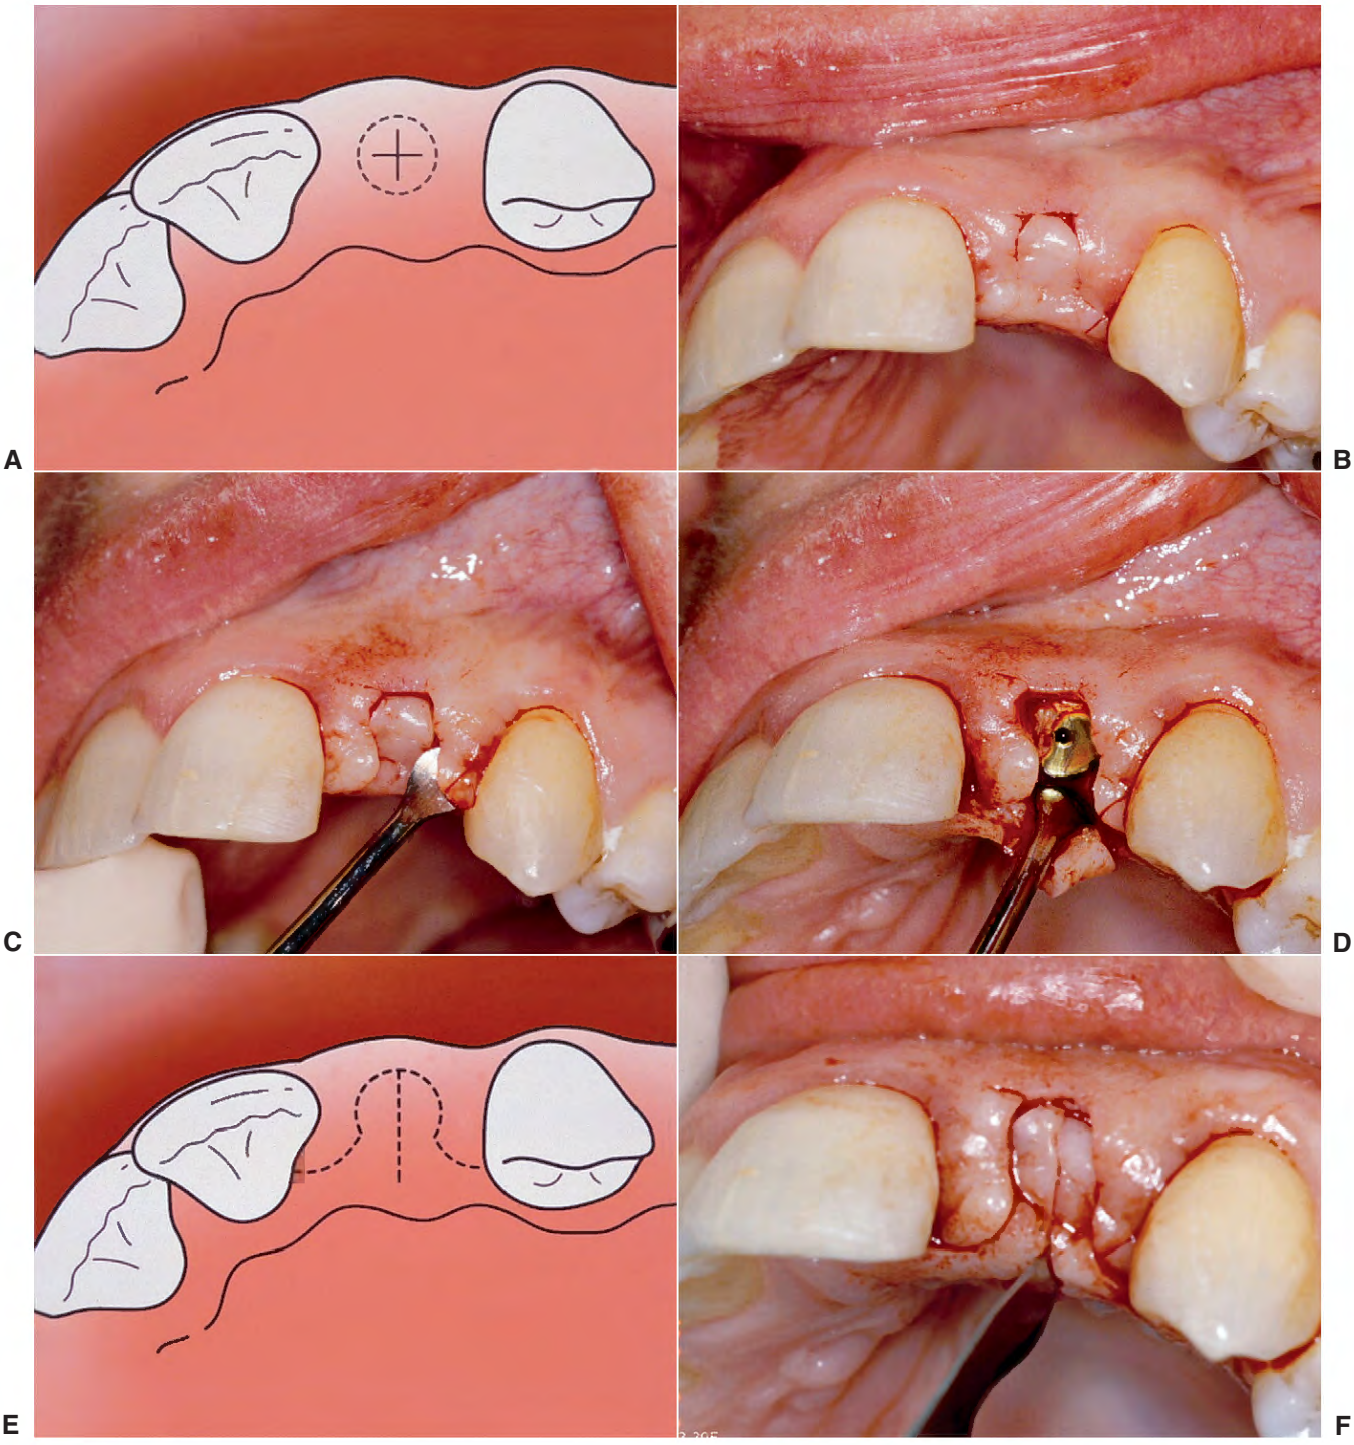

Figure 33-39 **A,** When the desired papilla height is almost perfect, a split-finger technique may be used. **B,** An incision is made in the sulcus of the adjacent teeth and continues from the palatal aspect of each tooth for 1.5 to 2.0 mm and loops to the facial, parallel to the adjacent interproximal teeth. The incisions then connect on the facial aspect at the desired midfacial emergence of the crown. **C,** The facial fingers are elevated facially. **D,** The palatal finger is reflected palatally. **E,** The palatal finger is split into two sections (mesial and distal). **F,** This creates four interfacing fingers (two on the facial and one toward the palate).

Continued

is the simplest option when using the team approach to implant dentistry.

In addition to the implant insertion, the surgeon may elect to make an impression to aid the restoring dentist in the fabrication of the abutment and crown. An additional silicone impression may be made at the implant insertion appointment or at the uncovery appointment, with an indirect impression transfer placed into the implant body. The indirect impression transfer is removed from the implant, connected to

WWW.HIGHDENT.IR

the implant body analog, and reinserted into the impression. A PME is inserted into the implant, and the patient is discharged.

A master cast is made in the laboratory from the impression. The laboratory may fabricate a soft tissue model and/or fabricate or select the abutment and fabricate a transitional or possibly final prosthesis. The soft tissue model may be modified in the laboratory to represent the contour of the desired final soft tissue and restoration. An abutment is placed and modified in the implant body analog, and a provisional restoration is fabricated to the soft tissue contour created on the model.

The patient returns to the restoring dentist after 14 days or more. The laboratory-created final abutment and temporary restoration are inserted, and the soft tissues are allowed to achieve full maturation around the best contours of the transitional restoration before

WWW.HIGHDENT.IR

Figure 33-40 The most common esthetic complication is the inadequate soft tissue drape around an implant crown. The patient's left central incisor exhibits black interproximal spaces.

making the final restoration. The advantage of this procedure is that the laboratory may select and prepare the final abutment, or it may fabricate a custom post and fabricate the transitional prosthesis with an ideal emergence profile to encourage maturation of the soft tissue in its final position.

When the surgeon is also the restoring dentist or is able to make a fixed transitional crown; the initial restoration appointment may be combined with the stage II uncovery procedure. A prefabricated, machined two-piece abutment is placed into the implant body at the conclusion of the soft tissue recontouring. The antirotational hex is engaged, and the abutment screw is hand tightened to approximately 5 to 10 N-cm (or moderate hand force). A periapical radiograph is taken of the crest module and abutment connection region to ensure proper component fit. Once confirmed, the abutment screw is then secured at 20 to 30 N-cm, while a hemostat holds the abutment with a countertorque resistance to reduce the shear forces to the crestal bone. The post is prepared in situ similarly to an anterior tooth preparation, with juxtagingival or supragingival margins. A transitional single crown is then fabricated completely out of occlusion. The soft tissue is then permitted to heal, using the transitional crown to help form the soft tissue drape.

COMPLICATIONS

The primary esthetic complications of maxillary anterior single-tooth implants include interdental papillae deficiency and gingival shrinkage after crown delivery.

Interdental Papilla Deficiency

The interproximal CEJ of a natural tooth exhibits a reverse scallop toward the incisal edge. The same pattern is followed by the alveolar interproximal bone, which is more coronal in the interproximal regions than in the facial or lingual plates. As a consequence, the probing depth in the papilla region of a natural tooth is quite similar to the facial or palatal probing depths. Interproximal bone around an implant does not follow such a contour. As a result, the interdental papillae, which look natural and rise to fill the interproximal regions between healthy adjacent teeth, exhibit greater probing depths than the other surfaces of the implant crown. In fact, because the interproximal bone height also may be lost next to the adjacent teeth, the dental and implant papilla also correspond to a greater proximal probing depth next to the natural tooth. A greater sulcus depth increases the risk of shrinkage after gingivoplasty, or later, even with good daily care. As a result, even years later the tissue may shrink and result in a poor interproximal esthetic situation (Figure 33-40).

As previously addressed, four surgical time sequences exist to address the interproximal tissue height: (1) before a bone graft with a connective tissue graft; (2) in conjunction with a bone graft, often using an acellular tissue graft (i.e., AlloDerm); (3) at implant insertion, with an elevation of the tissue over a PME; and (4) at implant uncovery (i.e., split-finger technique). There are several other methods to improve the soft tissue drape. These approaches used to modify the soft tissue are prosthetic-related methods.

The most common prosthodontic solution to alleviate soft tissue limitations is helpful when soft tissue surgery has not recreated an ideal interproximal papilla height. The interproximal region may be treated similarly to the pontic interproximal region of a three-unit FPD (Figure 33-41). Rarely are interdental papillae present next to the pontics of a fixed prosthesis. Instead, rather than raising the tissue to the interproximal contact of the crown, the interproximal contact is extended toward the tissue, and the cervical region of the pontic is slightly overcontoured. A similar approach may be applied to the single-tooth implant. The interproximal contacts of the adjacent teeth are recontoured, especially on the palatal line angle, to become oblong and extend toward the tissue. The contact areas of the single-tooth crown are extended, especially on the palatal line angle, toward the gingiva. The cervical region of the single-tooth implant is slightly overcontoured in width, similarly to the pontic of a fixed prosthesis. This concept does slightly compromise the interproximal esthetics. The papilla is not as high next to the implant crowns as it is between the natural teeth, and the cervical width of the crown is 0.5 mm wider.

However, the sulcus depth is reduced on the tooth and implant crown, and the daily hygiene conditions are improved. In addition, long-term shrinkage of the tissue is less likely to occur. This option should be the method of choice whenever possible and especially when the high lip position during smiling does not display the gingival regions around the teeth.

WWW.HIGHDENT.IR

Figure 33-41 **A,** A prosthetic solution for inadequate papilla height is to lower the interproximal contact of the crown by reshaping the adjacent teeth. **B,** The canine implant crown fills the space and eliminates the interdental spaces caused by the lack of papilla height.

SUMMARY

The replacement of a single tooth in the premaxilla is challenging because of the highly specific soft and hard tissue criteria, in addition to all other esthetic, phonetic, functional, and occlusal requirements. Anterior tooth loss usually compromises ideal bone volume and position for proper implant placement. Implant diameter, compared with that of natural teeth, results in challenging cervical esthetics. Unique surgical and prosthetic concepts are implemented for proper results. In spite of all the technical difficulties that the restoring dentist may face, the anterior single-tooth implant is the modality of choice to replace a missing anterior maxillary tooth.

Chapter 34

Premaxilla Surgery: Implant Insertion, Bone Spreading, Nasal Floor Elevation, and Incisive Foramen Implants

Carl E. Misch

INTRODUCTION

Seventeen percent of the U.S. population (30 million adults) has no maxillary natural teeth. A large segment of the population is also missing multiple maxillary anterior teeth, often from trauma or failed fixed partial dentures (FPDs). Therefore the premaxilla is a region often in need of implant abutments for either fixed or overdenture prostheses. In a 20-year review of the literature by Goodacre et al., restorations associated with the edentulous maxillae have the highest early implant failure rate (19% for overdentures and 10% for fixed prostheses). In comparison, mandibular overdentures or fixed restorations have some of the highest implant survival rates (3% failure rate).[1]

Several factors affect the condition of the edentulous maxilla and may result in a decrease in implant survival or an increase in surgical complications. After tooth loss, the facial cortical plate rapidly resorbs during initial bone remodeling, and the anterior ridge loses 25% of its width within the first year, as well as 40% to 50% within the next 3 to 5 years, mostly at the expense of the labial contour. As a result, the residual available bone migrates to a more palatal position.[2-7] The farther forward the maxillary anterior teeth are positioned from the more palatal bone position implants, the greater the moment force leverage on the bone-implant interface, abutment screws, and implants. Coupled with an angled force in both centric and excursions, more stress is transmitted to premaxillary implants than those in anterior mandibles. This often mandates more implants and larger-diameter implants with bone augmentation by bone-spreading or bone graft procedures before or in conjunction with implant placement.

In most patients with available bone, the bone is less dense in the anterior maxilla than in the anterior mandible. The maxilla presents thin porous bone on the labial aspect, very thin porous cortical bone on the floor of the nasal and sinus region, and a more dense cortical bone on the palatal aspect.[8,9] The trabecular bone in the premaxilla is usually fine and less dense than the anterior region of the mandible. This usually results in more overload implant failures or crestal bone loss. However, this type of bone lends itself to bone spreading or a compaction technique to insert implants.

In the anterior maxilla, the moderately resorbed bone categories of Division B to C–w often remain narrow almost to the floor of the nose; therefore osteoplasty to gain width is inappropriate. Once the tissues are reflected, the unusual anatomy may confuse the surgeon, and the resultant angulation of implant insertion complicates the restoration of the prosthesis (Figure 34-1). On occasion, osteoplasty to gain bone width results in a Division C–h or D bone volume. The incisive foramen may be used as an implant site in a C–w or C–h bone volume. Nasal elevation and implant insertion may also modify the opposing landmark in C–h bone volume. Therefore unique force factors and implant insertion procedures are more often observed in the anterior maxilla compared with the anterior mandible.

PREMAXILLA EDENTULOUS TREATMENT PLANS

Key Implant Positions

If a patient desires a fixed restoration, implants are required whenever any of the following three combinations of adjacent teeth are missing: (1) the first premolar, canine, and lateral incisor; (2) the canine,

WWW.HIGHDENT.IR

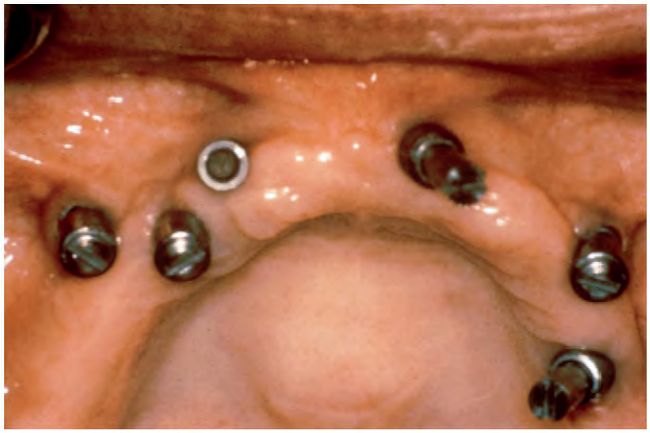

Figure 34-1 The maxillary bone often remains narrow to the floor of the nose. As a consequence, osteoplasty to gain width is often inappropriate. The surgical placement of implants in bone of minimal width is more challenging and may result in poor angulation and difficulty in restoring the implants.

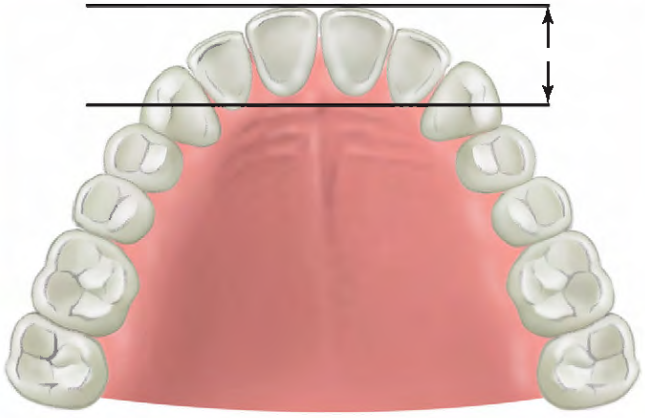

Figure 34-2 Two parallel lines perpendicular to the midline are drawn in the premaxilla to determine the dentate arch form. The anterior line is through the facial aspect of the central incisors. The posterior line is drawn through the tips of the canine cusps. A distance between these two lines of less than 8 mm is a square dentate arch form. An ovoid dentate arch form is 8 to 12 mm. A tapered dentate arch is more than 12 mm.

lateral incisor, and central incisor; and (3) the canine, first premolar, and second premolar. When any of these conditions exist, a fixed restoration is contraindicated because of the length of the span (three pontics), the amount of force (forces greater in the canine region compared with the anterior region), and the direction of the force (angled forces to the canine region).[10]

Under the condition of a missing canine and two adjacent teeth, at least two implants are indicated to support an independent fixed restoration (usually in the terminal positions of the span to eliminate cantilever forces). Therefore the canine implant position is one of the more important key positions in an edentulous premaxilla.

When one canine region cannot be used to place an implant in the edentulous premaxilla, at least one implant on each side of the missing canine is required to compensate for this vital position (a first premolar and lateral incisor implant). An incisor and canine position implant in the contralateral section can be splinted to these other two implants to act as abutments for the fixed or overdenture restoration in the edentulous premaxilla.

PREMAXILLA ARCH FORM AND IMPLANT NUMBER

The distance between two horizontal lines, drawn from the two canine tips and the facial of the central incisors, determines the dental arch form in the anterior maxilla. (Figure 34-2). A distance less than 8 mm corresponds to a square dental arch form. Lateral and central incisors are not cantilevered very much facially from the canine position, and therefore mandibular excursions and occlusal forces exert less stress on the canine implants.

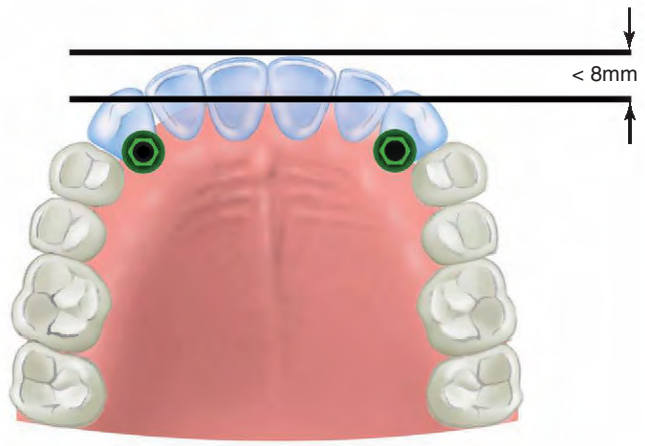

Figure 34-3 In a square arch form, implants in the canine region splinted to posterior implants may be sufficient with low patient force factors because the anterior cantilever is less than 8 mm.

Implants in the canine positions to replace the six anterior teeth may suffice when the force factors are low and if they are splinted to additional posterior implants (Figure 34-3).

An ovoid dentate arch form corresponds to a distance from the canine to central incisor horizontal lines between 8 and 12 mm. At least three implants should be inserted into the premaxilla, one in each canine and preferably one in a central incisor position (Figure 34-4). The central incisor position increases the anteroposterior (A-P) distance from the canine to central and provides improved biomechanical support to the prosthesis. In long-term edentulous maxillae, this most likely will require bone augmentation before implant insertion (Figure 34-5). When patient force factors are low to moderate, the anterior implant may be positioned in a lateral incisor site.

WWW.HIGHDENT.IR

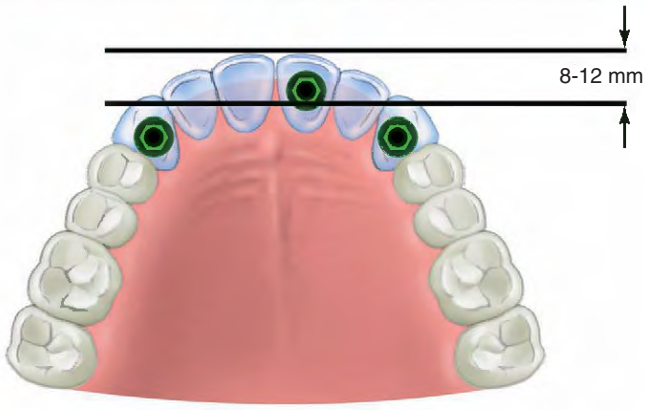

Figure 34-4 An ovoid dentate arch form has implants in the canine and an additional implant in the premaxilla. When posterior teeth are missing, additional posterior implants splinted to the anterior component are necessary.

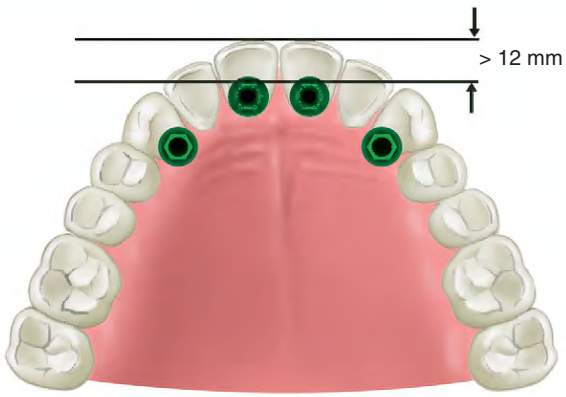

Figure 34-6 A tapered dentate arch form is subject to greater anterior moment forces, because the teeth are cantilevered farthest from the canines. As a result, two canine and two additional implants are usually indicated in the premaxilla.

Figure 34-5 **A,** An FP-3 prosthesis for an ovoid arch form. **B,** An intraoral view of maxillary and mandibular FP-3 prostheses. **C,** A panoramic radiograph of the FP-3 prostheses. The maxilla was restored with an iliac crest graft and bilateral sinus grafts. Three implants are found in the premaxilla (canines and central incisor) splinted to posterior implants. **D,** The high smile line lip dynamics of the maxillary FP-3 prosthesis.

When the distance between the canine and central incisor horizontal lines is greater than 12 mm, the dentate arch form is tapering and the restoration of a tapered dental arch form places the greatest forces on anterior implants, especially during mandibular excursions (Figure 34-6). The anterior teeth create a significant facial cantilever from the canine position. As such, four implants should be considered to replace the six anterior teeth. When more than six anterior teeth are missing, additional posterior implants should also be splinted to the anterior segment (Figure 34-7).

As a consequence of bone resorption, the residual ridge form becomes more squared. The edentulous ridge arch form may be different from the dentate arch form (which is determined by the final teeth position in the premaxilla and not the arch shape of the residual

WWW.HIGHDENT.IR

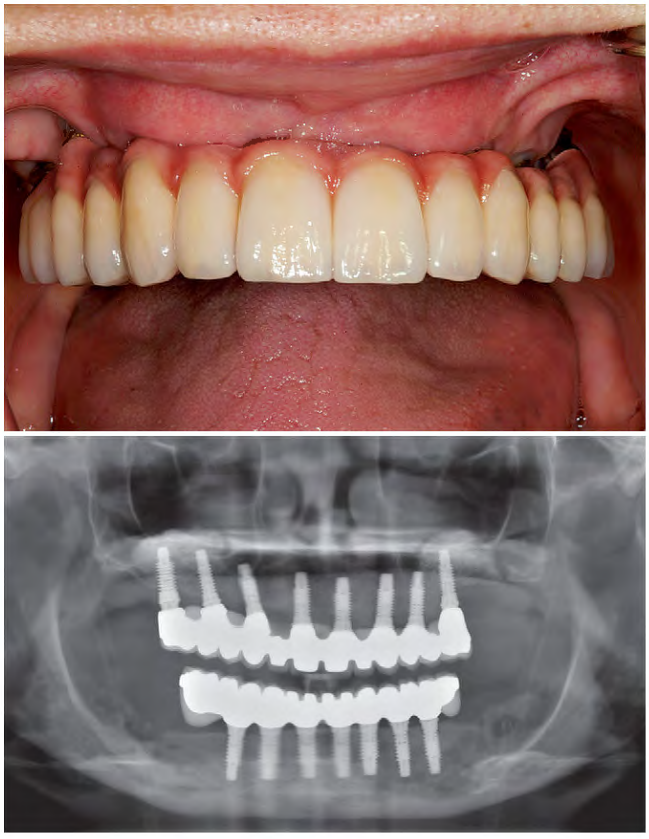

Figure 34-7 **A,** An intraoral view of the maxillary FP-3 prosthesis. The edentulous maxilla with an ovoid to tapered dentate arch form should have three to four implants in the premaxilla and additional posterior implants to support a full-arch prosthesis. **B,** A panoramic radiograph illustrating a cantilevered restoration in the mandible and a fixed maxillary restoration with four anterior implants and four posterior implants splinted together without a cantilever.

ridge). The number and position of implants are related to the arch form of the final dentition (restoration), not the existing edentulous arch form. The worst-case scenario is a patient requiring restoration of a dental tapered arch form with a square residual ridge form. When force factors are greater than usual in any arch form, four implants in the premaxilla should be splinted together and share any lateral forces during excursions. In this patient condition, four implants in the premaxilla are required to compensate for the cantilevered anterior tooth position. These implants should be connected to additional posterior implants, preferably to include implants as far distal as the second molar sites, to increase the A-P position of the implants (Figure 34-8).

The edentulous square-to-ovoid residual bone arch form dimension often does not accommodate interimplant spacing for more than four anterior implants. The largest interimplant distance is typically found in a tapered arch form. As the radius of the circle becomes smaller (from labial resorption, arch shape, and/or patient size), the premaxilla interimplant distance is reduced. As a result, no more than four implants are

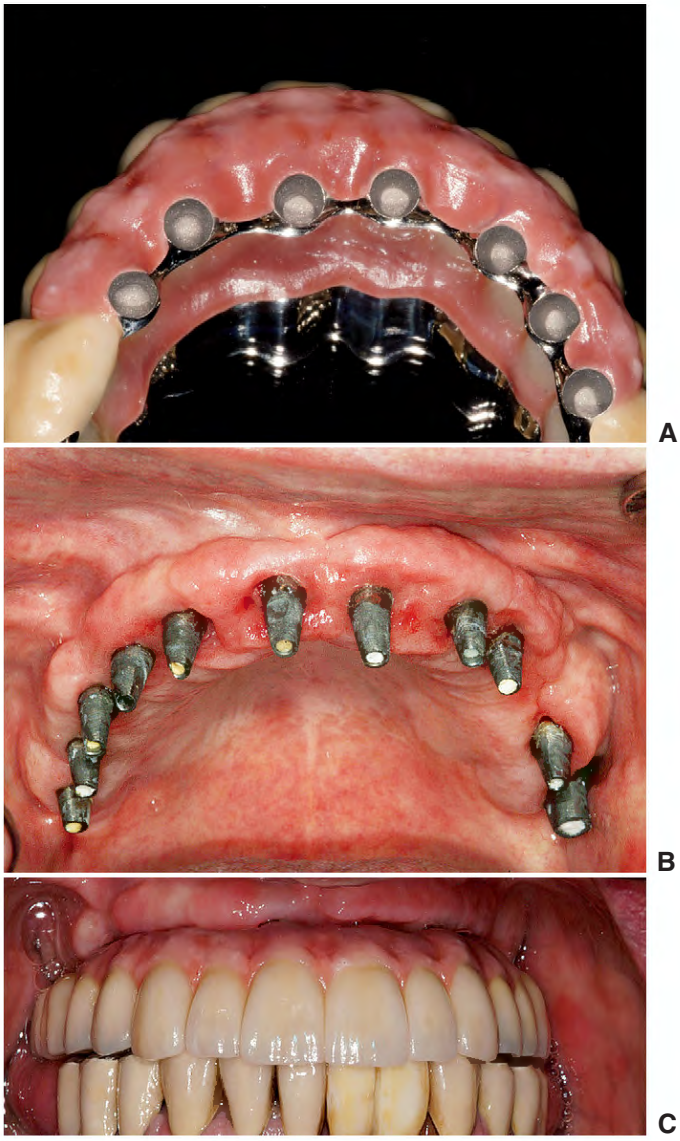

Figure 34-8 **A,** A square residual ridge arch may need to be restored with a tapered dentate arch form. As a result, the prosthesis is cantilevered from the more palatally positioned implants. **B,** An intraoral view of a tapered dentate arch form and a square residual ridge arch form. The four premaxillary implants should be splinted to posterior implants to compensate for the facial cantilever. **C,** Intraoral view of the prosthesis. A greater number of implants is indicated to compensate for the biomechanical force factors.

typically used to replace the anterior six teeth, regardless of the force factors.

Restorations with posterior pontics that are cantilevered should not be placed on maxillary anterior implants. The forces are two to five times greater in the posterior regions compared with the anterior region of the mouth. A cantilever magnifies these higher bite forces. As a result, the anterior implant abutments with a cantilever may receive a tenfold greater load compared with implants without a cantilever. If posterior teeth also are being replaced in the prosthesis, then additional implants are required. Seven to 10 implants often are inserted to restore a completely edentulous maxilla with

WWW.HIGHDENT.IR

Figure 34-9 When the bone loss occurs in the premaxilla, the smaller radius of the arch mandates only four implants to be positioned from canine to canine.

Figure 34-10 A FP-3 prosthesis does not require an exact tooth position for the implants, because the gingival porcelain separates the implants from the teeth. The implants in the canine positions are slightly more distal than desirable, and the patient's left lateral incisor implant is too mesial. Although the implant positions are not ideal in this intraoral view of the previous FP-3 prosthesis, no esthetic compromise exists.

a fixed prosthesis, especially when opposing natural dentition or a fixed restoration.

It should be noted that most full-arch maxillary prostheses are FP-3 fixed restorations or RP-4 overdentures. In either scenario, mesiodistal implant position does not have to strictly correlate with tooth position. The faciopalatal position may also be more flexible, because the emergence profile of the prosthesis is usually outside of the esthetic zone and because the gingival aspect of the restoration separates the clinical crown from the implant site. As such, the implant sites are determined more for biomechanics, interimplant spacing, or available bone, rather than a strict tooth position (as in an FP-1 prosthesis) (Figures 34-9 and 34-10).

When the natural canines are present and the missing teeth are the four maxillary incisors, the implant number is not as dependent on the dental arch form. Therefore the most common scenario is to place three Division B root forms (3.5 mm wide) in the lateral incisors and one central incisor region. When four anterior teeth are missing in a square dentate arch form, it may be easier to develop acceptable esthetics around central incisor pontics, compared with two implants in the central incisor regions. Therefore when biomechanics are favorable, the treatment plan may include only two implants in the lateral incisor sites. This two-implant treatment option is often designed for a square dental arch form in an older female, with little to no parafunction to fabricate an FP-1 prosthesis and a high lip line, when the natural canines are present.

MULTIPLE ANTERIOR IMPLANT DIAMETER

Several conditions should be considered for the proper implant diameter: tooth size, distance from an adjacent tooth, interimplant distance, facial bone dimension, and loading forces. A primary factor for the implant size when multiple anterior teeth are missing is the distance between the adjacent teeth or implants. The horizontal dimension of a wedge-shaped bone defect around an implant at the crest of the ridge from the biological width, implant design, or occlusal overload ranges from 0.5 to 1.4 mm.[11,12] Therefore when implants are placed adjacent to each other, a minimum interimplant distance of 3 mm is suggested to accommodate for eventual crestal bone loss and maintain interseptal bone levels.[11] This is of importance for an FP-1 restoration because the interseptal bone height in part determines the incidence of presence or absence of a lack of interdental papillae between the teeth or implants, with the most ideal results having a distance of 5 mm or less from the interproximal bone to the interproximal crown contact.[13,14]

Implants with 3 mm or greater interimplant space permit the development of papilla between the implants. When two adjacent teeth are missing in the premaxilla, the natural teeth adjacent to the edentulous span provide the interdental papilla support for proper esthetics, and an FP-1 restoration is often fabricated (Figure 34-11). However, the interdental papilla between the two implants is more difficult to restore.

The usual range of interimplant papillary height is 2 to 4 mm, even when the implants are 3 mm or more apart.[15] Therefore when an FP-1 restoration is desired, the prosthesis design (square-tooth forms) and implant positions may need to be altered accordingly to improve the esthetic result (Figure 34-12). Implants less than 3 mm apart often have a depressed interimplant papilla. As a result the crown contour is modified to a square form to lower the interproximal contact to the soft tissue. Although this technique reduces the black triangular space over the papilla, it is not an ideal result (Figure 34-13).

When four anterior adjacent teeth are missing, the soft tissue drape is usually inadequate to restore the height of the interimplant papillae; therefore the anatomy rarely permits an FP-1 prosthesis design. FP-2 or FP-3 prostheses are most always fabricated, dependent

WWW.HIGHDENT.IR

Figure 34-11 **A,** The two implants are farther than 3 mm apart. The interimplant papilla is easier to develop with the additional space. **B,** The two adjacent implant crowns have distal papilla developed from the adjacent natural teeth. The interimplant papilla is slightly reduced in height; however the crown shape lowers the interproximal contact, and the interproximal region is acceptable.

Figure 34-12 When two implants are adjacent to each other and an FP-1 prosthesis is desired, the implants should be 3 mm or farther apart to help develop the interproximal soft tissue papilla regions. The implants are too loose; therefore the papilla is often reduced in height between the implants, so the crowns should be more square in shape to eliminate the space above the lack of soft tissue height.

on the high lip dynamics of smiling within the esthetic zones (Figure 34-14).

The difference in the emergence profile from an anterior crown between a 4-mm-diameter implant and a 5-mm-diameter implant is negligible and is often not clinically relevant. However, it is more difficult to control the creation of an interdental papilla for FP-1 prosthesis on larger-implant diameters. Therefore when in doubt, a smaller-size diameter implant should be selected in the esthetic zone; thus a 3.5- to 4-mm-diameter implant often is used in the central implant position for an FP-1 prosthesis. Likewise, a 3.0- to 3.5-mm-diameter implant often is used for a lateral incisor FP-1 restoration.

When multiple adjacent teeth are missing in the premaxilla, rarely is an FP-1 prosthesis and ideal soft tissue contour a realistic goal. Instead, most often FP-2 restorations are fabricated for low smile line patients and FP-3 restorations for ideal to high smile line patients. The exact mesiodistal tooth position is not required for an FP-2 or FP-3 restoration or a removable overdenture. It is more important to have adequate width of bone on all the sides of the implants. Therefore the interproximal spaces of bone may be used without complication in either the anterior or posterior regions of the mouth. As a result, the mesiodistal position of the implants is often less specific in the edentulous premaxilla.

MAXILLARY OVERDENTURE TREATMENT PLANS

The edentulous maxilla has the lowest implant survival for removable implant restorations.[1,16,17] All reports concur that maxillary bone tends to be of poorer quality and volume and presents several biomechanical disadvantages. To compensate for the poor local conditions, a greater number of implants should be treatment planned, along with a greater A-P distance. With these concerns in mind, the minimum implant number for a completely edentulous maxillary overdenture prosthesis is four implants splinted in the premaxilla. The most usual sites are one central (or lateral) incisor position, bilateral canine positions, and at least one in the contralateral central or premolar site. Additional implants are often indicated when force factors are greater or for a RP-4 prosthesis overdenture.

WWW.HIGHDENT.IR

Figure 34-13 **A,** When four adjacent incisors are missing, the soft tissue drape is often inadequate in the interimplant region. **B,** When four anterior teeth are missing, the papillae are often depressed, and square-crown forms reduce the height requirement of the interimplant papillae.

Figure 34-14 FP-3 prostheses are often the more adequate prosthetic option to restore the interproximal papilla.

Figure 34-15 The flange on a removable prosthesis may be removed to evaluated the volume of graft required for lip support for a fixed prosthesis.

PREMAXILLA SURGERY

Maxillary Lip Support

The maxillary lip support above a fixed prosthesis should be evaluated before surgery. The maxillary lip should be more facial than the mandibular lip at repose, yet a depressed philtrum should be maintained, especially in a younger patient. As a general rule, when a vertical line is drawn along the patient profile, the maxillary lip should be 1 to 2 mm in front of the lower lip, and the chin should be 2 mm behind the lower lip position when the patient has the jaw in a vertical rest position. If the patient wears a labial flange on the removable prosthesis that provides acceptable maxillary lip support, or one exists at the prosthetic try-in, and a fixed prosthesis is desired, then a soft tissue template may be fabricated from the removable prosthetic try-in to indicate the soft tissue support required (Figures 34-15 and 34-16).

When the maxillary lip requires greater horizontal support, yet adequate bone is present to place implants, an acellular tissue graft (AlloDerm) and/or or dense hydroxyapatite (HA) graft may be used on the facial aspect of the bone before closure of the soft tissue over the implant (Figure 34-17). A bone graft may be used to support the maxillary lip above the prosthesis. This is often indicated when insufficient bone is present for the proper implant size, position, and/or number (Figure 34-18). The added labial tissue thickness will support the maxillary lip above the cervical regions of the teeth, increase the crestal tissue thickness, and improve ridge contour. In addition, the soft tissue augmentation to support the maxillary lip may also create sufficient volume of tissue to allow the sculpture of an interdental papilla around the implant crowns at stage II uncovery.

An RP-5 or RP-4 prosthesis does not require bone, HA, and/or AlloDerm to support the maxillary lip. Instead the flange of the overdenture may be designed similarly to a traditional denture to support the lip (Figure 34-19).

Division A Premaxilla

The maxillary anterior root form surgery with Division A bone is similar to that described in the maxillary anterior single-tooth implant (see Chapter 33). For a successful placement of standard-diameter endosteal

WWW.HIGHDENT.IR

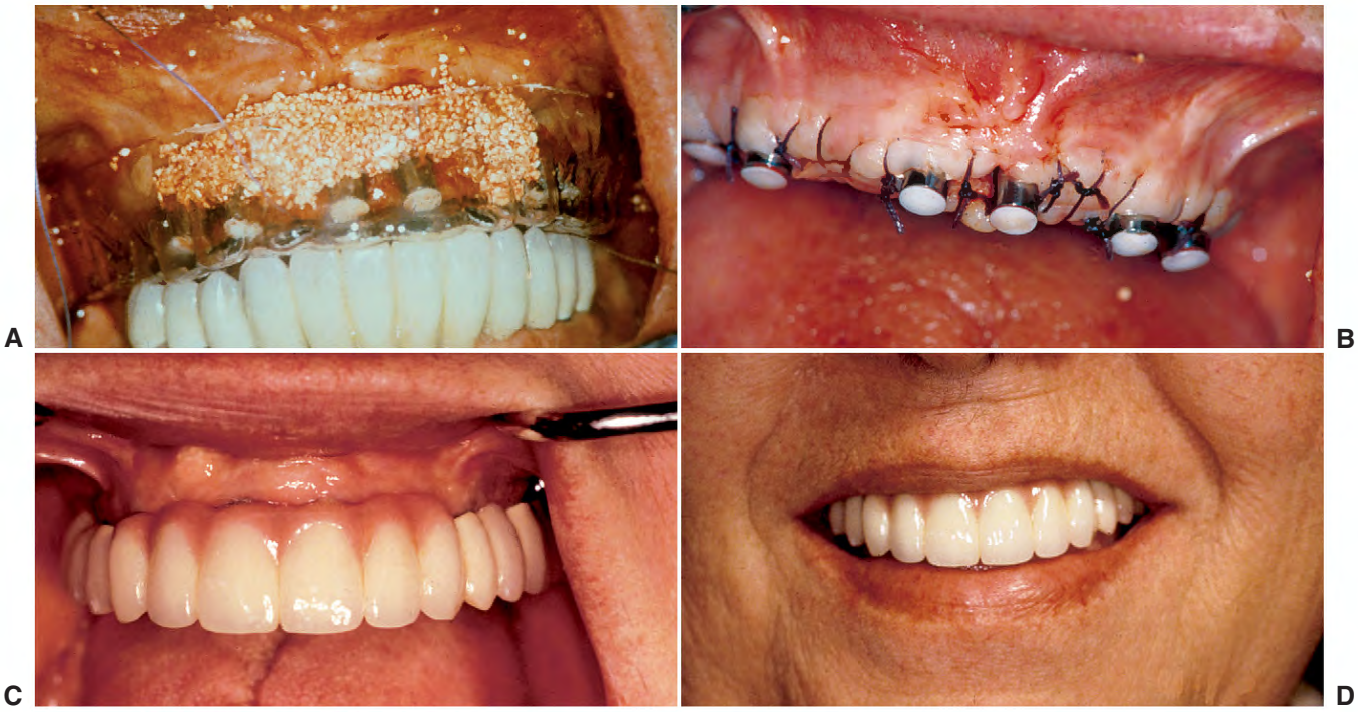

Figure 34-16 **A,** A soft tissue template evaluates the amount of dense hydroxyapatite (HA) required on the facial bone above the implants to support the maxillary lip similar to the removable restoration. **B,** The soft tissue is approximated over the HA graft. **C** and **D,** An FP-3 prosthesis supports the lip below the facial soft tissue from the HA graft and the prosthesis.

implants in the Division A anterior maxillary region, the recipient bone bed should be greater than 6 mm wide, greater than 12 mm high, and have a crown/residual bone height ratio less than 1.

When ideal anterior bone is present and the treatment plan is for an FP-1 prosthesis, a surgical template should identify the incisal edges and the mesiodistal tooth position of the final prosthesis. This template should be designed to rest on adjacent teeth (when present) or on the reflected ridge with a computed tomography (CT) bone model or index of the lower teeth to aid in correct positioning for the edentulous maxilla (Figure 34-20, *A* to *G*). The soft tissue crestal incision may be made on the lingual aspect of the edentulous ridge, providing additional keratinized tissue to the facial aspect (Figure 34-20, *H*). A vertical-release incision most often is made distal to the last tooth in each quadrant and includes the interdental papilla (Figure 34-20, *I*). When the mesial papilla is ideal, a "papilla-saving" incision may be medial to the papilla, similar to a single-tooth site.

When the premaxilla requires augmentation to give additional support to the maxillary lip, the facial flap is reflected to the inferior piriform rim. An adequate maxillary anterior ridge does not require reflection of the facial flap beyond the mucogingival junction. Once the soft tissues are reflected, the canine sites are first addressed. A surgical template helps guide their position and angulation. A large intraoral photographic mirror may be used to evaluate the parallelism of the two canine implants. It is not unusual for the facial trajectory of bone to complicate parallel preparation of the canine osteotomies. When multiple anterior teeth are missing, one to two implants between the canines may be inserted. The central incisor implant site is prepared next and should be placed slightly distal to the center of the final crown's mesiodistal length (Figure 34-20, *J* to *M*).

The incisive foramen often expands laterally within the palatal bone, and the central incisor implant osteotomy may inadvertently encroach on this structure and, as a result, form fibrous tissue at the interface in the mesiopalatal region. A more distal implant placement in the central incisor region prevents this complication. Because most restorations in an edentulous premaxilla are FP-2 or FP-3, the most favorable sites for bone width are selected, even when they are in the interproximal region of central and lateral sites.

When the labial soft tissue is not reflected to the inferior piriform rim of the nose, the facial tissues are palpated with the fingers of the hand not holding the hand piece during the actual bone preparation to feel whether the rotation of the drill can be detected underneath the tissue. After preparation, the anterior implant osteotomy is evaluated with a probe, especially on the facial aspect before implant placement, because labial undercuts often are present above the level of the facial flap reflection and may result in facial fenestrations during the osteotomy or implant placement process. When in doubt of a bone fenestration, the

labial tissue should be completely reflected and the area evaluated.

A 2-mm end-cutting drill prepares the implant sites with the angulation determined by the incisal edge of the prosthesis. A direction indicator is then positioned into the sites. The stop on the direction indicator is often 4 mm in diameter, which may be used to evaluate the final implant position and bone volume around the final implant site. If the labial hard tissue on the facial of the implants is not greater than 1.5 mm, then bone loss after remodeling or early loading may cause a facial fenestration over the implant. When the bone is inadequate in width, bone expansion may be used to increase the facial plate of bone, which is presented later in the chapter (Figure 34-20, *N* and *O*).

When abundant bone exists 3 mm below the future implant crown and abundant soft tissue is present, an FP-1 prosthesis may be planned. The implant body should be placed approximately 3 mm below the facial free gingival margin of the future implant crown, which is level with the crestal bone (Figure 34-20, *P* to *R*). In an FP-2 or FP-3 prosthesis, the level of the soft tissue and bone relationship is not relevant. When placing implants in Division A bone to support an implant overdenture (IOD), the crown height space is evaluated to ensure a minimum of 12 mm for prosthetic components. When not present, an osteoplasty before implant insertion is indicated.

The anterior implant site should ideally have greater than 6 mm of available bone width for Division A root forms. When a less than ideal bone width does not provide a minimum of 1.0 to 1.5 mm of facial bone, a Division B root form (3.5 to 3.75 mm), a membrane ridge augmentation with a layered approach at the time of implant insertion, or a bone-spreading technique is indicated.

The soft tissue drape of an FP-1 restoration on multiple implants is easiest to obtain when the soft tissue is at the desired height of the interproximal papillae. Elevating and increasing the tissue thickness at the insertion surgery may accomplish this. Permucosal extensions 3 mm in height and an acellular dermis matrix graft (AlloDerm) may be used to elevate the tissue with primary closure over these components (Figure 34-20, *S* to *Y*).

WWW.HIGHDENT.IR

Figure 34-18 **A,** An iliac crest bone graft can help support the maxillary lip of an edentulous maxilla. **B,** The maxillary FP-3, porcelain-fused-to-metal implant prosthesis opposing a hybrid denture tooth, acrylic-to-metal framework in the mandible. **C,** A panoramic radiograph of the maxillary implants inserted into the iliac crest graft and supporting the FP-3 prosthesis. **D,** The iliac crest bone graft and the FP-3 prosthesis support the maxillary lip. A philtrum is present, and the maxillary lip is in front of the mandibular lip.

If a fenestration occurs on the apical one half of the implant during the osteotomy or implant insertion, or if a thin ridge presents inadequate bone width, then a layered bone graft of autogenous bone over the implant site, covered with a mixture of demineralized freeze-dried bone (DFDB) cortical fibers, resorbable HA, and platelet-rich plasma (PRP) and covered with a resorbable collagen or acellular dermal tissue membrane may prevent further bone loss and resultant implant thread exposure. The labial flange of a soft tissue–borne transitional prosthesis should be completely removed to decrease the risk of incision line opening when implants are placed into an edentulous premaxilla (Figure 34-20, *Z* and *AA*). A subtraction soft tissue technique recontours the tissue and creates the emergence profile of the crowns and the interdental papilla at stage II uncovery.

BONE SPREADING

The faciopalatal bone is often only 4 to 6 mm wide at the crest and/or presents a facial "hourglass" concavity. Bone spreading may be used to expand the available bone width before implant placement (Figure 34-21). Tatum[18-20] developed bone spreading in the early 1970s. He performed this technique using calibrated osteotomies ("graduated wedges"), matching the dimension of endosteal implants specifically designed for this procedure (Figure 34-22). Tatum inserted more than 5000 maxillary anterior implants with this procedure before 1985.

Over the years the bone expansion technique has been primarily used in regions of Division B bone to increase the bony width, rather than using onlay grafts. However, the easiest edentulous ridges to expand are Division A bone volume and D3 or D4 bone density. The narrower the bone, the greater the risk of fracture of the facial plate. The softer the trabecular bone quality, the lower the elastic modulus and the greater the viscoelastic nature of the ridge. Therefore the less dense the bone, the easier and more predictable the bone expansion. Maxillary edentulous Division A bone is the most ideal to expand and provides the best situation to develop a learning curve for the bone-spreading technique, which is also advantageous in Division B ridges (although more technique sensitive).

Figure 34-19 **A,** An intraoral view of a RP-4 overdenture bar. **B,** A maxillary RP-4 overdenture from the previous intraoral view (in place). A labial flange is designed to support the maxillary lip. **C,** The denture teeth and flange of the overdenture support the maxillary lip.

Division A Bone Expansion

Bone expansion does not affect the facial and palatal plates equally. The thicker palatal bone is more difficult to manipulate; therefore the expansion process is primarily in the direction of the thinner facial plate. This is a benefit because the bone defect or deficit is also facial. Bone expansion provides a more normal facial contour to the region. The implant osteotomy is begun with a No. 6 bur or a 2.0-mm starter drill and positioned 0.5 mm more palatal than the usual midcrest position, to place a slightly thicker amount of bone on the facial aspect and decrease the risk of labial plate fracture during the expansion process (Figure 34-23, *A* and *B*). The No. 6 round bur can be used to prepare the osteotomy several millimeters in depth and to remove a portion of the thicker palatal plate on the lingual of the osteotomy site.

Bone expansion requires tapping on an osteotome with a surgical mallet (almost like tapping a nail into balsa to white pine wood). As a result, patient sedation is recommended because the tapping may elicit greater patient concern and response than the use of drills to prepare the osteotomy. Advantages exist to using an osteotome and mallet to prepare an implant site, even in Division A bone. The less dense bone may be compressed, which results in a denser interface after healing.[21] Less risk of causing a facial fenestration also exists compared with drilling, because the bone is being pushed facially, not removed with rotating drills.

A 2-mm end-cutting pilot drill is then used at 2500 rpm, with copious amounts of cooled sterile saline. The drill penetrates along the initial pilot hole prepared with the No. 6 bur at the angulation corresponding to the final ideal angulation, directly under the incisal edge and parallel to the cervical third contour of the adjacent natural teeth. The bone is prepared to the opposing landmark, which is often 2 to 4 mm deeper than the final implant length. The presence of a thick palatal plate tends to push the drill toward the facial plate. This occurs because the side of the end-cutting drill is in contact with dense palatal bone. Rather than removing equal amounts of bone from each side of the osteotomy, the drill, which is not designed to be side cutting, is pushed facially, and the osteotomy is only enlarged from that aspect. In such situations, the surgeon should stop and use a side-cutting drill (e.g., Lindemann drill) to enlarge the palatal side of the osteotomy before using the 2.0-mm drill to completion.

Once the 2-mm drill has prepared the bone 2 to 4 mm beyond the final implant depth, specifically designed osteotomes are used to further widen the osteotomy (Figure 34-23, *C*). The implant is round in cross section and will be inserted at the same time as the bone expansion; therefore the osteotomes are also round in cross section. The ends of the osteotomes are tapered for the last 2 to 3 mm to create a gradual bone expansion. The osteotomes are provided in increasing diameters, preferably in increments of 0.5 mm. Larger-diameter increments increase the risk of labial plate bone fracture.

The first osteotome used in the osteotomy is 2 mm in diameter. It is gently tapped with a surgical mallet into the bone 4 mm beyond the final implant length (Figure 34-23, *D*). This process should be easy because the drill already prepared an osteotomy of the same dimension. The angulation is evaluated—at least 2 mm of bone should be on the facial aspect of the instrument. If not, then the osteotome is removed, and a side-cutting drill is used to remove some bone on the palatal aspect of the osteotomy. To remove a bone-spreading osteotome, it should not be luxated as a tooth; instead it is rotated in the socket and unscrewed with a gentle axial tensile force.

A 2.5-mm round, tapered osteotome is then inserted into the osteotomy (Figure 34-23, *E*). A surgical mallet

then gently taps the osteotome so that it proceeds into the bone for about 1 mm for every tap (Figure 34-23, *F*). At each 5-mm depth, a pause of 15 to 30 seconds is allowed (the harder the tap required to proceed 1 mm, the longer the wait). Once this instrument proceeds 3 mm beyond the final length, or 0.5 to 1.0 mm less in final depth than the previous osteotome, the surgeon should pause 1 to 2 minutes before removing the instrument (Figure 34-23, *G*).

The periodic pauses are an intrinsic part of the procedure that takes advantage of the viscoelastic nature of bone, to expand it without fracture. During the pauses, the intraosseus and extraosseous fluids between the compressed trabeculae escape from the intratrabecular spaces, thus decreasing the risk of fracture of the facial plate. In addition, the biomechanical creep change in bone over time permits the bone to expand without fracture.

A 3-mm round, tapered osteotome is then tapped into position (Figure 34-23, *H*). This process is more difficult than the previous two steps. It is beneficial to have the assistant hold and direct the osteotome once it is engaged for the first 6 to 8 mm. The fingertips of the nontapping hand of the surgeon hold and brace the facial and palatal plates over the edentulous site. If pressure is felt in the fingertips while the tapping commences, then the process slows down and each step is extended in time.

The intensity of the tapping is sufficient when the osteotome proceeds 0.5 mm to 1 mm deep for each tap. A pause every 5 mm is 30 to 60 seconds in duration (Figure 34-23, *I*). The final osteotome penetrates 2 mm shorter than the original 2.0-mm osteotome. Once completely inserted, the osteotome is left in position for 2 to 4 minutes, depending on the difficulty to proceed and the pressure felt on the labial plate. A surgical forceps may be required to rotate and pull the osteotome out from the bony site.

On occasion, the osteotome handle may tend to drift facially such that the angulation of the osteotomy flares

Continued

out beyond the incisal edge position. This is caused by the presence of the thicker palatal bone resisting expansion on the palatal side of the osteotome and facially pushing the instrument. When this occurs, the osteotome is removed, and a side-cutting drill is used to remove some of the palatal bone within the osteotomy (Figure 34-23, *J*). The osteotome is reinserted and proceeds in the previous fashion.

At the 3.0-mm-diameter point, the clinical decision must be made regarding whether a 3.5- or 4.0-mm-diameter implant will be selected. If little bone is present on the facial aspect of the 3.0-mm osteotome

and/or the bone was difficult to prepare, then a 3.5-mm implant is selected. The final drill for the 3.5-mm-diameter implant (usually 3.0 mm in diameter) is used to finalize the osteotomy after the last osteotome. Many maxillary ridges, however, can be further spread to receive a larger 4.0-mm-diameter implant.

When the larger diameter implant is selected, a 3.5-mm round, tapered osteotome is then inserted into the osteotomy and proceeds in a similar fashion (Figure 34-23, *K*). The final depth of the 3.5-mm osteotome is 1 mm shorter than for the 3.0-mm-diameter osteotome, similarly to a "step back" approach in canal preparation

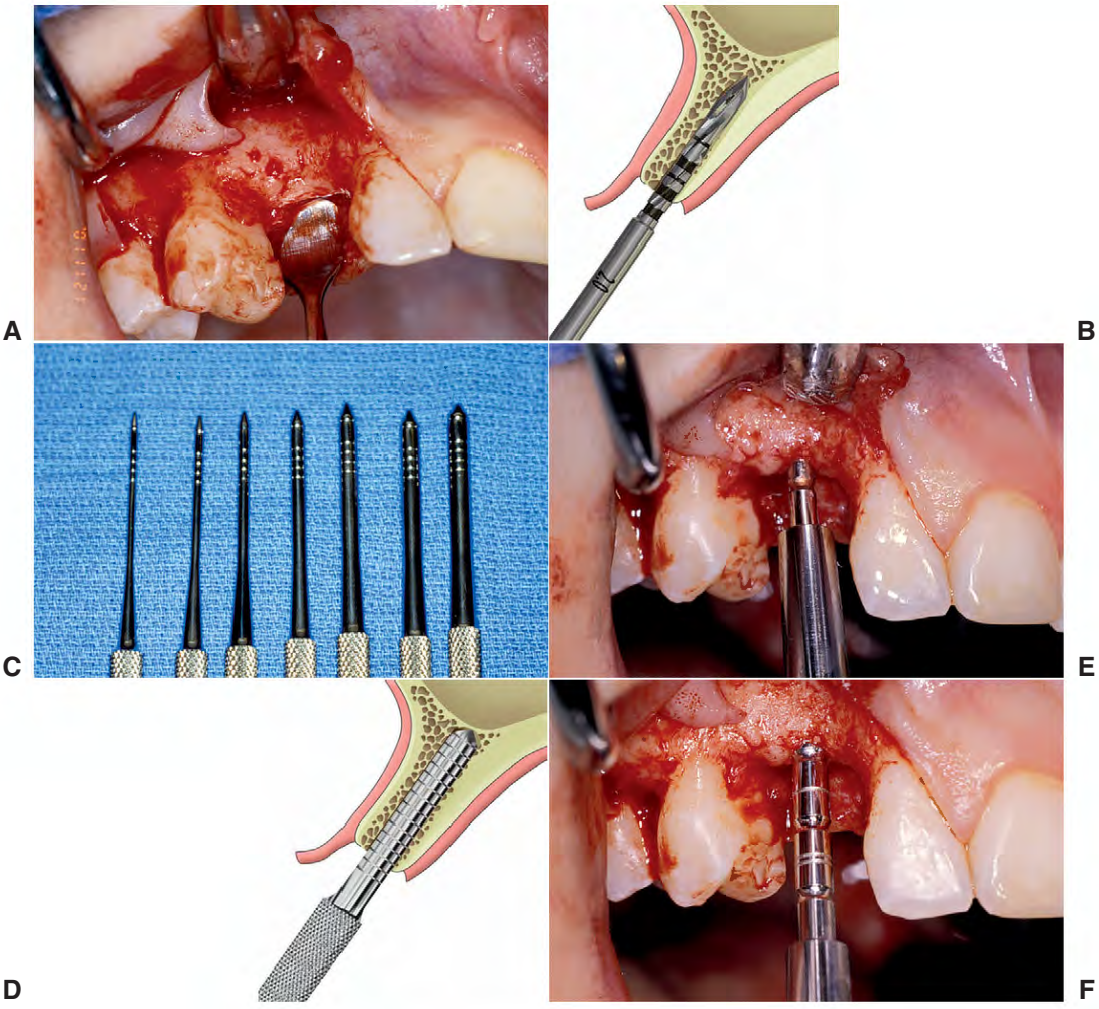

Figure 34-23 **A,** A Division A site that is D3 bone is a good site to develop the technique of bone spreading. **B,** A starter drill begins the osteotomy 0.5 mm toward the palate to increase the facial bone volume. **C,** The osteotomes for bone spreading and implant insertion are round, proceed with 0.5-mm-diameter increments, and have a tapered apical 2- to 3-mm end. **D,** A 2.0-mm bone-spreading osteotome is tapped into position in 3- to 5-mm increments. This process proceeds without difficulty because the 2.0-mm twist drill has already prepared the site. **E,** A 2.5-mm osteotome is tapped into position in 3- to 5-mm increments. Every 3 to 5 mm, a waiting period of 30 to 60 seconds permits bone to expand without fracture. **F,** A 2.5-mm bone-spreading osteotome continues to be tapped into the site in 3- to 4-mm increments and 30- to 60-minute waiting periods.

Continued

for endodontics (Figure 34-23, *L*). The reader should remember that the depth of the initial osteotome is 3 mm deeper than the desired implant length. Each successive, larger osteotome is inserted 0.5 mm shorter than the preceding instrument. This expands the base of the osteotomy in a V shape, rather than a U shape, and it is less likely to fracture the labial cortical plate. When conditions warrant, additional pauses and extended time intervals for each 5-mm-deep segment should be incorporated.

The final diameter drill of the manufacturer can now be used for the 4.0-mm-diameter threaded implant. This diameter often approaches 3.2 to 3.4 mm (depending on implant design and bone density). Although a 3.5-mm osteotome was used last, the bone will relapse back to a smaller diameter, shortly after each bone-spreading instrument is used. By drilling the final osteotomy size and extracting bone, rather than just using the expansion technique that only compresses the bone, the final osteotomy will be of the proper width and depth (Figure 34-23, *M*). Because the bone most often is wider at its base, compared with the crestal region, even when the gradually increasing tapered osteotomes do not expand the apical region, the end-cutting drill can prepare the site without consequence.

The labial tissue is palpated during the actual bone preparation to feel whether the drill can be detected. The final implant osteotomy is also inspected with a probe, especially on the facial aspect before implant placement. Labial undercuts or fractures may cause fenestrations. Once the labial tissues have been reflected, the blood supply to the labial porous compact bone is diminished. The mesiolingual aspect of a central incisor implant is also checked to ensure the lack of communication

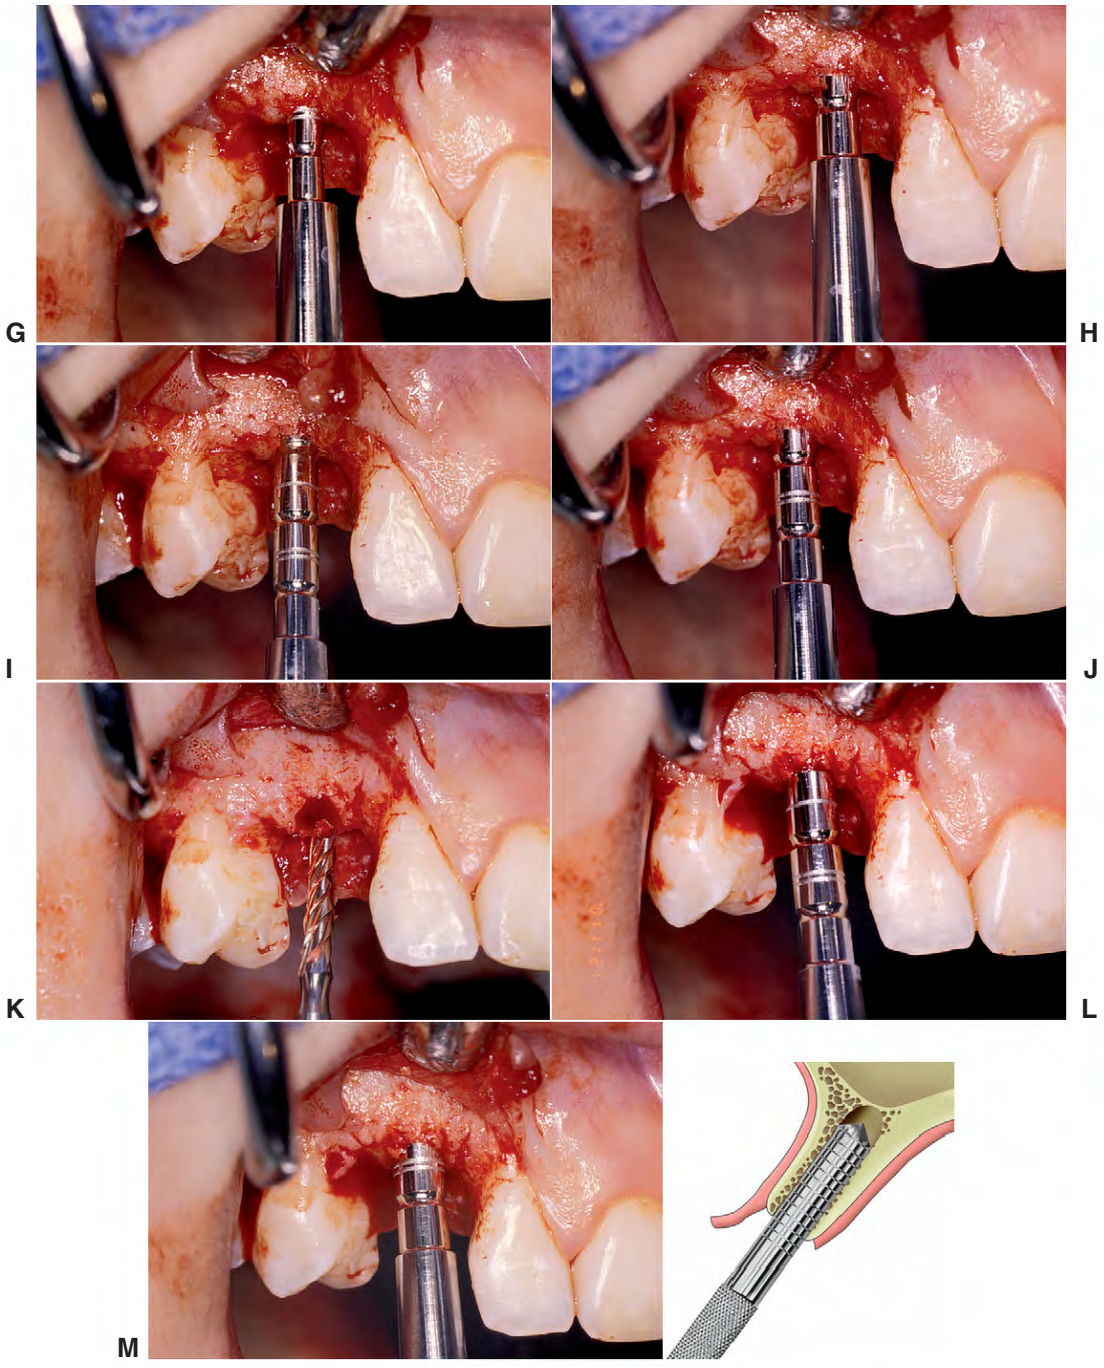

Figure 34-23, cont'd **G,** The 2.5-mm bone-spreading osteotome is tapped into the implant site 3 mm beyond the length of the implant. **H,** A 3.0-mm bone-spreading osteotome is placed into the site and tapped in 3- to 5-mm increments. **I,** The 3.0-mm bone-spreading osteotome requires a firmer tap, shorter increments, and longer waiting periods. **J,** A side-cutting Lindemann drill used to remove some of the palatal bone of the osteotome is pushed to the facial. **K,** A 3.5-mm osteotome is used to prepare the final osteotomy diameter for a 4.0-mm implant. **L,** A 3.5-mm bone-spreading osteotome is tapped to the final implant length. **M,** Because the bone has a modulus of elasticity and is not expanded beyond permanent deformation, the size of the expanded osteotomy rebounds to a smaller diameter after each osteotome. Therefore after the final osteotome *(left)* a 3.4-mm drill is used to prepare the final diameter for the implant.

Continued

with the incisive canal. When in doubt, the labial tissue should be reflected and the area inspected. If a perforation is present, then an autologous graft and/or barrier membrane is used to augment the site on top of the cortical plate. When the facial plate is not violated but is less than 1.5 mm thick, a resorbable calcium phosphate and a resorbable membrane are placed over the grafted region to prevent further bone loss from remodeling and causing subsequent implant thread exposure.

WWW.HIGHDENT.IR

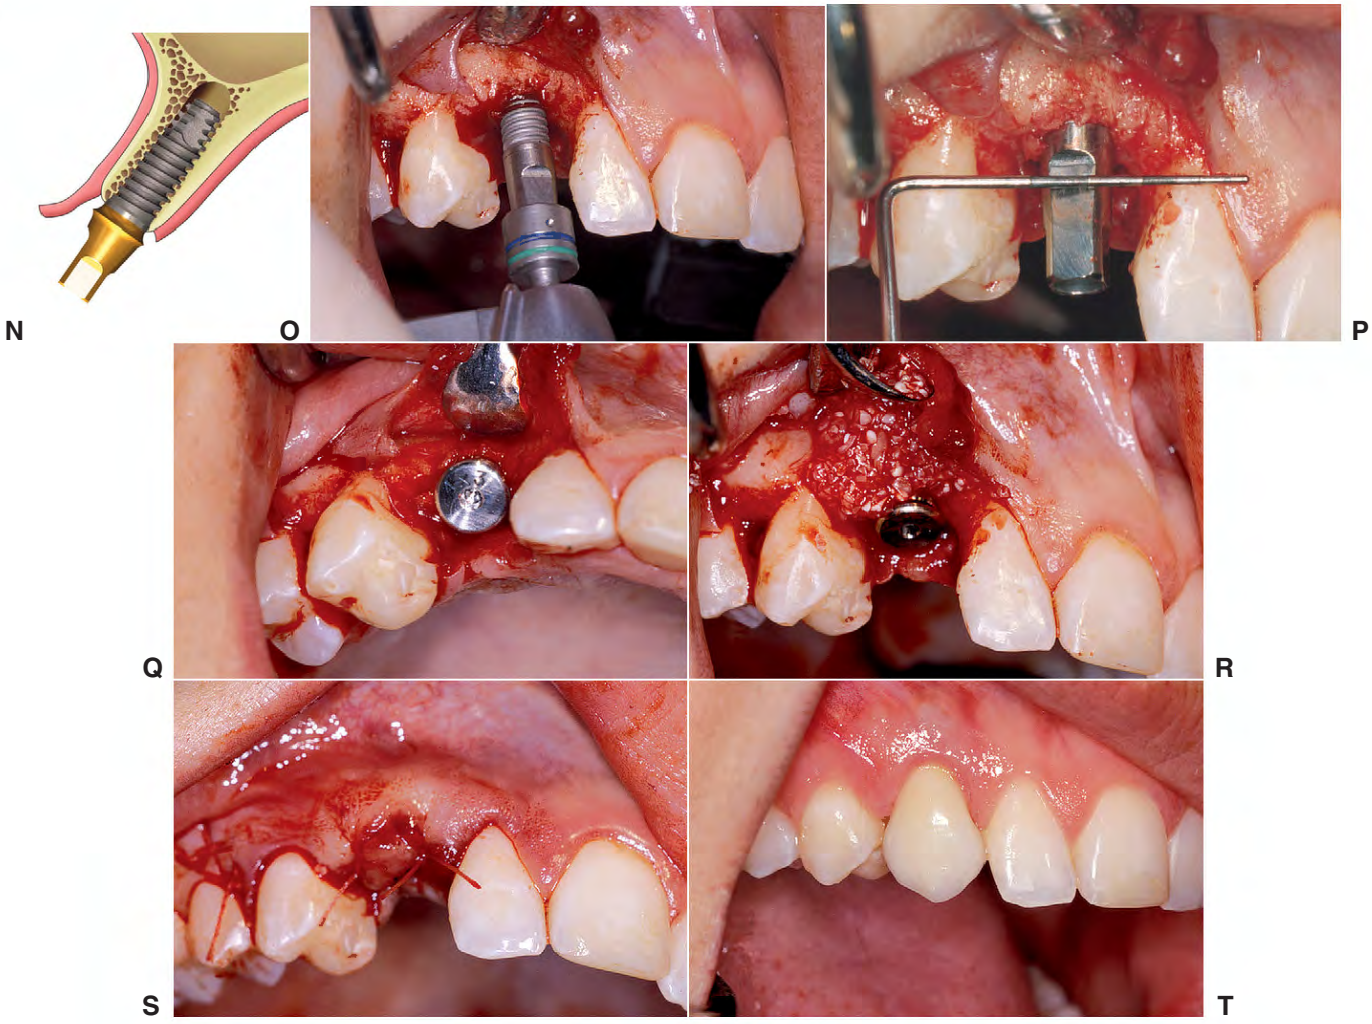

Figure 34-23, cont'd **N, O,** The implant is threaded into position with a hand piece at 30 rpm after a bone tap prepared the threads within the bone. **P,** The implant is seated 3 mm below the facial free gingival margin of the future implant crown. **Q,** A 3-mm-high permucosal extension (PME) is inserted into the implant. **R,** A layered bone graft of autograft, then mineralized and demineralized bone, is placed over the facial bone to decrease the risk of thread exposure after bone spreading. **S,** The soft tissue covers the PME and bone graft. This augments the facial bone and the soft tissue for the interproximal tissue. **T,** After a subtraction technique for stage II uncovery and the development of proper emergence profile with a temporary crown, the final crown is delivered.

A crestal bone drill is rarely indicated with the bone expansion technique. However, a bone tap is often used to prepare the dense palatal bone for a threaded implant. When a tap is not used before implant insertion, a threaded implant may be pushed through the facial softer bone, rather than threading the more dense palatal bone. The bone tap helps prevent the less efficient threads of the implant from being pushed facial and fenestrating the facial plate.

The final implant may be threaded into position using a slow-speed, high-torque hand piece (Figure 34-23, *N*). The implant is seated at the depth appropriate for the prosthesis type (3 mm below free gingival margin of the future implant crown for FP-1 restoration) (Figure 34-23, *O*). When the soft tissue in the interproximal area requires augmentation, a 3-mm PME may be placed into the implant (Figure 34-23, *O*). This device may act as a tenting screw to elevate the tissue. A layered bone graft with an autograft, then demineralized and mineralized bone, is placed on the facial bone over the implant, concentrating on the crestal region (Figure 34-23, *P*). The graft procedure decreases the risk of crestal bone loss after the bone expansion and also aids in the modeling process of bone to change bone volume. The soft tissue is approximated over the PME (Figure 34-23, *Q*). This elevates the interproximal tissue and is a benefit to the layered graft. The final implant uncovery may use a subtraction technique to carve the interdental papillae and develop the soft tissue drape. The final crown develops the emergence contour for acceptable esthetics (Figure 34-23, *R*).

Bone spreading may be performed in either arch; in general, it is most often used in the maxilla. It may be used in several sites or one site only. The soft tissues

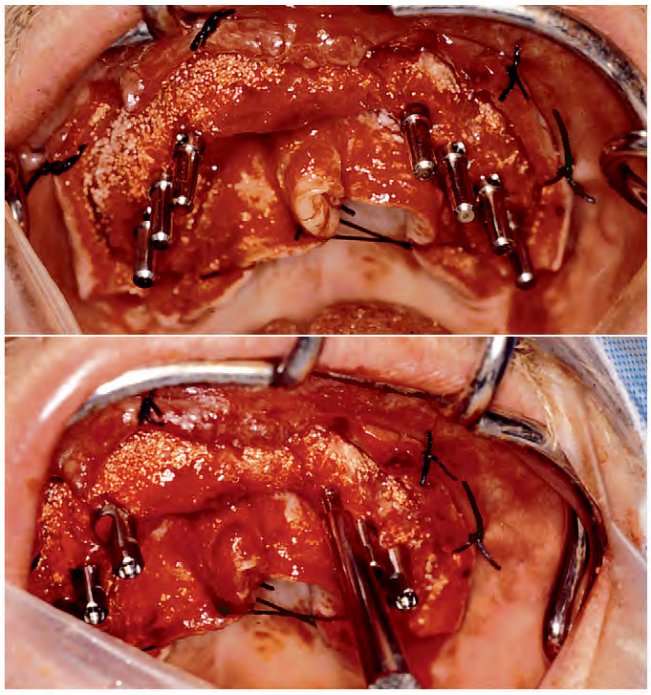

Figure 34-24 **A,** The maxillary soft tissue is reflected and a 2.0-mm-diameter drill is followed by 2.0-mm-diameter direction indicators. The stop on the direction indicator is 4.0 mm and can be used to evaluate the thickness of the bone around the site. The patient's left lateral site is too narrow for the implant. **B,** A bone-spreading osteotome is used in the lateral incisor site.

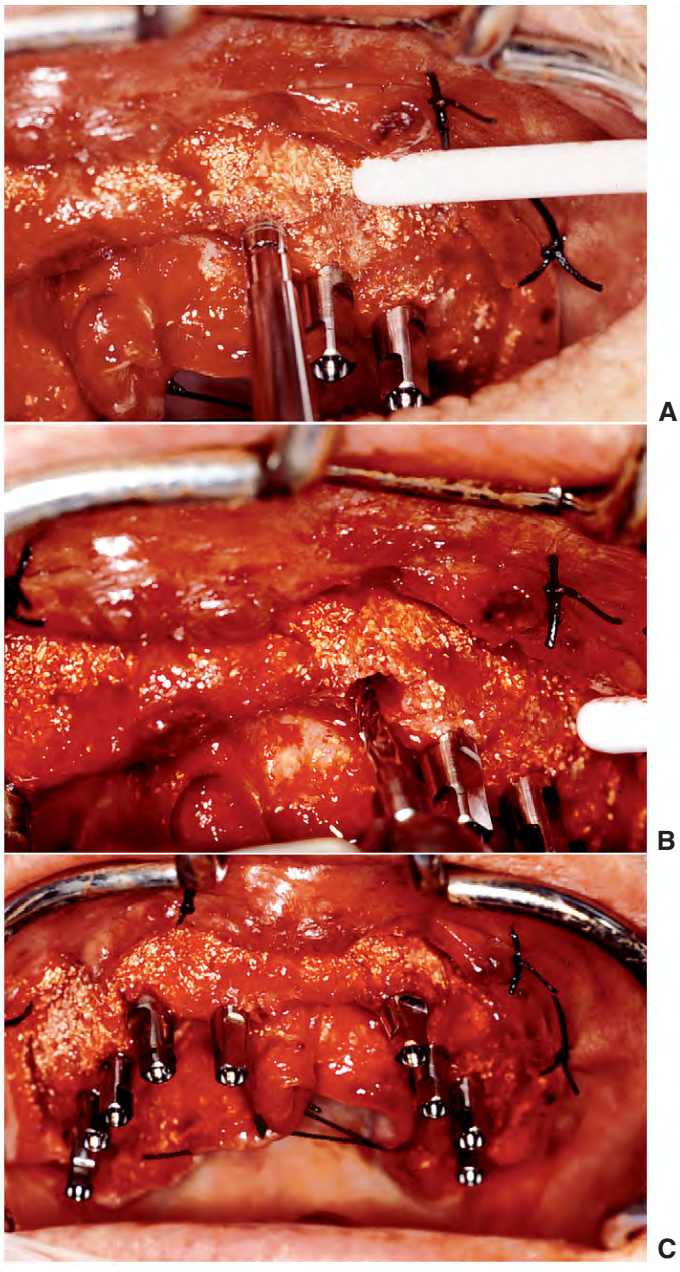

Figure 34-25 **A,** A 3.0-mm osteotome is used in the lateral site. **B,** A side-cutting Lindemann drill is used to prepare the palatal aspect of the osteotomy. **C,** A 3.5-mm implant is positioned into the lateral incisor implant site.

are reflected, and the initial implant osteotomy is made with a 2-mm-diameter starter drill. Direction indicators are then placed into the prospective implant site (Figure 34-24, *A*). The stops on the direction indicators are 4 mm in diameter, represent the diameter of the implant, and may be used to evaluate the facial and palatal bone thickness next to the 4-mm stop. When inadequate, bone spreading is a surgical option to allow implant insertion with more bone positioned to the facial (Figure 34-24, *B*). The site is expanded in a similar fashion to the previous discussion (Figure 34-25, *A*). A Lindemann side-cutting drill is often used on the palatal aspect of the bone-spreading osteotomy (Figure 34-25, *B*). The implants may then be inserted with additional bone on the facial to decrease risk of crestal bone loss after loading (Figure 34-25, *C*).

Division B Bone Spreading

When D2 bone is present in Division A or B ridges, labial bone fracture is more likely during bone expansion. To decrease this risk, bone spreading is accomplished after a narrow channel-shaped osteotomy is made with a 700 XXL surgical bur, similar to a plate form (blade implant) osteotomy (Figure 34-26). The narrow horizontal channel osteotomy is made the complete mesiodistal dimension of the implant site. In other words, if the mesiodistal implant site is 7 mm, then the horizontal groove is 7 mm wide. It is more predictable to spread a Division B width ridge that is 7 mm long, compared with a Division B ridge that is 4 mm long. When adjacent implant sites require bone spreading, the horizontal groove is made continuously from one implant site to the other. It is more predictable to spread a 14- to 21-mm mesiodistal ridge with a horizontal groove

WWW.HIGHDENT.IR

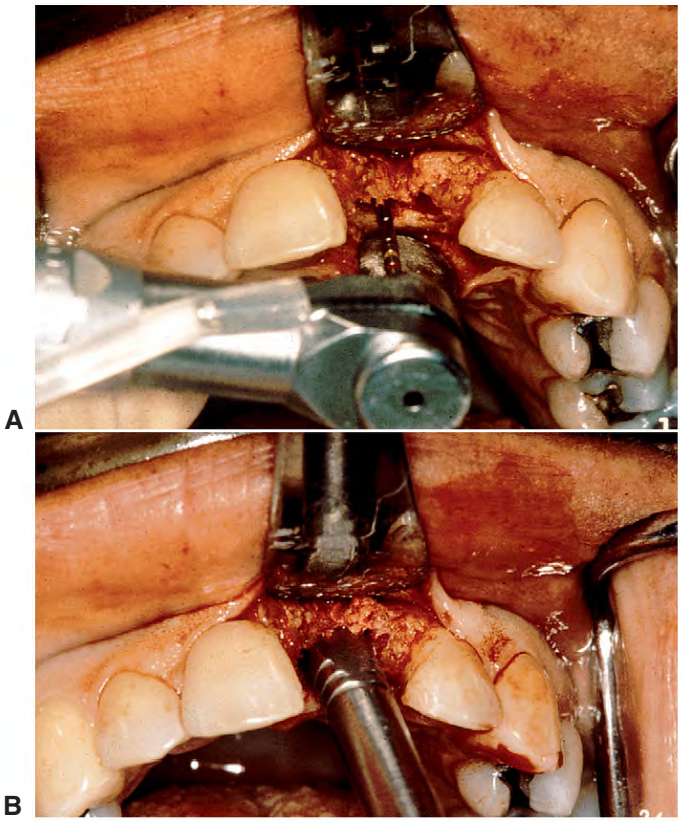

Figure 34-26 **A,** A Division B volume ridge is easier to expand when a mesiodistal horizontal slot is made with a 700 XXL surgical bur. **B,** A bone-spreading osteotome is tapped gently into the horizontal slot, and the facial bone is expanded.

than it is to spread two 4-mm adjacent sites within a 14- to 21-mm space. The horizontal osteotomy is also made several millimeters deeper than the length of the desired implant. It is more predictable to spread a deeper site than to spread one the same depth as the implants (see Figure 34-28).

When a Division B maxillary ridge is 4 to 5 mm, several options are available to the practitioner, including bone expansion and simultaneous implant placement, which is often performed when the bone is D3 or D4 in density. The Tatum approach for bone expansion limits periosteal reflection to the crest of the ridge to maintain the blood supply to the labial cortex. However, this surgical approach does not permit direct evaluation of the labial bone for potential splitting. In addition, the bone on the labial aspect of the implant is rarely 1.5 mm thick. As a result, crestal bone loss is more evident after healing and occlusal loading. Therefore after bone spreading and implant insertion is performed, a layered bone graft and resorbable membrane are most always placed on the labial aspect of the residual ridge. To this effect, a full reflection of the labial flap and soft tissue expansion for primary closure is almost always required.

Another option for Division B bone with D2 or D3 bone quality is an onlay graft, which requires a labial periosteal reflection. A tent screw is placed before the graft to maintain the space under the membrane. A layer of autogenous bone is placed on the labial surface of the recipient site, then a mix of resorbable HA with DFDB cortical fibers is placed on the facial of the ridge. A resorbable barrier membrane is then positioned over the top of the graft to assist in guided bone regeneration (GBR). A cortical block graft may also be used without a barrier membrane for augmentation in Division B sites but usually requires a mandibular donor site (see Chapter 39).

Complications

The most common complication of bone spreading, especially in Division B bone that is D2 quality, is splitting the facial plate during the procedure. Once this occurs, the surgeon must decide whether to continue, place the implant, and perform a barrier membrane layered bone graft, or abort the procedure and only place a bone graft. The implant may be inserted when the following factors are positive: (1) the implant is rigid at the proper depth, (2) the implant is in a favorable angulation, and (3) the facial plate is farther facial than the implant (it is fractured, but expanded). Under these conditions, the barrier membrane layered graft procedure is predictable to restore the facial bone and the implant is not compromised. If one of these three factors is negative, then it is more prudent to remove the implant, harvest additional autograft, and perform the bone graft without the implant in situ.

Another complication of spreading is the dehiscence of the labial plate after healing and bone remodeling around the implant (Figure 34-27, *A*). Because of its modulus of elasticity and because the expansion of the labial plate was not beyond the permanent deformation, the bone does not fracture, but it attempts to rebound to its original size during remodeling. As a result, during bone remodeling the bone does not heal in its expanded position; instead it returns to its initial narrow dimension, and the implant fenestrates the labial plate. This is not seen on a radiograph because it does not affect the interproximal bone. As a result, when bone expansion was performed at implant placement, a stage II uncovery with reflection of the facial soft tissue is advantageous. When a dehiscence is observed, a barrier membrane with layered graft approach are indicated to restore the facial plate (Figure 34-27, *B* and *C*).[22] Because the implant is integrated to the remaining bone, the implant may be progressively loaded after a 3- to 4-month period, rather than waiting 6 to 9 months, as with augmentation by barrier grafts alone.

The third complication of bone expansion is a poor implant position, usually more facial than ideal. The thicker palatal cortical plate pushes the osteotomes to the facial; if the surgeon is unaware, then the implant angulation slowly becomes too facial. Constant attention

WWW.HIGHDENT.IR

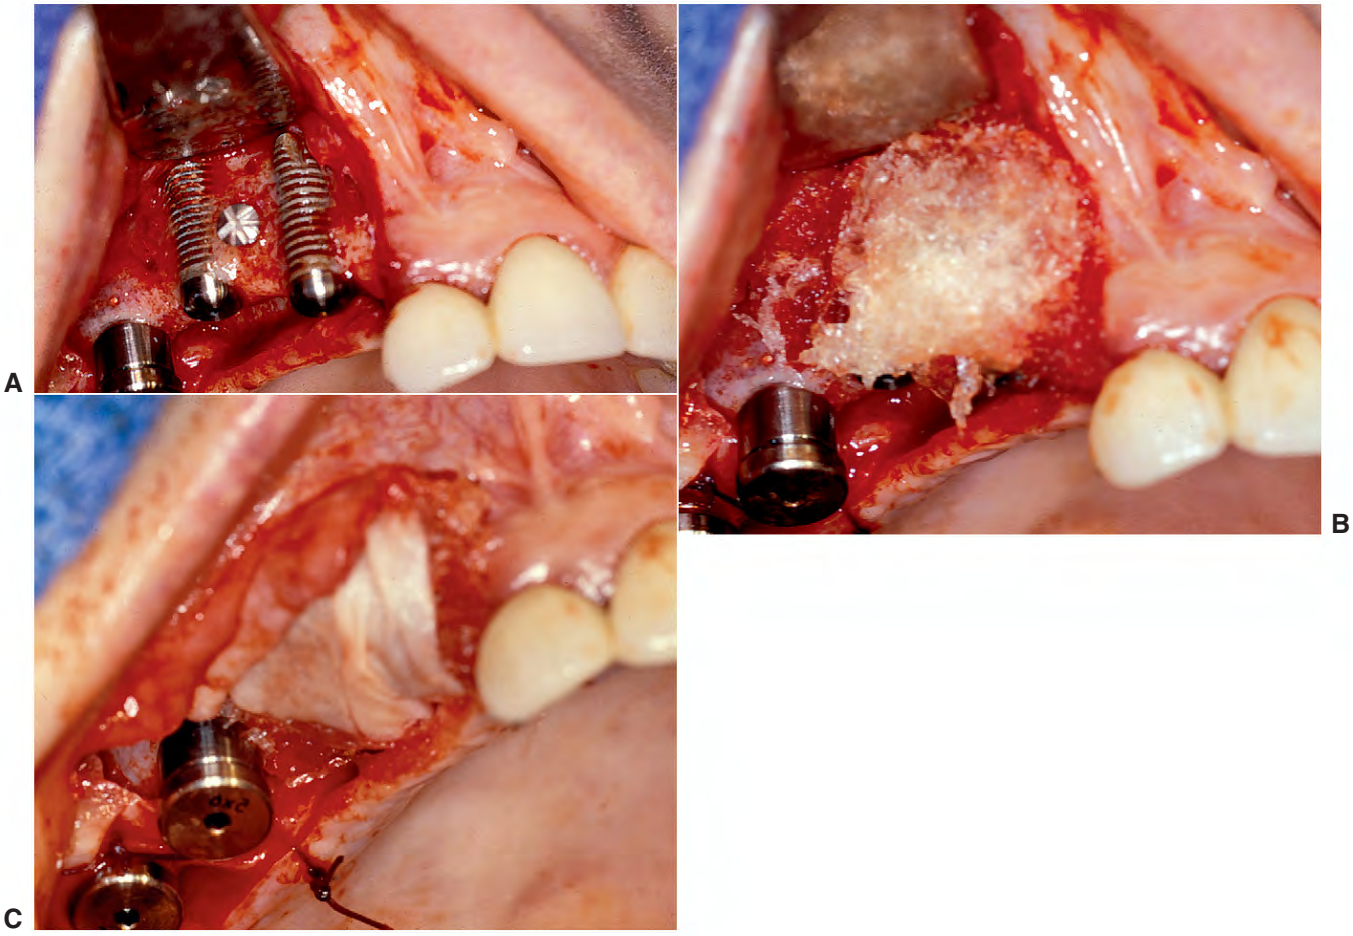

Figure 34-27 **A,** One of the more common complications of bone spreading is facial dehiscence of the implant after initial bone healing. When this occurs, a tent screw and layered bone graft is suggested to augment the width deficient ridge. **B,** Autologous bone, covered with mineralized and demineralized bone, is placed on the facial of the implants. **C,** A collagen barrier membrane or acellular dermal tissue graft (AlloDerm) is placed over the layered bone graft. The area is left to heal for a few additional months.

to angulation and modification of the palatal bone with side-cutting drills is necessary to prevent this problem. The final prosthesis should not be compromised for the sake of placing the implant during the surgery. Bone augmentation and reentry 6 months later often improves the implant position and, as a result, the final restoration (Figure 34-28).

SUBNASAL ELEVATION

The C–w bone volume ridge in the maxilla often does not increase in width after osteoplasty until inadequate remaining height is present. However, when anatomy permits, the osteoplasty of C–w bone may improve the crestal width to a Division C–h ridge. The C–h edentulous patient with a compromised anterior maxillary region has an available bone height of 7 to 11 mm, with a crown height/residual bone height ratio greater than 1.

A C–h premaxilla most often requires a removable overdenture, because the maxillary lip requires greater support than a fixed restoration can render. The partially edentulous patient with a C–h premaxilla who desires a FP-1 fixed restoration often requires an extraoral autogenous bone graft. Full-arch onlay grafts can be used to increase vertical height or bone, reduce the crown height space, and improve the arch's size and shape, which may be required for a fixed restoration.

The osteoplasty technique eliminates the need for autologous bone grafts and the associated healing time, discomfort, and cost of the procedure. The ideal dimensions required in a maxillary anterior C–h bone include a ridge width of greater than 6 mm, allowing at least 1 mm of bone on the lateral aspects of the implant. When the residual crest in the anterior maxilla is adequate in width but only 7 to 11 mm in height, a Division C–h root form and subnasal elevation and/or lateral piriform rim modification may be considered to provide adequate height for implant placement.[10,23-25]

Subnasal elevation may be used in the C–h premaxilla, because the nasal floor can be elevated from 0 to 4 mm in the central or lateral incisor region and up to 4 mm in the canine area.

WWW.HIGHDENT.IR

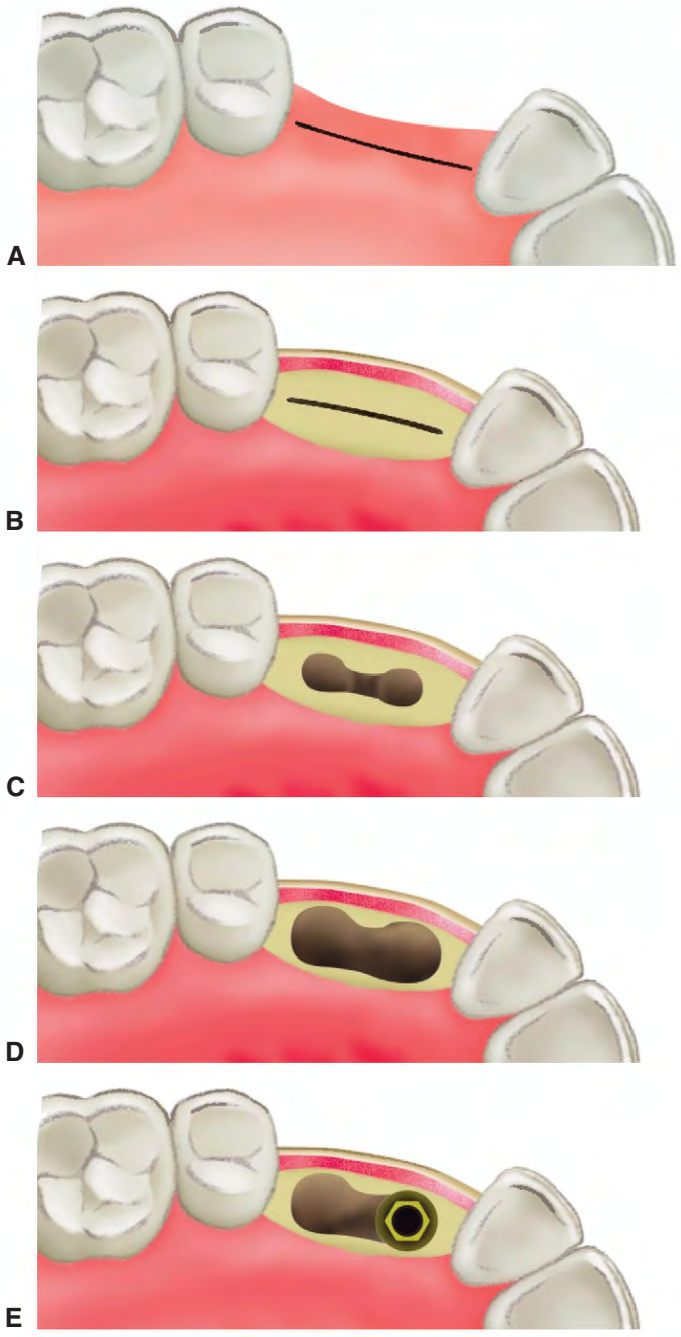

Figure 34-28 **A,** A midcrestal incision is made with keratinized tissue on the facial aspect. **B,** A narrow osteotomy is prepared with a surgical bur. **C** and **D,** The edentulous ridge is gradually expanded facially with round-shaped osteotomes. **E,** The implant may be inserted; however, if the facial plate breaks, then a layered graft with a membrane is added on the facial aspect in addition to an intrapositional bone graft placed after bone expansion to increase the width.

Anatomical Considerations

The anterior nasal spine has an anterior component that averages 4.1 mm (0 to 9 mm) in adults.[26] Posterior and lateral to it, two flat processes, the alae of the premaxilla, project superiorly and laterally (Figure 34-29). The piriform aperture is bounded below and laterally by the maxilla. The breadth of the piriform aperture

Figure 34-29 The natural canine root is distal to the lateral piriform rim of the nose. However, a nasal recess extends distal, behind the piriform rim and over the canine site of a resorbed maxilla, which is more palatal than the tooth root position. The inferior concha of the nose is 4 to 6 mm superior to this recess region.

in adults ranges from 20 to 28 mm and averages 23.6 mm.[26,27] The lower border of inferior piriform rim may be sharp or rounded. This border often rises from the premaxillary bone and ends anteromedially in the anterior nasal spine. The anatomy of the nasal floor is variable in relation to the inferior turbinate and is typically situated 5 to 9 mm below the level of this structure.[28]

When maxillary anterior teeth are present or have maintained the residual bone, the inferior piriform rim is usually level or a few millimeters above the floor of the nose in the central and lateral region.[29] The inferior piriform rim above the nasal floor forms a prenasal fossa, found in 12% of patients.[27,30] In these cases a shallow depression extends toward the alveolar arch behind a sharp border of the inferior piriform rim. As a result, when the inferior piriform rim is used as a guideline for the height of the opposing cortical plate from the crest of the ridge in the maxilla during surgery to determine implant length, the lowest portion of the nasal floor and nasal mucosa may be inadvertently perforated during the implant osteotomy and placement. Instead, the nasal floor may be elevated and grafted before implant placement.

The canine tooth position is immediately distal to the lateral piriform rim. The canine eminence in this area is lost after several years of edentulism, and the crest of the residual C–h bone volume ridge is palatal to the original tooth position. The nasal cavity is usually above, medial, and palatal to the canine position in the dentate patient. However, a nasal recess is present behind the lateral piriform rim. This nasal recess corresponds to the apical region of the canine position in the C–h maxilla, which has resorbed palatally and is now under the nasal cavity. Implants placed in the canine position of a C–h bone volume may extend more superior than the natural canine root and penetrate into the nasal cavity because of the nasal recess behind

WWW.HIGHDENT.IR

the lateral piriform rim. One study reported that during healing, no undesirable side effects occurred secondary to penetration of titanium screws into the nasal cavity.[31] However, because the whole implant length is not placed in bone, soft tissue will encapsulate the apical end, and the functional surface area of the implant is unknowingly reduced.

The lateral and inferior piriform rim may be identified and the nasal mucosa elevated up to 4 mm off the rim and the floor of the nasal cavity or within the recess distal to the lateral rim, creating a subnasal pocket for augmentation. This procedure has also been performed in conjunction with bone augmentation from the iliac crest or with mandibular blocks.[32-37]

The arterial blood supply to the nose is derived from both the external and internal carotid arteries. The terminal branch of the maxillary artery (a branch of the external carotid) supplies the sphenopalatine artery, which supplies the lateral and medial wall of the nasal chamber. The anterior and posterior ethmoid arteries (branches of the ophthalmic artery) supply the nasal vestibule and the anterior portion of the septum. In addition, a few vessels from the greater palatine artery pass through the incisive canal of the palate to reach the anterior part of the nose.

At the junction between the squamous epithelium of the nasal vestibule and the respiratory epithelium of the nasal cavity lies a strip about 1.5 mm wide covering a region of wide and long capillary loops, known as *Kiesselbach's plexus*.[38] It extends to the lower and central part of the cartilaginous septum and is a common region for nose bleeds. The subnasal graft is positioned anterior to this region.

The fifth cranial nerve innervates the region of the subnasal graft. Infiltration anesthesia has been successfully used; however, a more significant regional anesthesia is achieved when the secondary division of the maxillary nerve (V2) is blocked. Using this technique, anesthesia of the hemimaxilla, side of the nose, cheek, lip, and maxillary sinus can be achieved. The use of a long-acting anesthetic (e.g., bupivacaine 0.5% with epinephrine 1:200,000) is preferred, because it may also decrease postoperative discomfort. Xylocaine 2% with 1:100,000 epinephrine is infiltrated into the labial mucosa and palatal region to evaluate the V2 block and may enhance local hemostasis.

SURGICAL TECHNIQUE

A full-thickness incision is made on the crest of the edentulous premaxilla, from the distal end of the edentulous site on one side to the distal end of the contralateral edentulous site. Vertical lateral relief incisions are then made at the distal aspect of the flap. A full-thickness mucoperiosteal reflection is accomplished first on the palatal aspect, then a similar flap exposes the facial aspect of the maxilla, the nasal spine, and the inferior and lateral piriform rim.

C–h Maxillary Canine Position Implant

The bone on the distal and inferior to the lateral piriform rim is identified. The nasal mucosa in the nasal recess is elevated using a curved soft-tissue curette, in a manner similar to elevation of the sinus mucosa in sinus graft procedures (Figure 34-30, *A*). The back side of the curette is positioned on the soft tissue, and pressure on the blunt aspect of the instrument pushes the nasal mucosa palatal, until the sharp portion of the curette is positioned on the lip of the lateral piriform rim. Because the nasal mucosa is generally thicker and more tear resistant, it is easier to elevate from the bony walls than its maxillary sinus counterpart. However, increased pressure against the bone is required, compared with membrane elevation in maxillary sinus procedures, because of the presence of elastic fibers in the periosteum, which adhere more tenaciously to the underlying bone. The curette then slides down the lateral aspect of the nasal fossa and along the distal aspect of the inferior piriform rim. Depending on the depth of the depression behind the lateral piriform rim, the nasal mucosa is elevated approximately 3 to 5 mm distally and superiorly.

Once the periosteum of the prenasal fossa is elevated, a sharp probe is used to aggressively scratch the floor and lateral walls of the nasal cavity in the pocket created to induce a regional acceleratory phenomenon (RAP). The pocket created for the lateral piriform rim elevation is approximately 5 × 5 mm, which is relatively small; therefore an autograft usually can fill the region (Figure 34-30, *B*). Autogenous bone has long been considered the gold standard and remains the material of choice for the subnasal graft because of its osteogenic, osteoinductive, and osteoconductive properties, which enhance bone formation and provide greater initial density after bone modeling. Because the donor site is usually chosen depending on the volume and type of bone desired, the subnasal graft generally requires less than 2 cc unilaterally and is easily filled with all autogenous bone from a maxillary harvest (Figure 34-30, *C* and *D*). It can usually be harvested from maxillary intraoral sites, maxillary tuberosity, exostoses, and/or debris from implant osteotomies. The cortical and trabecular autogenous bone chips are applied from the most posterior regions of the nasal space to the most anterior labial region of the piriform rim.

The implant may be inserted in conjunction with the subnasal elevation, because the augmentation only concerns the apical region of the implant.

When implants are inserted simultaneously with the nasal augmentation, the implant osteotomy in the canine position stops 1 to 2 mm short of the nasal

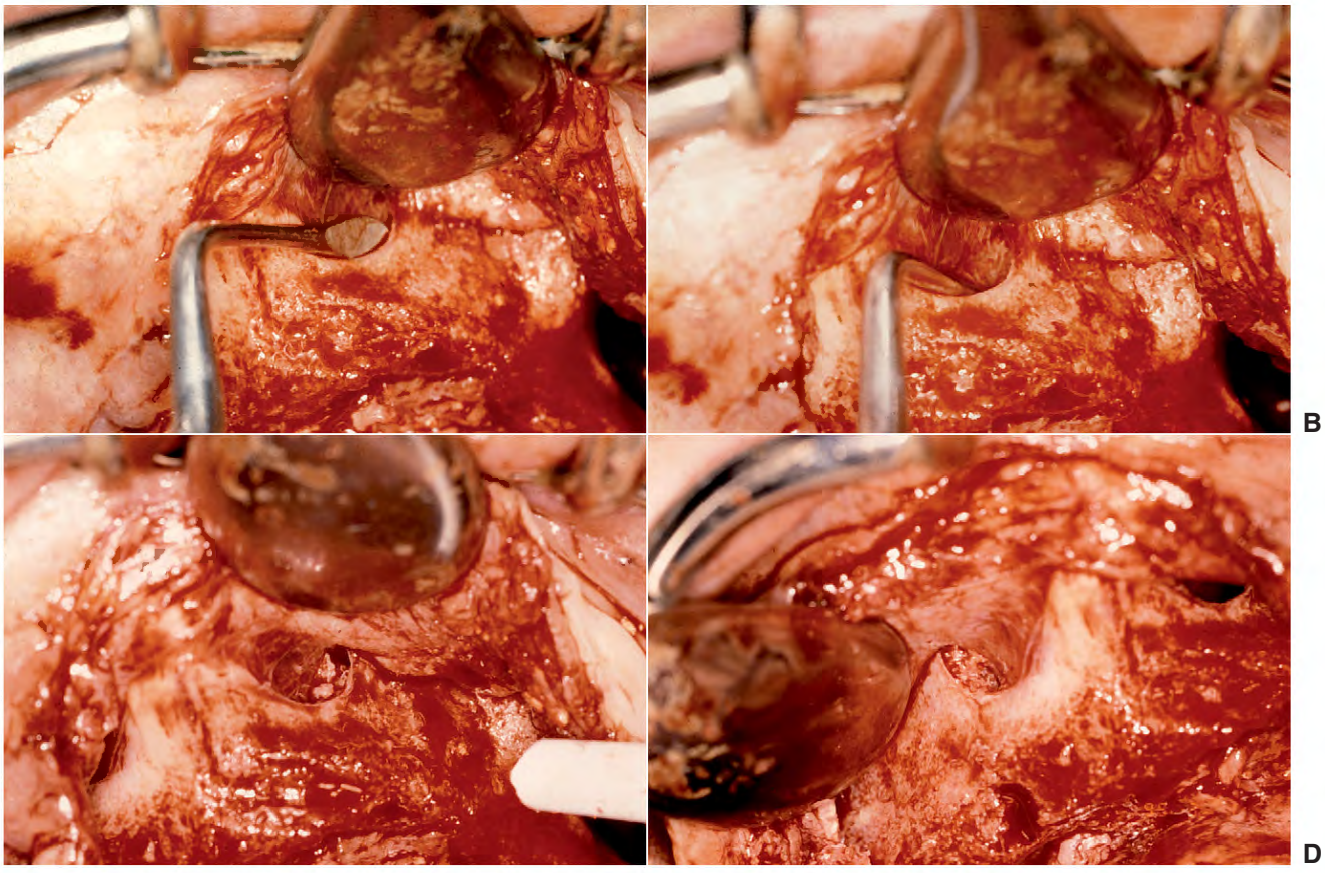

Figure 34-30 **A,** A soft tissue currette is used to elevate the nasal mucosa off the left canine recess region of the premaxilla. **B,** The soft tissue curette creates a submucosal space approximately 4 mm in height, 5 mm deep, and extends to the vertical wall of bone on the distal of the canine recess site. **C** and **D,** An autograft (tuberosity) is used to fill the left and right canine recess site.

floor (similar to an SA2 sinus lift approach). The final diameter of the implant osteotome is obtained in the usual sequence of drill diameters. A flat-ended osteotome, similar to the sinus lift design, is used to create a greenstick fracture to the floor (this also enhances the RAP phenomenon). Bleeding (although rarely a concern during the subnasal elevation) may be controlled with pressure, collagen, or electrocautery. If bleeding originates from the Kiesselbach's plexus, then pressure is applied through a nasal packing for 15 to 30 minutes. A cotton roll, lightly coated with petroleum jelly, is a convenient nasal-packing material. A string of dental floss may be tied around one end of the cotton roll to allow the removal of the sponge with ease.

During installation of an implant in the canine position, the osteotomy may inadvertently penetrate the maxillary sinus, because this structure often interfaces with the lateral piriform rim and nasal cavity in the long-term edentulous patient. A sinus graft procedure is most often performed with posterior implants inserted, which decreases this risk when the sinus floor is filled to the anterior wall. Rigid fixation of the implants should always be confirmed at the time of surgery, and any implant that is mobile or not adequately stabilized should be removed because it may perforate the nasal mucosa, become dislodged into the nares, and ultimately end up in the trachea (Figures 34-31 to 34-33).

C–h Maxillary Central to Lateral Incisor Implant

The maxillary central to lateral incisor region in C–h cases presents 7 to 11 mm of vertical bone and more than 6 mm of available bone width. The crest of the residual ridge is palatal to the original incisor position, and the prosthesis should most often be an overdenture. The subnasal elevation procedure is performed in a fashion similar to the C–h canine implant (Figure 34-34). The elevation takes place from the inferior piriform rim and onto the floor of the nasal cavity (Figure 34-35). During subnasal elevation in the incisal regions, the soft tissue curette should stay against the bone lip and follow the depression when evident. The nasal depression below the inferior piriform rim may drop as much as 2 to 4 mm. When this occurs, the nasal floor augmentation is more predictable, because a facial bony wall improves the number of walls of host bone for the new bone formation. The subperiosteal space in the nasal floor is usually 5 mm deep and 2 to 4 mm

high. Autologous bone is harvested from the maxilla and fills the space. The implant osteotomy is prepared to the final drill diameter for the implant, 2 mm short of the nasal floor (not the piriform rim) (Figure 34-36). An implant 11 to 13 mm may then be placed into the osteotomy, which extends 2 to 4 mm above the original nasal floor (Figure 34-37). The prenasal fossa augmentation procedure may also be performed in conjunction with autogenous bone grafts to decrease the height requirement for the onlay graft before the placement of implants.

Postoperative Instructions for Subnasal Elevation

The postoperative instructions for subnasal grafts and/or implant insertion are similar to those for most oral surgical procedures. In addition, the patient is instructed not to place fingers in the nose to prevent retrograde pressure and implant mobility.

Complications

The unique complications associated with nasal elevation and implant insertion include tearing the nasal

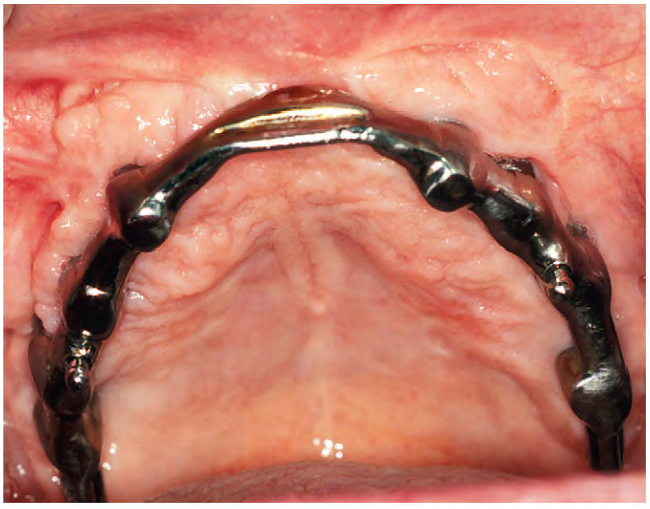

Figure 34-33 The eight implants are splinted together with a bar. A keratinized tissue graft was placed on the facial aspect of the canine implants.

Figure 34-34 A nasal recess area often exists behind the inferior piriform rim of the nose. This region may be elevated 2 to 4 mm in a C–h anterior maxilla for additional implant length.

mucosa and the implant extending into the nares proper. When the nasal mucosa is torn, bacteria from the nasal cavity may infect the implant site. As a result, the nasal mucosa tear should be closed with a horizontal mattress suture and a water-tight closure. No tension should exist on the suture line over the graft and implant, which may result in a delayed incision opening. This is more complicated, because the healing mucosa may feel inflamed and patients often rub the area with their fingers, resulting in reopening of the tear.

On occasion, the implant does not perforate the nasal mucosa during the surgery; however, years later the implant may become exposed in the nares proper. The threaded design may capture mucous or nasal scabs and contribute to odor or even rhinosinusitis. A bone graft before implant insertion decreases this risk. However, when this occurs to a rigid implant, consideration

may be given to perform an implant apicoectomy and remove the protruding aspect of the implant.

Incisive Foramen Implant

The incisive foramen region, rather than a central incisor site, may also be used to insert an endosteal implant, especially when an overdenture is the intended final prosthesis.[39] The incisive canal ranges in length from 4 to 26 mm and is directly related to the height of bone in the premaxilla.

As alveolus height is resorbed, the canal reduces in length; therefore Division A, B, and C–w bone has greater canal length than Division C–h and D. The incisive canal has an average axis of 70 degrees with a range of 57.0 to 89.5 degrees from the horizontal plane.[30] This structure contains terminal branches of the nasopalatine nerve, the greater palatine artery, and a short mucosal canal (i.e., Stensen's organ). However, the reflection of the palate rarely results in bleeding (and almost never arterial bleeding); although an artery may be present, it appears that a venous return structure rather than an arterial source is present to the palate. A vertical projection above the incisive canal along the nasal floor is called the *premaxillary wing*. The nasal process of the maxillary premaxilla rises 2 to 3 mm above the nasal floor. As a result, when 7 to 11 mm of bone is present below the nasal floor, a large osteotome may create a greenstick fracture in this process above the foramen and permit the placement of a 9- to 14-mm implant. The foramen is usually 4 to 6 mm in diameter at the crest and narrows down to 4 mm at the apex. Therefore implants inserted at the same time as the soft tissue is curetted are usually 5 to 6 mm in diameter.

The incisive foramen is first reflected and identified, and a periodontal probe evaluates the angle and depth of the bony canal to ensure a minimum length of 9 mm. The soft tissues in the incisive canal are curetted from the canal site, which is approximately 4 mm in diameter at its apex. A large round drill may be used to this effect.

Once the soft tissue is removed, drills progressively increase the diameter to the final implant osteotomy diameter 2 mm below the final height of the canal. A blunt osteotome and gentle, sudden impact force with a mallet then prepares the apical 2 mm of the implant site. A large-diameter threaded implant (>5 mm) is generally used and should be greater than the diameter of the foramen (Figure 34-38). When the foramen diameter is greater than that of the implant available, the canal is augmented with an autologous bone graft, and the implant insertion is delayed for several months (Figure 34-39).

Complications

Some unique complications may be found with an incisive canal implant: two surgical complications, one short-term complication, and one long-term complication.

The first surgical complication of an incisive foramen implant is related to the implant that is too small for the foramen and not properly fixated. The implant may be inadvertently pushed through the incisive canal and into the nares proper (Figure 34-40). Because the patient is lying on their back during the surgery, the implant may fall back into the soft plate, then into the trachea or esophagus. If the implant disappears from the oral site, the patient's head should be turned to the side immediately, then down and forward. A nasal speculum and tissue forceps may then be used to recover the implant.

A second surgical complication may include bleeding from the incisive foramen. Although this complication is very rare, it is possible. When reflection of the palatal tissue off the incisive canal is associated with arterial bleeding, a blunt bone tap (mirror handle) may be placed over the canal and a mallet used to hit the instrument firmly, crushing the bone over the artery. After several minutes the procedure may continue, and the implant insertion will obdurate the site and arrest the bleeding.

The short-term complication of an incisive foramen implant is associated with enucleation of the soft tissue from the foramen. Although the author has not witnessed this complication, neurological impairment of the soft tissues in the anterior palate may exist. These complications may be paresthesia to the soft tissue or a dysesthesia as burning sensation. It is logical to include this risk in an informed consent. If it should occur, then removal of the implant for dysesthesia is warranted, whereas paresthesia of the palate most likely is a condition the patient can tolerate without significant issues.

A long-term complication that has been observed twice by the author is the regeneration of the soft tissue in the incisive canal, resulting in bone loss around the implant (Figure 34-41). When the implant is removed and the soft tissue biopsied, nerve fibers can be seen reinvading the site. This most likely occurs because the implant was too small for the size of the foramen, and the soft tissue can reform around the implant. Treatment of this complication includes removing the implant and, if necessary for the treatment plan, then regrafting and/or reimplantation.

SUMMARY

The maxillary surgical considerations for multiple implants in Division A bone are very similar to implant insertion for single-tooth implants. However, more often FP-3 or RP-4 prostheses are fabricated. As such, implant insertion is less critical, and the soft tissue drape is more often restored with the prosthesis. However, when the

patient desires an FP-1 restoration, multiple adjacent implants make this goal more difficult than for a single tooth.

The maxillary lip often requires support when multiple anterior teeth are missing. When a fixed prosthesis is indicated, ridge augmentation is often required to support the lip above the prosthesis. This modality presents unique surgical requirements. Division B bone volume in the maxilla often may be addressed by bone-spreading techniques in conjunction with implant insertion. These procedures require a learning curve that is best developed in Division A bone with D3 or D4 bone density.

The C–h bone volume in the premaxilla may be treated with unique surgical techniques to alter the floor and lateral aspects of the nose or permit implant placement in the incisive foramen. These procedures are most often used for RP-4 or RP-5 restorations.

Chapter 35

Immediate Load and Restoration in Implant Dentistry: Rationale and Treatment

Carl E. Misch, Gerard M. Scortecci

Predictable formation of a direct bone-implant interface is a consistent treatment goal in implant dentistry. The two-stage surgical protocol established by Brånemark et al.[1] to accomplish osseointegration consisted of several prerequisites, including the following: countersinking the implant below the crestal bone, obtaining and maintaining a soft tissue covering over the implant for 3 to 6 months, and maintaining a nonloaded implant environment for 3 to 6 months. The primary reasons cited for the submerged, countersunk surgical approach to implant placement were to reduce and minimize the risk of bacterial infection, to prevent apical migration of the oral epithelium along the body of the implant, and to reduce and minimize the risk of early implant loading during bone remodeling. After this procedure, a second-stage surgery is necessary to uncover these implants and place a prosthetic abutment. A high degree of long-term, clinical rigid fixation has been observed with this protocol in completely and partially edentulous patients.[2,3]

During the last 15 years, several authors have reported that root form implants may osseointegrate, even though they reside above the bone and through the soft tissue during early bone remodeling.[4-6] This surgical approach has been called a *one-stage* or *nonsubmerged implant procedure* and eliminates the second-stage implant uncovery surgery. As a result, the tissue discomfort and healing associated with second-stage surgery are eliminated for the patient. The dentist also eliminates the surgical time for uncovery and suture removal. In addition, the soft tissue is already mature before fabrication of the final prosthesis.

Immediate loading of a dental implant not only includes a nonsubmerged, one-stage surgery but also actually loads the implant with a provisional restoration at the same appointment or shortly thereafter. Immediate loading was the initial protocol suggested with dental implants. These implants yielded a wide range of clinical survival.[7-11] On occasion, a direct bone interface could be developed and maintained for more than 20 years[12] (Figure 35-1).

TERMINOLOGY

Immediate restoration of dental implants not only includes a nonsubmerged first-stage surgery but also implies the occlusal surfaces and implants are loaded with a provisional or definitive restoration. Discussions have involved whether a restoration must be delivered at the time of surgery for this description. Because the restoration is not truly loaded immediately after implant insertion, regardless of the technique, an agreement should be established as to what guidelines and language may be acceptable to a majority of the profession. Misch et al.[13] suggested a terminology for immediate restoration and/or occlusal loading. The *immediate occlusal-loading* protocol is an implant-supported temporary or definitive restoration in occlusal contact within 2 weeks of the implant insertion. *Early occlusal loading* refers to an implant-supported restoration in occlusion between 2 weeks and 3 months after implant placement and may use the time period in parentheses (i.e., early [5-week] occlusal loading). *Delayed* or *staged occlusal loading* refers to an implant prosthesis with an occlusal load after more than 3 months after implant insertion. The delayed occlusal-loading approach may use either a two-stage surgical procedure that covers the implants with soft tissue or a one-stage approach that exposes a portion of the implant at the initial surgery. *Nonfunctional immediate restoration* describes an implant prosthesis with no direct occlusal load within 2 weeks of implant insertion and is primarily considered in partially edentulous patients. *Nonfunctional early restoration* describes a restoration in a partially edentulous patient delivered between 2 weeks and 3 months after the implant insertion.

Linkow.)*

COMPLETELY EDENTULOUS PATIENTS

Early studies in immediate loading with root form implants, with a primary goal of a direct bone-implant contact, have been proposed and have shown encouraging results.[14] In general, two different approaches have emerged. The first approach involves placing several more implants than the usual treatment plan for a conventional healing period (Figure 35-2, *A*). Selected implants around the arch (three or more) then are loaded immediately with a transitional prosthesis (Figure 35-2, *B*). Enough implants are left submerged

WWW.HIGHDENT.IR

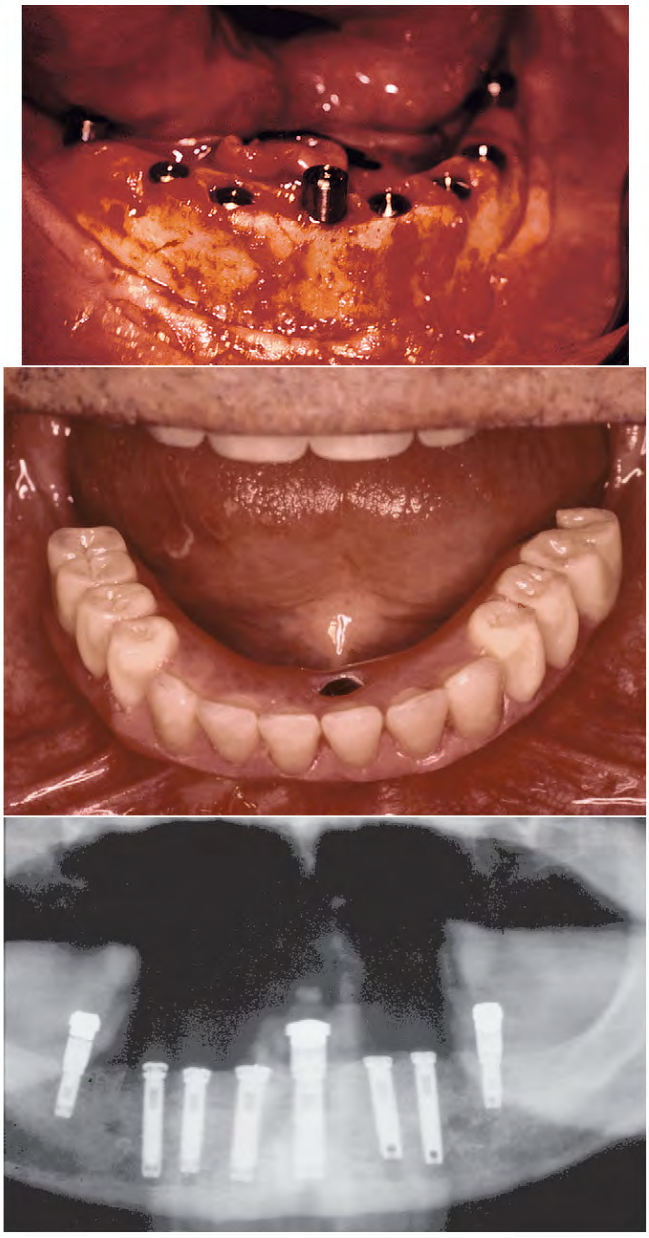

Figure 35-2 **A,** Five implants are inserted between the mental foramens with a two-stage approach. for a regular healing period to allow delivery of a fixed prosthesis, even if all immediately loaded implants fail (Figure 35-2, *C*). If any of the implants survive, then they also are used in the final restoration. This protocol was first published by Schnitman et al.[15] in 1990, using 28 screw-shaped implants in 10 mandibles to support a fixed transitional prosthesis. Schnitman et al.[16] suggested that this procedure be used only in the completely edentulous mandible, where moderate to abundant bone was present posterior and anterior to the mental foramens. Using this approach, 100% of the submerged unloaded implant survived, whereas three immediately loaded implants failed before 6 months and one implant failed 18 months after surgery (84% survival) over 9 years.

In 1997, Tarnow et al.[17] reported on immediate loading with a fixed prosthesis, using threaded implants in 10 consecutive completely edentulous cases over 5 years. Sixty-six of 69 implants were integrated in six mandibular and four maxillary completely edentulous arches (96% survival) using a total of 10 to 13 implants in each arch for the final prosthesis. Like Schnitman et al.,[15,16] Tarnow et al. did not immediately load all the implants for the transitional prosthesis.

The other protocol for immediate occlusal loading of dental implants initially loads all of the implants inserted. The implants are splinted together, which decreases the stresses on all the developing interfaces and increases the stability, retention, and strength of the transitional prosthesis during the initial healing phase (Figure 35-3). Often additional implants also are used with this technique compared with the traditional healing method.[18-22]

The immediate-load concept provides all the advantages of the one-stage surgical approach. In addition, implants are splinted together, which decreases the risk of overload because of a greater surface area and improved biomechanical distribution. The patient does not need to wear a removable restoration during initial bone healing, which greatly increases comfort, psychological factors, function, and stability during the transition period. Over the last few years, authors have reported on immediate loading in the completely edentulous patient, with 95% to 100% success rates. However, the influence of immediate loading on crestal bone loss has few animal and clinical reports so as to compare the differences of immediate loading to a more traditional bone-healing time with no functional load.

Rationale for Implant Immediate Loading

Surgical Trauma

The immediate implant–loading concept challenges the conventional healing time of 3 to 6 months of no loading before the restoration of the implant. Often the risks of this procedure are perceived to be during the first week after the implant insertion surgery. In reality, the bone interface is stronger on the day of implant placement compared with 3 months later[23] (Figure 35-4).

The surgical process of the implant osteotomy preparation and implant insertion cause a regional acceleratory phenomenon of bone repair around the implant interface.[24] As a result of the surgical placement, organized, mineralized lamellar bone in the preparation site becomes unorganized, less-mineralized, woven bone of repair next to the implant.[25] The implant-bone interface is weakest and most at risk of overload at

Continued

3 to 6 weeks after surgical insertion because the surgical trauma causes bone remodeling at the interface that is least mineralized and unorganized during this time frame. A clinical report by Buchs et al.[26] found immediately loaded implant failure occurred primarily between 3 and 5 weeks after implant insertion from mobility without infection. At 4 months the bone is still only 60% mineralized, organized lamellar bone.[27] However, this has proved to be sufficient in most bone types and clinical situations for two-stage healing and delayed implant loading.

One method to decrease the risk of immediate occlusal overload is to decrease the surgical trauma and amount of initial bone remodeling at implant placement. Roberts et al.[28] reported a devital zone of bone for 1 mm or more around the implant as a result

WWW.HIGHDENT.IR

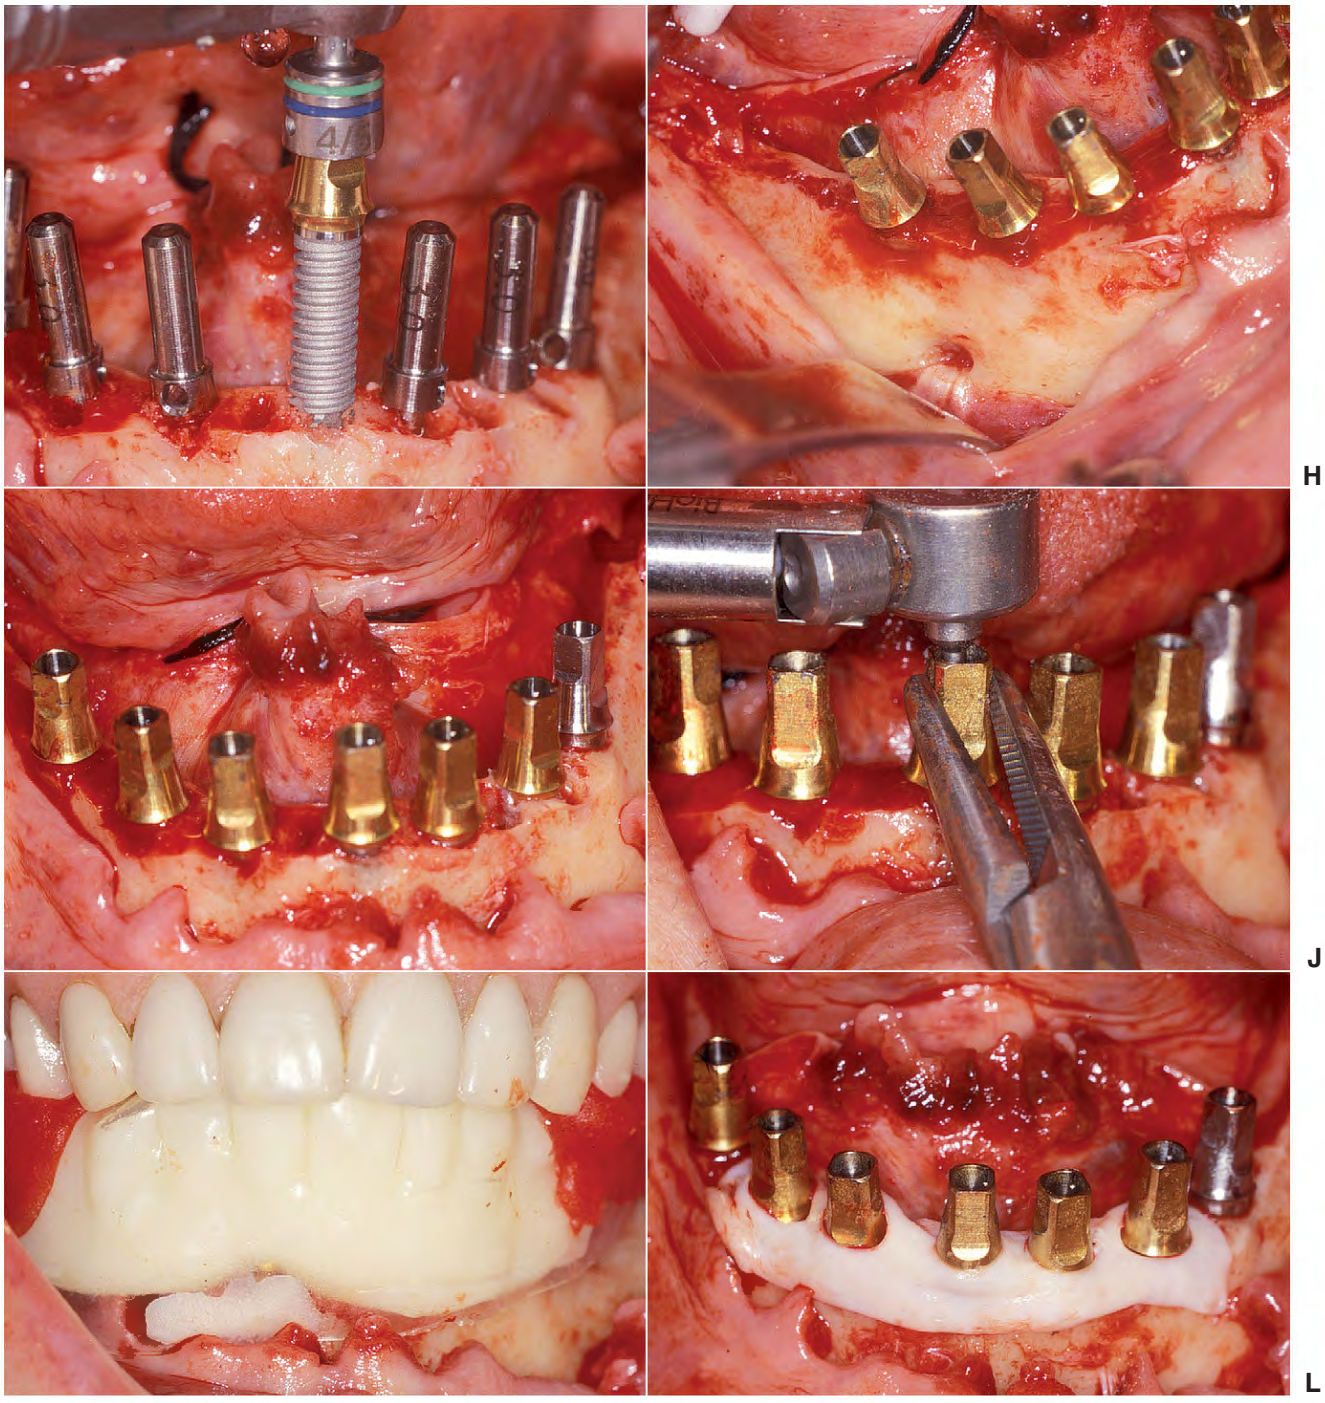

Figure 35-3, cont'd **G,** BioHorizons Maestro implants (BioHorizons; Birmingham, Ala.), which are 15 mm long and 4 mm in diameter, are inserted between the foramens. Longer implants are used when possible for immediate occlusal loading. **H,** An implant is positioned over each foramen to increase the number of implants, increase the anterioposterior (A-P) distance, and decrease the cantilever length of the final prosthesis. **I,** The completed surgery demonstrates seven BioHorizons implants: five between the mental foramens and two above the foramens. **J,** A torque wrench is used to tighten the abutment screws to 30 N-cm to decrease abutment screw loosening during the initial loading period. **K,** A light-cured material (e.g., Triad, Dentsply) is used for the transitional restoration to eliminate acrylic monomer contact on the bone and decrease restorative material shrinkage during setting. **L,** An acellular dermal matrix (AlloDerm; LifeCell, Branchburg, N.J.) is used around the implants to act as a barrier membrane for the extraction sites and to develop a zone of nonmobile tissue around the implants.

Continued

of the surgical trauma (Figure 35-5). Causes of trauma include thermal injury and microfracture of bone during implant placement. Excessive surgical trauma and thermal injury may lead to osteonecrosis and result in fibrous encapsulation around the implant.[29] Eriksson and Albrektsson[30] have reported bone cell death at temperatures as low as 40° C. Sharawy et al.[31] have shown that the amount of heat generated in the bone next to the implant drills depends on the drill design and speed. The temperature next to the drill ranged from

38° C to more than 41° C, from a baseline of 37° C, and required 34 to 58 seconds to return to baseline. In this report, the two implant drill systems with internal-cooled drills cut at a higher temperature than the two systems tested with external irrigation. Other factors related to heat generated to bone include the amount of bone prepared, drill sharpness, depth of the osteotomy, and variation in cortical thickness.[32,33]

A self-tapping implant causes greater bone remodeling (woven bone) around the implant during initial healing compared with a bone tap and implant placement technique.[34] The implant should be nonmobile on insertion, but excess strain from additional torque also may increase the risk of microdamage at the interface. The dentist may believe a protocol for immediate load is to tighten the implant within the bone to 45 to 60 N-cm. Although this concept helps ensure that the implant has rigid fixation and is in good-quality bone, the additional torque used to secure or evaluate fixation of an implant in bone actually may increase the strain at the interface and therefore increase the amount of remodeling, which decreases the strength of the bone-implant interface. Therefore it is prudent to minimize factors related to thermal injury and surgical trauma when considering immediate load to the implant interface.

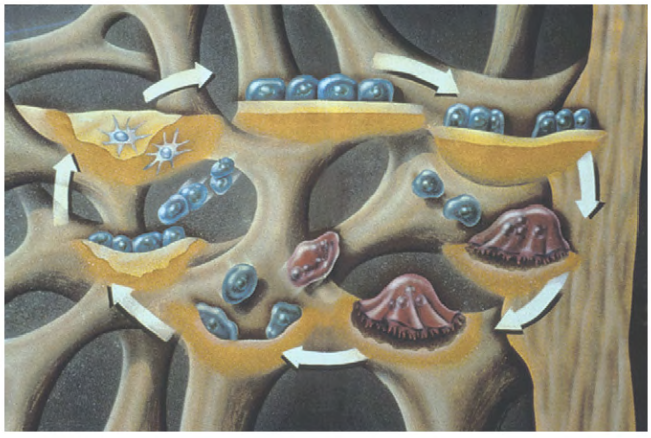

Figure 35-6 Bone remodeling replaces the existing bone with new bone and is controlled primarily by the amount of microstrain within the bone. The rate of the bone remodeling also is related directly to the amount of microstrain.

Bone-Loading Trauma

Cortical and trabecular bone may be modified by modeling or remodeling.[25] Remodeling, or bone turnover, permits the repair of bone after trauma or allows the bone to respond to its local mechanical environment. The bone most often is lamellar but may become woven bone during the repair or remodeling process, so the bone may respond more rapidly to the current situation. Lamellar bone and woven bone are the primary bone tissue types found around a dental implant. Lamellar bone is organized, highly mineralized, is the strongest bone type, has the highest modulus of elasticity, and is called *load-bearing bone*. By comparison, woven bone is unorganized, less mineralized, weaker, and more flexible (lower modulus of elasticity). Woven bone may form at a rate of 60 µm per day, whereas lamellar bone forms at a rate of 1 to 5 µm per day.[27] The classic two-stage surgical approach to implant dentistry permitted the surgical repair of the implant to be separated from the early loading response by 3 to 6 months. Therefore the majority of the woven bone that formed to repair the initial surgical trauma was replaced with lamellar bone. Lamellar bone is stronger and able to respond to the mechanical environment of occlusal loading. Therefore a rationale for immediate loading is not only to reduce the risk of fibrous tissue formation (which results in clinical failure) but also to minimize woven bone formation and promote lamellar bone maturation to sustain occlusal load. The woven bone of surgical trauma has been called *repair bone*, and the woven bone formed from the mechanical response may be called *reactive woven bone*.[35] Remodeling also is called *bone turnover* and not only repairs damaged bone but also allows the implant interface to adapt to its biomechanical situation (Figure 35-6). The interface-remodeling rate is the period of time for bone at

WWW.HIGHDENT.IR

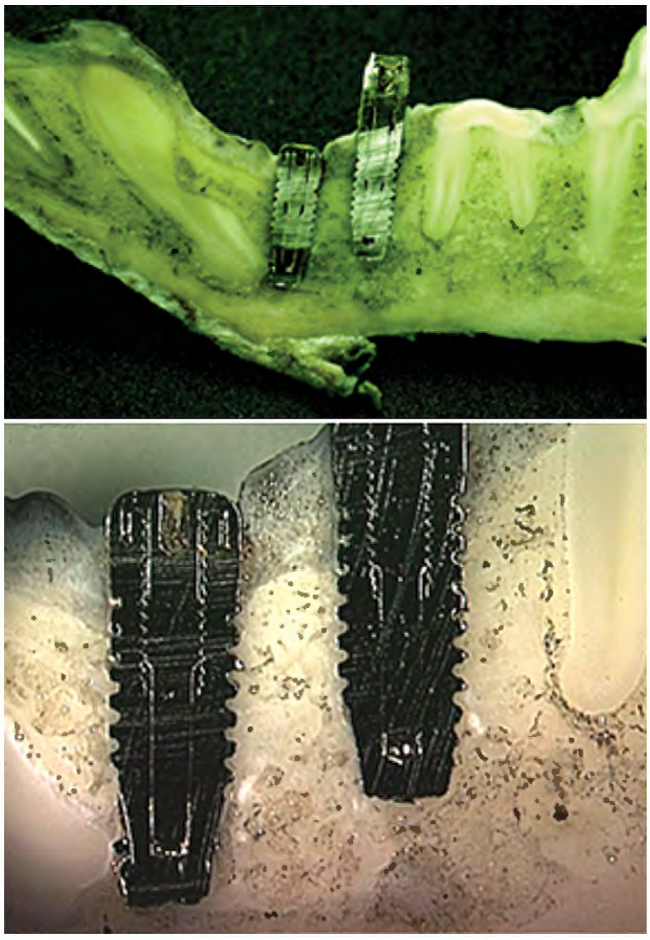

Figure 35-7 Paired BioHorizons Maestro implants inserted into a canine model, with one implant not loaded and the other immediately placed into function for 4 weeks.

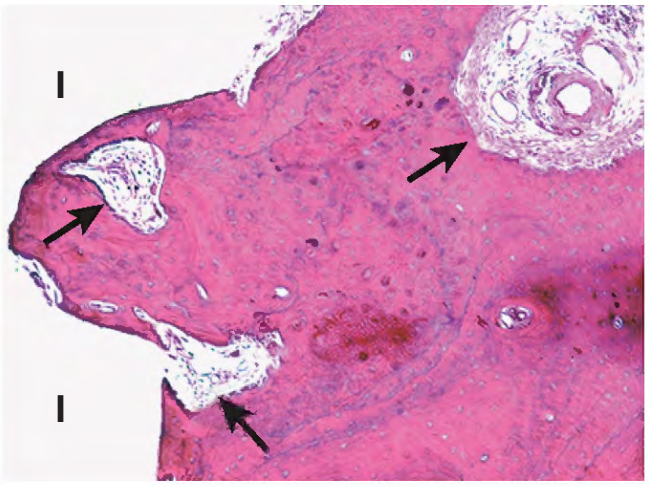

Figure 35-8 No statistical difference in bone-implant contact percent and the volume fractions of the interface were found between the implants immediately loaded and those with no load for 1 month.

the implant interface to be replaced with new bone. Once the bone is loaded by the implant prosthesis, the interface begins to remodel again. However, this time the trigger for this process is strain, rather than the trauma of implant placement. *Strain* is defined as the change in length of a material divided by the original length and is measured as the percentage of change. When the surgical trauma is too great or the mechanical situation is too severe, fibrous tissue may form rather than bone. Fibrous tissue at an implant interface may result with clinical mobility rather than rigid fixation.

Histologic Evaluation: Short Term

General agreement is that excess stresses to an implant interface may cause overload and implant failure. However, immediate loading of an implant does not necessarily result in excessive stresses. The initial histologic response of bone at the implant interface has been evaluated on immediately loaded implants. A direct bone-implant contact with favorable bone quality around the implants is reported. For example, Romanos et al.[36] demonstrated no statistical difference between immediate- and delayed-loaded implants. Sharawy[37] evaluated the immediate- versus delayed-healing interface of 20 BioHorizons dental implants in five adult beagle dogs (Figure 35-7). All implants were inserted into premolar grafted bone defect sites. The implants were paired, so one half the implants were submerged and the adjacent implants received an abutment and were subjected to immediate function for 4 weeks. The implants then were evaluated with histometric analyses of plastic embedded calcified sections. No statistically significant difference ($p > 0.05$) was found in the bone-implant contact ratios between the submerged and loaded implants (Figure 35-8). Similarly, the volume fractions of the interface bone were not significantly different. The bone next to the implants appeared mature and showed evidence of remodeling.

Suzuki et al.[38] performed a clinical and histological evaluation of immediate-loaded posterior implants in nonhuman primates. After loading 10 implants for 90 days, they were compared with 5 control implants with no loading. The bone-implant contact percent (BIC) ranged from 50.3% to 64.1%, with an average of 56.3% for the controls. The immediate-loaded group had one implant failure, seven implants with an average of 67.6% BIC, and two implants with 43.2% and 45.6% BIC, respectively. Therefore the study demonstrated immediate-loaded implants may have a higher BIC than nonloaded implants, most likely a response to the strain conditions in the bone. However, three implants had less BIC or failure when compared with controls. Although benefits exist related to immediate loading, it appears some risks are involved in the procedure.

Testori et al.[39] reported on the histologic interface of two implants in human beings that were immediately loaded after 4 months. The bone contact ranged from

WWW.HIGHDENT.IR

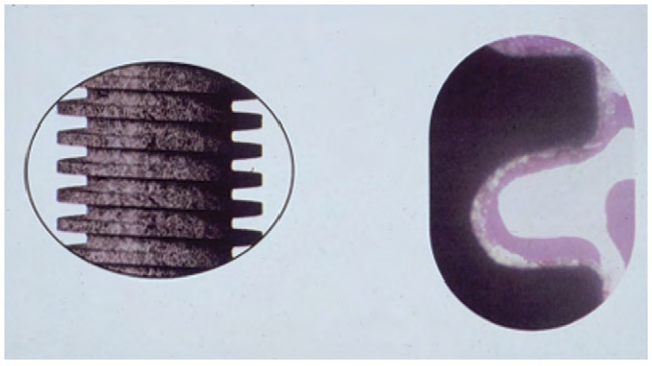

Figure 35-9 A BioHorizons Maestro D4 immediate-loaded implant for 1 year in function from a posterior maxilla in a human being. The bone-implant contact was 83%. *(Courtesy M. Degidi and A. Piatelli.)*

78% to 85%, with no epithelial migration. Therefore immediately loading an implant interface apparently does not necessarily place the interface at increased risk of fibrous tissue formation.

Histologic Evaluation: Long Term

Piatelli et al.[40] evaluated bone reactions and the bone and titanium interface in early loaded implants in monkeys compared with unloaded implants in the same arch several months after immediate loading. No statistically significant differences were detected in the BIC after 8 months. However, loaded implants had less marrow spaces and more compact bone. A later study by the same group demonstrated greater bone contact in immediately loaded implants at 9 months.[41] No fibrous tissue was found at the interface. After 15 months, unloaded and immediately loaded implants were compared, and loaded implants exhibited greater (almost twice) direct bone contact at the interface. In particular, early loaded screws demonstrated thicker lamellar and cortical bone than unloaded implants.[42] This finding suggests that early occlusal loading may enhance bone remodeling and further increase bone density.

Randow et al.[43] evaluated the bone interface in a human patient after 18 months in an immediate-loading situation. They noted a direct bone-implant interface. Ledermann[44] confirmed these results in a 95-year-old patient who had an immediately loaded, bar-connected overdenture in function for 12 years (Figure 35-9). Thus a long-lasting direct bone-implant contact relationship appears possible.

Immediate Occlusal Loading: Factors That Decrease Risks

Bone Microstrain

Loaded bone changes its shape. This change may be measured as strain. Microstrain conditions 100 times less than the ultimate strength of bone may trigger a cellular response. Frost[45] has developed a microstrain language for bone based on its biological response at different microstrain levels (Figure 35-10). Bone fractures at 10,000 to 20,000 microstrain (με) units

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

Figure 35-10 Frost has reported on four distinct microstrain patterns within the bone. The acute disuse window results in atrophy, the adapted window is the physiologic response of organized bone, the mild overload zone corresponds to fatigue fractures with reactive woven bone formation, and the pathologic overload zone causes bone resorption. *(Data from Frost HM: Mechanical adaption of Frost's mechanostat theory. In Martin DB, Burr DB, editors:* Structure, function and adaption of compact bone, *New York, 1989, Raven Press.)*

WWW.HIGHDENT.IR

(1% to 2% strain). However, at levels of 20% to 40% of this value, bone already starts to disappear or form fibrous tissue and is called the *pathologic overload zone*. The ideal microstrain for bone is called the *physiologic* or *adapted zone*. The remodeling rate of the bone in the jaws of a dentate canine or human being that is in the physiologic zone is about 40% each year.[46] At these levels of strain, the bone is allowed to remodel and remain an organized, mineralized lamellar bone. This is called the *ideal load-bearing zone* for an implant interface. The mild overload zone corresponds to an intermediate level of microstrain between the ideal load-bearing zone and pathologic overload. In this strain region, bone begins a healing process to repair microfractures, which are often caused by fatigue. Histologically, the bone in this range is called *reactive woven bone*. Rather than the surgical trauma causing this accelerated bone repair, the microstrain causes the trauma from overload. In either condition, the bone is less mineralized, less organized, weaker, and has a lower modulus of elasticity.

One goal for an immediately loaded implant-prosthesis system is to decrease the risk of occlusal overload and its resultant increase in the remodeling rate of bone. Under these conditions the surgical regional acceleratory phenomenon may replace the bone interface without the additional risk of biomechanical overload.

When strain is placed on the horizontal axis and stress is positioned on the vertical axis, the relationship between these two mechanical indexes results in the flexibility or modulus of elasticity of a material. Therefore the modulus conveys the amount of deformation in a material (strain) for a given load (stress) level. The lower the stress applied to the bone (force divided by the functional surface area that receives the load), the lower the microstrain in the bone (Figure 35-11). Therefore one method to decrease microstrain and the remodeling rate in bone is to provide conditions that increase functional surface area to the implant-bone interface.[47] The surface area of load may be increased in a number of ways: implant number, implant size, implant design, and implant body surface conditions. The force to the prosthesis also is related to the strain and may be altered in magnitude, duration, direction, or type. Methods that affect the amount of force include patient conditions, implant position, and direction of occlusal load.

Increased Surface Area

Implant Number

The dentist may increase the functional surface area of occlusal load at an implant interface by increasing implant number.[48] Therefore rather than three to five implants to support a fixed restoration, use of additional implants when immediate loading is planned is more prudent. Immediate-loading reports in the literature with the lowest percentage survival correspond to fewer implants loaded.[15,16,49] Alternatively, a clinical system has been developed specifically for immediate loading with a definitive prosthesis using only three mandibular implants. A 3-year study demonstrated 98% implant survival rates.[50] However, if even one implant fails in this approach, then the patient treatment may require extended time for bone grafting and implant reinsertion before the fabrication of another fixed restoration.

When 10 to 13 implants were inserted and splinted together per arch, implant survival may be greater than 97%.[19-22] The increased number of implants also increases the retention of the restoration and reduces the number of pontics (Figure 35-12, *A*). The increased retention minimizes the occurrence of partially unretained restorations during healing, which can overload the implants still supporting the restoration. The decrease in pontics may decrease the risk of fracture of the transitional prosthesis, which also may be a source of overload to the remaining implants supporting the prosthesis (Figure 35-12, *B*). More implants typically are used in the maxilla (eight to 12) compared with the mandible (five to nine) (Figure 35-13). This approach helps compensate for the less dense bone and increased directions of force often found in the upper arch.

Implant Size

The dentist also may increase the surface area of implant support by the size of the implant. The length of the implant in most systems increases in increments of 2 to 4 mm. Each 3-mm increase in length can improve surface area support by more than 20%.[51] The benefit of increased length is not found at the crestal bone interface but rather in initial stability of the bone-implant interface. Most of the stresses to an implant-bone interface are concentrated at the crestal bone, so the increased implant length does

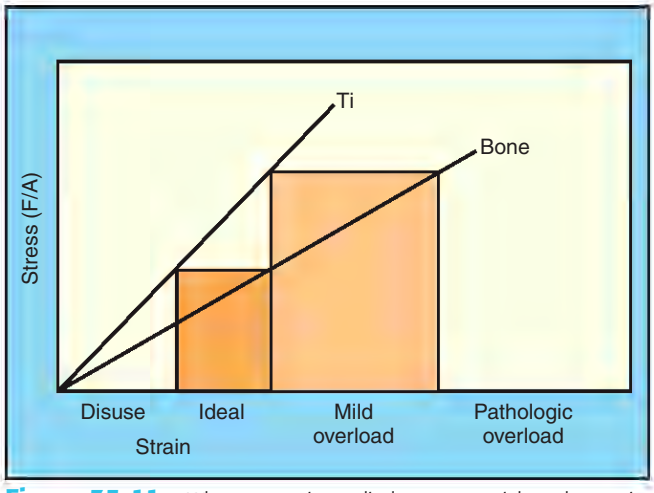

Figure 35-11 When stress is applied to a material, a change in shape occurs (strain). The modulus of elasticity of a material represents the interaction of stress and strain. Titanium (Ti) has a higher modulus of elasticity than bone. When stress is applied to both of these materials, the microstrain difference between the two in the Frost microstrain zone at the interface at 50 units or less is disuse atrophy. When the microstrain difference is 50 to 2500 units, the ideal loading zone is present. Between 2500 and 4000 units, the zone is in mild overload. At more than 4000 units, the zone is in pathologic overload.

little to decrease the stress that occurs at the transosteal region around the implant.[52] Therefore length is not an effective method to decrease stress because it does not address the problem in the functional surface area region of the bone-implant interface. However, because the implant is loaded before the establishment of a histologic interface, implant length is more relevant for immediate-load applications, especially in softer bone types. The additional implant length also may permit the implant to engage the opposing cortical plate, which further increases implant initial stability.

The functional surface area of each implant support system is related primarily to the width and the design of the implant. Wider root form implants provide a greater area of bone contact than narrow implants (of similar design). The crest of the ridge is where the occlusal stresses are greatest. As a result, width is more

WWW.HIGHDENT.IR

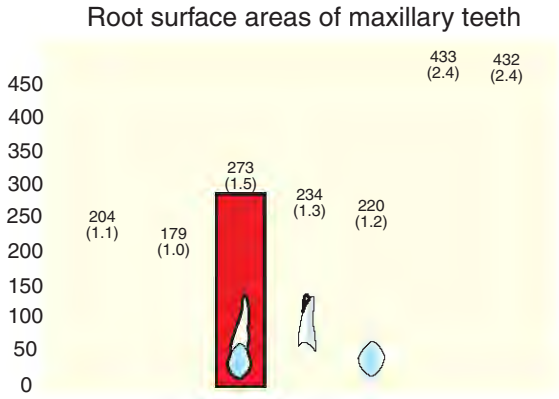

Figure 35-14 The natural dentition root surface area is two times greater in the molar region compared with any other tooth position. Treatment plans for immediate loading should consider implant size or number to increase surface area in this region, especially in the maxilla.

Figure 35-15 The implant body design is more specific for immediate load because the bone does not have time to attach to the surface conditions of the implant before occlusal load. A press-fit implant (the cylinder design on the far right) is least indicated for immediate-load application.

important than length of implant (once a minimum length has been obtained for initial fixation). Bone augmentation in width may be indicated to increase implant diameter when forces are greater, as in cases of moderate to severe parafunction. The major increase in tooth size occurs in the molar regions for natural teeth, where root surface area doubles compared with the rest of the dentition (Figure 35-14). Therefore implant diameter often is increased in the molar region. When a larger-diameter implant is not possible without additional augmentation surgery, more implants may be inserted (i.e., two for each molar), which also is a method to double the overall surface area in the posterior region.

Implant Body Design

The implant body design should be more specific for immediate loading because the bone has not had time to grow into recesses or undercuts in the design or attach to a surface condition before the application of occlusal load. For example, a press-fit implant with a cylinder design does not have bone integration the day of implant placement (Figure 35-15). An implant body with a series of horizontal plates that is tapped or pressed into place does not have bone present between the plates the day of surgical placement. Macrospheres on an implant surface do not have bone present within or around the porous surfaces of the implant the day of implant placement. In general, press-fit implants exhibit decreased initial stability and have an inherent design flaw for immediate-load applications. The surface condition of the implant, although vital for a cylinder implant, is less relevant during immediate-load protocols.

For a threaded implant, bone is present in the depth of the threads from the day of insertion. Therefore the functional surface area is greater during the immediate-load format. The number of the threads also affects

Figure 35-16 A threaded implant design has bone between the threads at the initial surgery. The number of threads per unit length is related to the initial functional surface area of the implant. The implant on the far right has more threads and the most surface area to resist the occlusal loads. The implant on the far left has less surface area.

the amount of area available to resist the forces during immediate loading. The greater the number of threads, the greater the functional surface area at the time of immediate load (Figure 35-16). Some threaded implants have a 1.2-mm distance between the threads (e.g., ITI dental implants), whereas others have a 0.4-mm distance (e.g., BioHorizons dental implants). The smaller the distance between the threads, the greater the thread number and corresponding surface area.[52]

The thread depth varies in implant design. The greater the thread depth, the greater the functional surface area for immediate-load application. The thread depth of some threaded implants is 0.2 mm, whereas the thread depth of other implant designs may reach

WWW.HIGHDENT.IR

0.42 mm.[52] Therefore one threaded implant may have more than two times the overall functional surface area compared with other implants of similar length and width (Figure 35-17).

The functional surface area of an implant body may affect the remodeling rate of bone during loading. A macrosphere implant with reduced surface area may have twice the remodeling rate of a typical threaded implant design. A square-threaded implant design, with deeper threads in greater number, is reported to have a tenfold reduction in remodeling rate under similar loading conditions and approximates 50% per year. The higher the remodeling rate, the weaker the bone interface. The teeth have a bone-remodeling rate of 40% per year, which maintains lamellar bone at the interface.[47]

Figure 35-17 The thread depth of the implant body is related to the initial functional surface area for immediate load. Not all implant designs have the same depth of thread. For example, some designs (i.e., Steri-Oss, Nobel Biocare) have a thread depth of 0.22 mm. BioHorizons Maestro implants have a thread depth up to 0.44 mm. Pictured are two BioHorizons implants. The implant on the right (Maestro D4) is better suited for immediate loading because it has more threads per unit length and is longer. The shorter implant on the left is better designed for a conventional two-stage healing sequence.

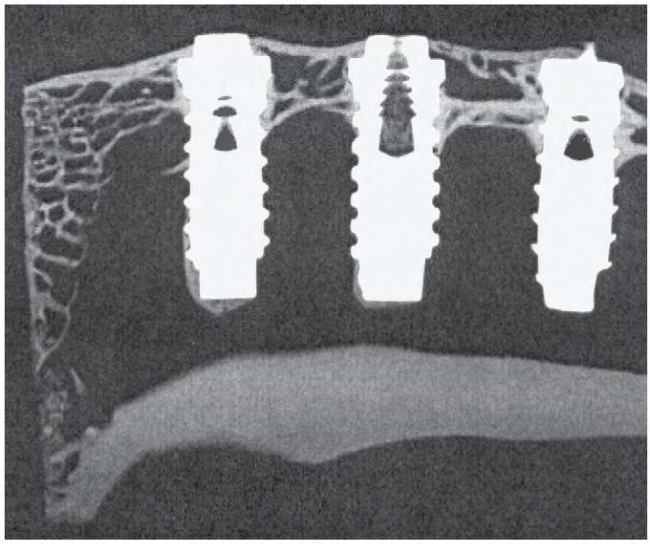

Figure 35-18 In evaluating the initial healing of 72 implants in rabbits, one third of the implants had a V-shaped thread *(left)*, one third a square thread *(center)*, and one third a reverse buttress thread *(right)*. The implants all had the same number of threads, same surface condition, and same size in length and width. The square thread shape resulted in higher bone-implant contact percent and greater reverse-torque values. These two conditions are more conducive for immediate-load applications. (*Courtesy J. Steigenga.*)

The thread geometry also may affect the strength of early osseointegration and the bone-implant interface. Steigenga[53] placed 72 implants into 12 rabbits and reverse-torque tested the unloaded implants after 12 weeks (Figure 35-18). One third of the implants had a V-thread, one third had a reverse buttress shape, and one third had a square thread. The number and depth of threads were the same, as were the width and length of each implant. The V and reverse buttress thread geometry yielded similar values for reverse-torque and BIC values. The square thread demonstrated statistically significantly higher values for both of these evaluations.

Implant thread design may affect the bone turnover rate (remodeling rate) during occlusal load conditions. For a V-shaped thread design, a tenfold greater shear force is applied to bone compared with a square thread shape.[52] Bone is strongest to compression and weakest to shear loading.[54] Compressive forces decrease the microstrain to bone compared with shear forces. Therefore the thread shape and implant design may decrease the early risks of immediate loading while the bone is repairing the surgical trauma.

Implant design affects functional surface area more than implant size. A larger-diameter cylinder implant has less surface area than a smaller-diameter threaded implant. As a result, threaded implants present considerable advantages compared with press-fit implants for immediate-load protocols, because their design features do not require histologic integration to resist loads, and they have greater surface area to resist occlusal forces.

A tapered-implant design presents some disadvantages for immediate-load applications. When the tapered osteotomy is prepared using tapered drills, the implant does not engage the bone physically until the implant is seated almost completely into the bone site. This reduces the initial fixation. In addition, the tapered implant has less overall surface area compared with a parallel-walled, threaded implant. Many tapered-design implants have less thread depth near the apical portion of the implant. This further reduces surface area and initial fixation. The tapered implant is also less likely to engage lateral cortical bone in the apical half of the implant. If the tapered implant should be unthreaded slightly to decrease the depth of placement or change the prosthetic platform position, then the tapered screw becomes less fixated. Therefore, at least in theory, the tapered design has fewer advantages for immediate-load application.

WWW.HIGHDENT.IR

A few clinical trials have compared immediate loading with different implant thread designs and tapered-implant bodies in the completely edentulous patient. The short-term clinical reports indicate a high success rate, regardless of implant design. As a result, overall shape and thread geometry apparently may not be the most important aspects for immediate occlusal load survival. Implant number, implant position, and patient factors most likely are more relevant components of success. Future studies in this area certainly are needed.

Implant Surface Conditions

Implant surface conditions may affect the rate of bone contact, lamellar bone formation, and the percentage of bone contact. The surface condition that allows bone formation in greatest percentage, higher BIC with higher mineralization rate, and fastest lamellar bone formation would be of benefit in immediate loading. These factors have been noted in delayed- and immediate-loading environments with hydroxyapatite (HA) coatings.[55] HA also has been shown to decrease the remodeling rate during occlusal loading.[56] Therefore if the bone is not of ideal density (D4) for immediate loading, then HA may decrease the risk of overload. However, Sullivan et al.[57] found that peak insertion torque and resonance frequency at initial implant insertion were related to implant design rather than surface condition in type 2 and 3 bone. Sirota et al.[58] compared various calcium phosphate ($CaPO_4$)–coated implants to noncoated titanium plasma–sprayed (TPS) implants in immediate-load applications and found a high BIC after 30 days of functional loading in both groups when in good-quality bone. Evans et al.[59] agree that HA-coated and noncoated screws have similar bone contact using a two-stage surgical approach in the mandible. The coating or surface condition of the implant is most beneficial during the initial healing and early loading conditions.

Implant design and surface condition are independent issues that use a different mechanism to reduce the risk of overloading. For example, an HA surface may be applied to a cylinder or a threaded implant. The thread design would be more beneficial to an immediate-load application. However, the HA or roughened surface also may be of benefit during the following healing period, especially at the 3 to 5 weeks when the bone is weakest. The majority of clinical studies have been made with threaded-implant designs. Surface conditions are more difficult to ascertain in the literature and have included a smooth machined surface, a roughened TPS surface, and an HA surface condition without a clear difference in clinical survival. However, evidence is increasing that the machine surface condition is inferior in softer bone types.

Decreased Force Conditions

The dentist may evaluate forces by magnitude, duration, direction, and type. The dentist should reduce conditions that magnify the noxious effects of these forces.

Patient Factors

The greater the occlusal force applied to the prosthesis, the greater the stress at the implant-bone interface and the greater the strain to the bone. Therefore force conditions that increase occlusal load increase the risks of immediate loading. Parafunction such as bruxism and clenching represents significant force factors because magnitude of the force is increased, the duration of the force is increased, and the direction of the force is more horizontal than axial to the implants with a greater shear component.[60] Balshi and Wolfinger[49] reported that 75% of all failure in immediate occlusal loading occurred in patients with bruxism. In their report, 130 implants were placed in 10 patients, with 40 implants immediately loaded and 90 implants following the traditional two-stage approach. The authors reported an 80% survival for immediately loaded implants compared with 96% for the traditional protocol. Grunder[61] appraised immediate loading in eight edentulous patients, four of whom exhibited bruxism. Overall success rates were 87% in the maxilla and 97% in the mandible, with five of the seven implant failures in the bruxism group. Parafunctional loads also increase the risk of abutment screw loosening, unretained prostheses, or fracture of the transitional restoration used for immediate loading (Figure 35-19). If any of these complications occur, then the remaining implants that are loaded are more likely to fail.

Figure 35-19 **A,** An immediate-load prosthesis resulted in overload failure of the left canine implant. This patient has moderate to severe bruxism. **B,** Bruxism caused the transitional prosthesis to fracture into several pieces, and the canine implant became overloaded and failed.

WWW.HIGHDENT.IR

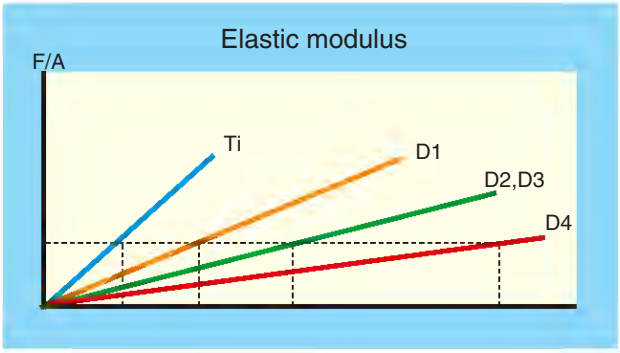

Figure 35-20 The modulus of elasticity is related to the bone density. Therefore the microstrain mismatch between titanium (Ti) and division 4 (D4) bone is greater than that between titanium and D1 bone, even when the stress amount is the same.

Occlusal Load Direction

The occlusal load direction may affect the remodeling rate. An axial load to an implant body maintains more lamellar bone and has a lower remodeling rate compared with an implant with an offset load. In an animal study, Barbier and Schepers[62] observed osteoclasts and inflammatory cells at the interface of offset-loaded implants and noted lamellar bone and a lower remodeling rate around axially loaded implants in the same animal. Therefore the clinician should eliminate posterior cantilevers in the immediate-load transitional restoration because they magnify the detrimental effects of force direction.

Implant Position

Dental implants have been used widely to retain and support cross arch fixed partial dentures (FPDs).[2,63,64] Implant position is often as important as implant number. For example, elimination of cantilevers on two implants supporting three teeth is recommended, rather than positioning the implants next to each other with a cantilever.[48] The cross arch splint forming an arch is an effective design to reduce stress to the entire implant support system. Therefore the splinted-arch position concept is advantageous for the immediate-load transitional prosthesis in completely edentulous patients.

Implant position is one of the more important factors in immediate loading for completely edentulous patients. The mandible may be divided into three sections around the arch: the canine-to-canine area and the bilateral posterior sections. Several clinical reports discuss immediate load in a mandible with only three implants, as long as the implants are positioned in the midline and each posterior region[15,16,50] (see Figure 35-2, *A* to *C*).

The maxilla requires more implant support than the mandible because the bone is less dense and the direction of force is outside of the arch in all eccentric movements. The maxilla is usually divided into five sections, depending on the intensity of the force conditions and the shape of the arch.[65] The minimum five sections include the incisor region, the bilateral canine areas, and the bilateral posterior regions. At least one implant should be inserted into each maxillary section and splinted together during the immediate-loading process.

Concerns have been raised regarding cross arch splinting in the mandible because of mandibular flexure and torsion distal to the mental foramens. Clinical reports indicate the acrylic used in the transitional prosthesis is flexible enough to alleviate these concerns. However, the final restoration should be fabricated in at least two independent sections when implants are placed in both posterior molar positions.[66]

Mechanical Properties of Bone

The modulus of elasticity is related to bone quality (Figure 35-20). The less dense the bone, the lower the modulus. The amount of BIC is also less for less dense bone. The strength of the bone also is related directly to the density of the bone. The softer the bone, the weaker the bone trabeculae.[65-68] In addition, the remodeling rate of cortical bone is slower than that of trabecular bone. As such, the cortical bone is more likely to remain lamellar in structure during the immediate-loading process compared with trabecular bone.

The bone in the anterior regions of the jaw may have cortical bone at the crestal and apical region of the root form implant, whenever the implant is long enough to engage both cortexes. The anterior root form implants should attempt to engage the opposing cortical plate when immediate load is contemplated. The improved biomechanical condition of the cortical bone and the additional implant surface area are advantageous. The maxillary cortical bone is thin compared with the mandibular counterpart at the crestal region and the opposing landmark. In the posterior regions, the maxillary sinus and mandibular canal usually negate the apical engagement of the opposing cortex of bone, which is also thin in the maxilla.

Cortical bone is also present on the lateral aspects of the residual ridge. Root form implants do not typically engage these plates unless the edentulous ridge is narrow. A disk-implant developed by Scortecci[18] is a three-dimensional implant designed to engage the lateral cortical bone plates and the crestal bone region. As such, the implant may have some particular advantage for immediate-load applications, especially in the posterior regions of the mouth when bone grafting is contraindicated or inadequate for traditional root form implant designs.

Bone grafting must depend on several factors to be predictable. Adequate blood supply and a lack of micromovement are two important conditions. The developing bone is woven bone and more at risk of overload. The bone graft in the region of the implant body may lead to less fixation and lower initial BIC. Bone augmentation is more predictable when soft tissue

WWW.HIGHDENT.IR

completely covers the graft (and membranes when present). All of these conditions make bone grafting, implant insertion, and immediate loading more at risk. Therefore the suggestion is that implants that are immediately loaded be placed in an existing bone volume adequate for early loading and the overall proper prosthetic design. Bone grafting, before implant placement and immediate loading, is suggested when inadequate bone volume is present for proper reconstructive procedures (Figure 35-21).

Immediate-Loading Procedures for Fixed Prostheses

Primarily two different options are available for immediate occlusal loading for the completely edentulous patient desiring a fixed prosthesis. The first option loads the implants the same day as the surgery. The second option is to place the implants and make an impression at surgery. Then at the suture removal appointment 7 to 12 days later, the dentist delivers the transitional fixed prosthesis.

Option 1

Before the surgical appointment, the dentist fabricates a surgical template for implant insertion. For delivery of the restoration the day of surgery, the dentist may take one of two different approaches. The first is to fabricate a denture on the edentulous arch using impressions, baseplate and wax rims, and denture teeth try-in procedures similar to fabrication of a new denture. The second approach modifies the patient's existing denture. In either case, in the region of the future implants, the dentist hollows the restoration to create a shell. If more than two pontics are designed in the transitional restoration, then a metal-reinforced structure is suggested. No posterior cantilevers are fabricated for the transitional restoration when they are out of the esthetic zones during smiling or speech.

The dentist inserts the implants into the preestablished positions (Figure 35-22, *A* to *F*). Implants in good-quality bone, with no crestal bone grafts at insertion, are included in the transitional restoration. The more implants that are loaded at this appointment, the lower the risk of complications. The dentist initially places at least three ideal implant positions in the mandible (bilateral premolars and central) and four ideal implant positions in the maxilla (bilateral molars, bilateral canines) into function. The more additional implants that are inserted, the lower the risk of overload failure, early crestal bone loss, unretained restoration, restoration fracture, and abutment screw loosening.

Once the implants are inserted, the dentist positions the final abutment and tightens it to a torque of

Continued

30 N-cm or more. Abutment screw loosening of any individual implant may increase the risk of other implants in the prosthetic-implant system. The dentist prepares the final abutments intraorally for parallelism and proper height requirements. The dentist relines the transitional prosthesis with a light-cured composite (e.g., a urethane methacrylate–based product [Triad; Dentsply, York, Pa.) to eliminate toxic monomer contact with the bone. This material also exhibits less dimensional change compared with acrylic (4% versus 17%), and no heat generation occurs during setting (which might cause bone injury). In addition, the risk of "locking" the prosthesis into place onto unparallel implant abutments is less, because the restoration may be removed and reinserted several times during the initial light-cure process.

The dentist adjusts the temporary prosthesis to fit the abutment before approximation of the tissues. In this way the dentist may inspect the interproximal and margin region thoroughly before soft tissue closure.

More implants were inserted into the left sinus graft region, because the bone was less dense. **L,** A porcelain-metal fixed prosthesis is fabricated.

Continued

The dentist approximates the tissues before cementing the prosthesis (see Figure 35-22, *G* and *H*). The dentist places sutures more than 5 mm away from the incision line margin to facilitate their removal at a later date without removing the transitional prosthesis. The dentist evaluates the transitional restoration for harmonious occlusal contact in central occlusion. An implant-protective occlusal philosophy is advantageous in this restoration.[66] The dentist cements the immediate-load relined transitional prosthesis with a definitive cement such as zinc phosphate or glass ionomer. If the restoration becomes uncemented during the early loading process, then the risk of overload and failure or crestal bone loss increases.

Option 2

The second option for the immediate occlusal load process is to split the surgical appointment from the prosthesis delivery appointment. The first step of this option is similar to option 1. The preoperative appointments and implant position during surgery are the same. However, in option 2 the dentist makes an

WWW.HIGHDENT.IR

impression of the implant body position with additional silicone. In addition, the dentist records a vertical occlusal dimension and centric bite registration. The bite registration may be made with the shell of the transitional restoration on the abutment or with a baseplate and wax rim (made before surgery and relined as necessary).

After the impression the dentist removes the abutments from the implant bodies and replaces them with permucosal extensions (PMEs). The dentist approximates the soft tissues similar to a one-stage surgical procedure.

The laboratory inserts the implant body analogs connected to the abutments into the impression, pours the impression with die stone, and mounts the cast to the opposing arch. The laboratory selects and prepares the abutments for the restoration and fabricates a transitional prosthesis.

The patient returns to the office 7 to 14 days after surgery. After removing the sutures, the dentist replaces the PMEs with the abutments that the laboratory selected and prepared. The dentist also delivers the transitional prosthesis and cements it with a definitive cement.

Diet

If the immediately loaded prosthesis becomes partially uncemented or fractures, the remaining implants holding the restoration are at increased risk of overload failure. Therefore the diet of the patient should be limited to only soft foods during the immediate-loading process. Pasta and fish are acceptable, whereas hard crust of bread, meat, and raw vegetables or fruits are contraindicated. In other words, the prosthesis and diet are similar to that for the first transitional restoration delivered in a progressive bone-loading approach.

Final Prosthesis

After healing 4 to 8 months (dependent on the bone density) the transitional restoration may be cut off and the final prosthesis fabricated (Figure 35-22, *I* to *S*).

Guidelines for Immediate Loading

Treatment plan guidelines for completely edentulous patients reflect methods to reduce stress and reduce microstrain at the developing interface.

Surface Area Factors

The dentist should consider the following surface area factors:

1. Implant number: Eight splinted implants or more are suggested for the completely edentulous maxillary arch and six splinted implants or more for the mandible—more implants if very soft bone (D4) is present or if force factors are greater (e.g., crown height or parafunction).
2. Implant size: Larger-diameter implants are required in the posterior regions of the mouth. If larger diameter is not possible, then bone grafting or greater implant number is suggested (e.g., two implants for each molar).
3. Implant design
   - High surface area implants (more threads, deeper threads)
   - Compressive versus shear loads (square- or plateau-shaped threads)
4. Implant surface condition:
   - HA-coated implants in poor bone density types (e.g., D4)
   - Rough versus smooth or machine surface condition implants in good bone density situations (e.g., D2 and D3)

Force Factors

The dentist should consider the following force factors:

1. Patient conditions: Parafunction, crown height, and muscular dynamics require more implant surface area. Severe parafunction may be a contraindication for the completely edentulous patient.
2. Implant position: In the completely edentulous maxilla, anterior implants should be at least in the bilateral canine position and posterior implants in the first- to second-molar position for the largest anteroposterior (A-P) dimension. When forces are greater, the dentist should insert an additional implant between the canines. In the mandible the largest A-P dimension possible should be used. At least three implants, one in the anterior and one in each posterior region, are necessary.
3. Occlusal load direction:
   - Narrow occlusal tables and no posterior offset loads on the transitional prosthesis
   - Long-axis loads to the implant bodies whenever possible

No posterior cantilevers should exist on transitional restorations in either arch. The cemented transitional restoration uses a definitive cement (e.g., zinc phosphate or glass ionomer cement) rather than a more temporary, weaker cement.

Implant Overdentures

The immediate-load concept for mandibular overdentures has been used in the literature for more than 50 years. The subperiosteal implant and the mandibular staple implant were loaded immediately after insertion.

WWW.HIGHDENT.IR

Babbush et al.[14] reported on immediately loaded overdentures in the early 1980s with threaded root form implants. More recently Chiapasco et al.[69] documented implant success rates of 88% to 97% over 5 to 13 years. The risk of joining implants together with a bar for an implant overdenture is less than for a fixed prosthesis, because the patient may remove the restoration at night to eliminate the risk of nocturnal parafunction. In addition, the overdenture may have some movement and load the soft tissue, which adds a stress relief system for the rigid implants.

The treatment plan for implant number and position for implant overdentures that are completely implant supported should be similar to a fixed restoration. If the prosthesis has no movement while in place, then it cannot gain support from the soft tissue. Although the restoration may be removed, it is completely implant supported during function or parafunction.

Implant overdentures with hard and soft tissue support may be at increased risk for immediate loading because the torque to the implants may be increased compared with completely implant-supported restorations. One should exercise care relative to the amount and direction of prosthesis movement during the initial loading period.

The immediately loaded overdenture procedure is similar to the second option with a fixed restoration. In other words, the dentist makes an implant body impression at the initial surgery. The position of the denture and teeth and the contours of the overdentures are important to know before fabrication of the bar and attachments that will connect the implants. One method to ascertain this information is to use a custom impression tray for the impression. The dentist makes a vacuum or press form with clear acrylic over the patient's denture before placing the implants. The dentist inserts the denture and press-form template into the mouth and makes a bite registration of the opposing arch. The dentist then removes the denture from the template, which then may act as a customized impression tray (Figure 35-23, *A* to *I*).

After inserting the implants, the dentist may place an indirect transfer coping into the implant bodies. The dentist places the customized impression tray over the implants, and the patient occludes into the attached bite registration, which helps seat the tray in the correct position (see Figure 35-23, *J*). The dentist then makes an impression, which because of the nature of fabrication also provides the vertical occlusal dimension, occlusal plane, position of the denture teeth, and contours of the overdenture (Figure 35-23, *K* and *L*). After making the impression, the dentist removes the indirect impression transfer copings and inserts the PMEs into the implant bodies. The dentist then may approximate the tissue with sutures in the usual fashion for a one-stage surgery (see Figure 35-23, *M* and *P*).

The bar and attachments are designed to be away from the denture teeth and contours of the restoration (see Figure 35-23, *Q* and *R*). When the crown height space is limited, the dentist fabricates a screw-retained bar directly to the implant bodies. When the crown height space is greater than 15 mm, the dentist most often designs a cemented bar on abutments greater than 6 mm in height. The dentist then delivers the bar for the implant overdentures at the suture removal appointment. The overdenture is hollowed out, and a soft conditioner is placed over the bar (see Figure 35-23, *S* to *U*).

The dentist asks the patient to leave the overdenture out of the mouth as much as possible. During sleeping hours, the patient does not wear the restoration to prevent nocturnal bruxism from overloading the developing bone interface. The diet is restricted to softer foods.

After 3 months or more, the final restoration may be fabricated (once the soft and hard tissues are mature). The previously constructed baseplate and wax rim make this portion of the overdenture fabrication simpler and more accurate (see Figure 35-23, *V* and *W*).

PARTIALLY EDENTULOUS PATIENTS

The immediate-load concept also may be used in the partially edentulous patient, including single-tooth applications. This concept has fewer clinical studies than full-arch cases, either fixed or removable. In 1998, Misch[70,71] published the first article during the "reinvention" of immediate "load" for partially edentulous patients. Most articles are case reports, especially for single-tooth applications. Rather than immediate loading of the implant, most reports suggest immediate restorations rather than full occlusal loading. Because the patient most often has enough remaining teeth in contact to function, the transitional restoration is primarily for esthetics, and the implant prosthesis is completely out of occlusion. Therefore a nonfunctional immediate teeth (N-FIT) concept is suggested (Box 35-1).

Box 35-1 Nonfunctional Immediate Teeth

Indications

- Partially edentulous patients with centric occlusal contacts and excursions on natural teeth (or healed implants)
- D1, D2, and D3 bone in regions of implants
- Screw-shaped implant bodies, 4 mm or more in diameter, with increased surface area designs to decrease crestal stresses (e.g., BioHorizons Maestro dental implant)

Contraindication

- Patients with parafunctional oral habits (i.e., anterior and lateral tongue thrust or biting on a pipe while smoking)

WWW.HIGHDENT.IR

The N-FIT concept presents a similar approach to the immediate-loading technique for the completely edentulous patient, with two major exceptions. Rather than submerge more than half the implants or place extra implants in case of failure, most often the ideal number of implants is positioned in the ideal locations for the final prosthesis. The second major difference is that the implant-supported transitional prosthesis is placed out of all direct opposing occlusal contacts during the bone-healing period. As a result, the dentist may fabricate an esthetic tooth replacement immediately for the patient but with no occlusal contact. The dentist also may develop the soft tissue contours with the transitional prosthesis during the bone-healing process and may evaluate them before making the final restoration.

Two clinical approaches to the N-FIT technique are similar to the fixed prosthesis for the edentulous patient. The first option is to use a surgical-prosthetic protocol similar to immediate loading with a diagnostic wax-up to fabricate the provisional restoration. Once the implants are inserted, the dentist recontours and relines the acrylic provisional prosthesis to the abutments (Figure 35-24). This alternative often is selected when the implant surgeon and restoring dentist are the same person or work in the same office.

A second alternative is to make an implant body impression with abutments or transfer copings that engage the antirotational hexagon (Figure 35-25, *A* to *C*). The dentist also makes a centric bite registration and opposing arch impression. The dentist then removes the abutments, places them into the impression with

implant body analogs, and places the permucosal healing abutments into the implant bodies before suturing (Figure 35-25, *D* and *E*; Box 35-2). This appointment is similar to a nonsubmerged implant technique, with the addition of impressions for the fabrication of a transitional prosthesis.

The laboratory fabricates working models from the impressions and mounts them with the centric registration (Figure 35-25, *E* and *F*). The laboratory may prepare the two-piece abutments for cement retention and fabricate two transitional prostheses. The first transitional prosthesis is completely out of occlusion 1 to 2 mm in centric occlusion and all excursions. The laboratory also may fabricate a second transitional restoration in occlusion.

At the suture removal appointment, the dentist removes the permucosal abutments and replaces them with the appropriate abutments for cement retention (Figure 35-25, *G*). The dentist delivers the transitional prosthesis with no occlusal contact and modifies the esthetics as required. This option is easier to use in the team approach because the restoring dentist does

The AlloDerm may be used as a barrier membrane for bone regeneration. *Continued*

not need to be present at the surgery. In addition, the laboratory can prepare the abutments or select an angled or custom abutment to correct nonparallel implant placement.

After the appropriate bone-remodeling period (3 to 8 months, depending on the bone density), the dentist removes the first transitional restoration, evaluates the implants, and inserts the second transitional acrylic restoration in light occlusion with a heavy bite force occlusal adjustment. This procedure allows progressive loading of the bone-implant interface and increases the bone density next to the implant[66] (Figure 35-25, *H* and *I*).

The advantages of the N-FIT concept include all those of the nonsubmerged approach with these added advantages (Box 35-3):

1. An esthetic restoration replaces the missing teeth, rather than exposed titanium.
2. The implants are splinted together, rather than healing as independent units. This is a considerable

WWW.HIGHDENT.IR

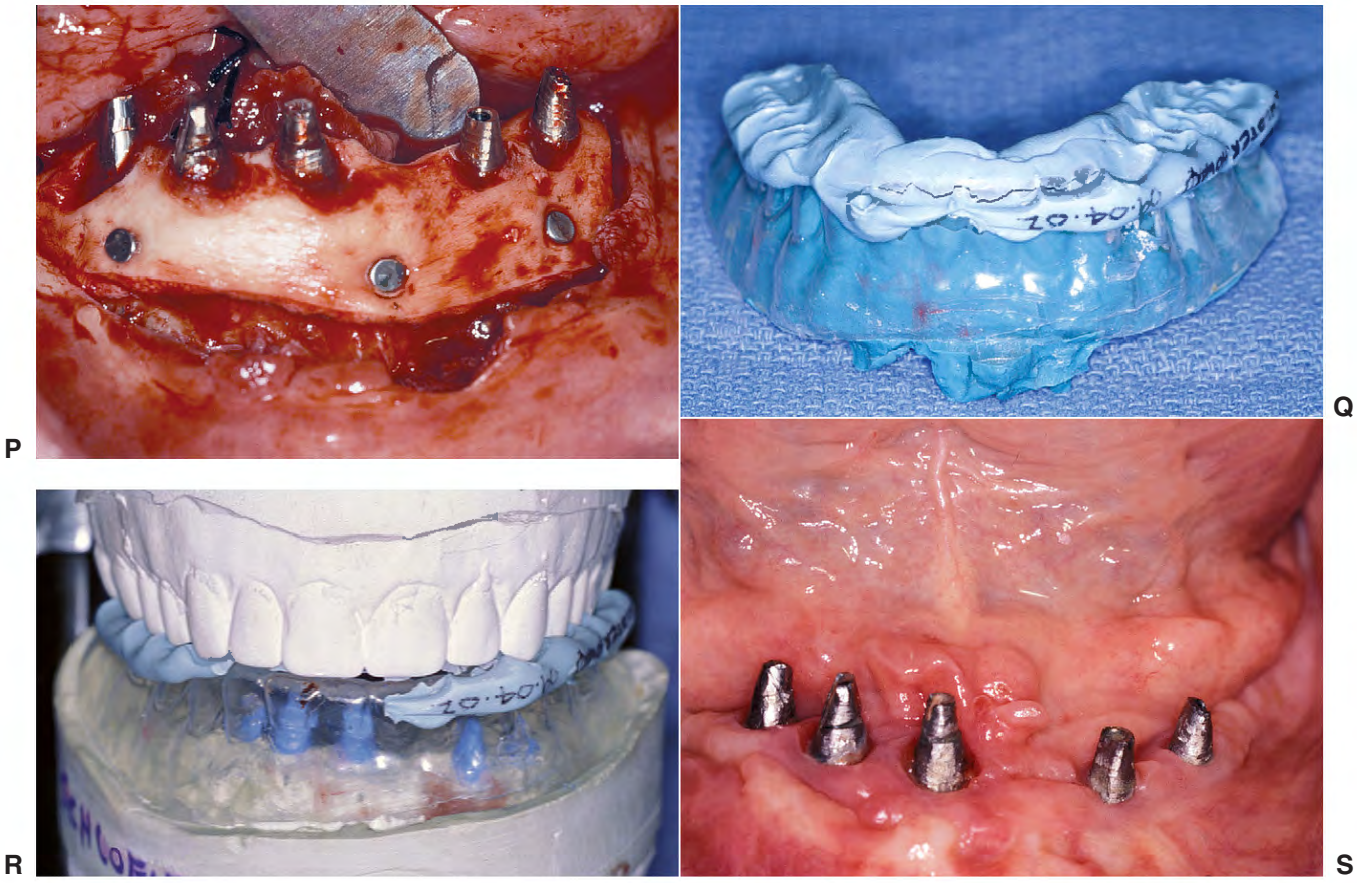

Figure 35-23, cont'd **P,** The membrane is tacked into position around the implants. Continued

biomechanical advantage to distribute stress and decrease crestal loads.

3. The emergence profile of the final restoration may be created with the transitional prosthesis. Interdental papillae are developed and maintained throughout the healing period.
4. The soft tissue is mature when the final restoration is fabricated because the tissue has been healing for many months. If surgical correction is required, then the dentist still may perform the correction before the final bone maturation.

The primary advantage of the N-FIT concept compared with immediate loading is the decreased risk of biomechanical overload from parafunction. The dentist encourages the patient to maintain a soft-food diet (e.g., pasta, fish) during the healing period and to avoid the implant sites. However, the bite forces during eating are less than 30 psi and are limited to less than 30 minutes per day.[72] A major concern for the immediate implant–loading concept is parafunction, which can generate 900 psi several hours a day and night. The N-FIT approach dramatically reduces the risk of parafunction. This concept even can be used for single-tooth replacement. However, if the region is out of the esthetic zone, then a more conventional approach is suggested (one stage or two stage).

The primary disadvantage of the N-FIT concept is the increased risk of biomechanical overload compared with the submerged, countersunk approach (Box 35-4). Because the surgeon does not reflect the tissue at a second-stage surgery, a direct observation of the bone is not possible to evaluate facial or lingual bone loss. In addition, impression material or acrylic may be trapped under the soft tissue. However, the decreased crestal bone loss from an implant that is not countersunk below the bone and the immediate esthetic advantages often outweigh the risk.

SINGLE-TOOTH NONFUCTIONAL IMMEDIATE-RESTORATION PROCEDURES

Worhle[73] and Misch[70,71] presented the single-tooth immediate restoration in 1998. The single-tooth implant

is considered for immediate restoration most often when the following occur:

1. The natural tooth requires extraction and is still present in the mouth.
2. The natural tooth is in the esthetic zone.
3. The soft tissue drape in its current form is ideal.
4. The bony housing around the natural tooth is intact, including the facial plate.

In Chapter 33, the concept of natural-tooth extraction and implant insertion is presented. This chapter presents the concept with the addition of immediate restoration.

The natural tooth is atraumatically extracted. The implant osteotomy is prepared to the opposing landmark, because additional implant length is a benefit for N-FIT. The bone filings are harvested from the drill. A bone tap is used so that the implant will not be pushed toward the facial during insertion. The bone filings are placed on the coronal third of the socket, especially on the facial aspect. The implant is threaded into position under the incisal edge of the future crown and 3 mm below the future facial free gingival margin of the implant crown.

An immediate-load restoration implant design may be one piece with no separate abutment screw. The advantage of this design is increased strength (for smaller-diameter implants) and elimination of the risk of abutment screw loosening. When a two-piece implant design is used for immediate-load restoration, tighten the abutment screw with 30 N-cm of torque and follow the prosthetic protocol (usually used several months later).

Transitional Restoration

Two options exist for the transitional restoration for a single-tooth immediate implant restoration. The first option is an acrylic crown. However, this crown has no occlusal load for 3 to 4 months. In addition, the transitional crown may be splinted to a natural tooth that has no clinical mobility (i.e., a canine). The diet should be restricted to only soft food, and the patient is told to avoid this restoration as much as possible during the initial healing period. After the initial healing, the

4. Make impression with additional silicone material.
5. Make sure no impression material is left under flap or around implants.
6. Remove ball impression pin and abutment for cement.
7. Place 3- to 6-mm-wide emergence permucosal healing cap.
8. Suture (tissue thickness should be less than 4 mm).

Laboratory Procedure

1. Thread ball impression pin and abutment for cement into implant body analog and reinsert into impression.
2. Pour impressions of both arches and mount on articulator.
3. Prepare abutments, if needed. (NOTE: Hexagon transfer locations are made with ball and abutment for cement transfer.)
4. Fabricate transitional prosthesis:
   a. Soft tissue emergence similar to final restoration
   b. Narrow occlusal table
   c. Transitional prosthesis 1 to 3 mm out of all occlusal contacts (centric relation and excursions)

10 to 14 Days after Stage I Surgery

1. Remove sutures.
2. Remove permucosal healing caps.
3. Insert two-piece abutment and abutment screw.
4. Use countertorque (hemostat) and tighten to 20 to 30 N-cm (which is less than final preload).
5. Insert transitional prosthesis and evaluate contour and occlusion (no occlusal contacts).
6. Cement transitional prosthesis with temporary definitive cement.
7. Instruct patient to eat soft foods (e.g., pasta, fish, cooked meat). No raw vegetables or hard bread are allowed until final prosthesis delivery. No oral habits, such as gum chewing, are permitted. When possible, the patient should avoid chewing food in implant regions.

Box 35-3 Advantages of Nonfunctional Immediate Teeth

- Patient has a fixed esthetic tooth replacement soon after stage I surgery.
- No stage II surgery is necessary (eliminates discomfort for the patient and decreases overhead for the doctor).
- Implants are splinted during initial healing for biomechanical advantage.
- The greatest bite force is only during eating and is less than 30 psi. No parafunctional forces from occlusion are possible.
- Countersinking the implant below the crestal bone is eliminated, which reduces early crestal bone loss.
- The soft tissue emergence may be developed with the transitional prosthesis and the tissue allowed to mature during the bone-healing process.
- The soft tissue hemidesmosome attachment on the implant body below the microgap connection may heal with an improved interface.

Box 35-4 Disadvantages of Nonfunctional Immediate Teeth

- Micromovement of implant that can cause crestal bone loss or implant failure is greater than with two-stage approach.
- The dentist is less likely to reflect the tissue at stage II and can evaluate implant crestal bone directly.
- Parafunction from tongue or foreign habits (pen biting) may cause trauma and crestal bone loss or implant failure.
- Impression material or acrylic may become trapped under tissue or between the implant and crestal bone. This problem is reduced greatly if the crest module of the implant is larger in diameter than the implant body.
- Bone that is too soft, small implant diameters, or implant designs with less surface area may cause too great crestal stress contours and cause bone loss or implant failure.

final restoration may be fabricated and the diet returned to normal.

The second option also uses a premade crown. The crown is modified to fit over the abutment and places the gingival margin in close approximation to the tissue. The premade crown is not relined with acrylic. A hole is then made in the mesial and distal interproximal surfaces of the crown. The adjacent teeth are acid

WWW.HIGHDENT.IR

etched, and composite resin is placed in the interproximal regions of the crown to lute it to the adjacent teeth. The occlusion is modified to eliminate occlusal contact. This approach provides an esthetic fixed replacement for the missing tooth, without the excess force on the implant. This approach will offer slightly less risk to the implant during initial healing, because the crown is not actually attached to the implant, and tooth contact will not overload the implant restoration. The diet is also restricted with this technique to soft foods for the initial bone-implant healing period. After 3 to 4 months the transitional crown is removed and a final restoration fabricated. Occlusal equilibration is performed to reduce the occlusal load. A periapical radiograph is taken to confirm the position of the crown and implant.

The most common congenital missing maxillary anterior tooth is a lateral incisor.[74] The restoration of one maxillary anterior crown is one of the more difficult prosthetic treatments in a general practice. A single-tooth implant is often the treatment of choice to replace

a congenitally missing lateral incisor. The implant and crown have the highest success rate of any treatment option, the adjacent teeth are usually unaffected, and the esthetic result is often ideal.[75] The following discussion presents the indications for a small-diameter implant and presents a case report of a patient missing one maxillary lateral incisor.

The average lateral incisor is 6.5 mm in width, 1 mm less than the canine, and 2 mm less than the central incisor.[76] When a permanent lateral incisor is missing, the deciduous tooth is retained longer than ideal, and the collapse of the permanent incisor mesiodistal space occurs as the canine positions itself in a more mesial position. In addition, when a lateral incisor is congenitally missing, the contralateral incisor is often peg-shaped or deficient in mesiodistal size.[74] This condition further reduces the space dimension. As a consequence, the missing lateral incisor space is often less than average and approaches 5 mm. Mandibular central and lateral incisors are missing less often but have a smaller mesiodistal dimension and average 5.4 mm.[76] Therefore single-tooth replacement may on occasion require implants of small diameter to restore the missing tooth situation.

Most manufacturers fabricate their smallest two-piece implants to a dimension of 3.5 mm or larger at the crest module, although the implant body may be smaller (e.g., 3.2 mm). A two-piece implant should have the microgap of the abutment at least 1.5 mm from the adjacent tooth.[77] As a result, the ideal minimum intertooth space for a dental implant with this dimension should be 6.5 mm (1.5 mm from each tooth and 3.5 mm for the top of the implant). This dimension is sufficient for the average dimension of a maxillary lateral incisor. Mandibular incisors are usually 5.2 to 5.4 mm in width, and congenitally missing maxillary lateral incisors are often less than 6.0 mm. As a result, most current implant designs are too large for smaller intratooth spaces.

A one-piece implant with a 3-mm-diameter was developed to overcome the challenge of small edentulous spaces in the anterior region of the mouth

WWW.HIGHDENT.IR

Figure 35-26 A one-piece implant may be positioned within 1 mm of an adjacent tooth with little risk of marginal bone loss.

(BioHorizons Maximus dental implants) (Figure 35-26). A one-piece implant does not have a microgap between the implant body and abutment connection, and therefore initial crestal bone loss over time may be reduced.[78] When the implant is not expected to lose proximal bone when positioned at the height of the crestal bone, the implant may be placed as close as 1 mm to the adjacent tooth root. Therefore mesiodistal spaces for a 3-mm-diameter implant used here may be as little as 5 mm. The primary indications for an implant of this dimension is for single maxillary lateral incisors and mandibular anterior lateral and/or central incisors.

Surgical Procedure

The surgical procedure for the 3-mm-diameter implant follows a similar protocol as other implants. A mucoperiosteal flap may be reflected, and direct observation of the bone can be made when the available bone is in question. However, when abundant keratinized tissue and bone are present, a tissue punch and implant osteotomy without tissue reflection is often the surgical protocol of choice. This was the surgical method used in this case report. An esthetic crown-lengthening procedure was also performed on the maxillary canines.

A 3-mm-diameter trephine bur was used to penetrate the soft tissue in the missing lateral incisor region (Figure 35-27, *A* and *B*). The soft tissue emergence was then contoured with a high-speed hand piece and coarse diamond so that the soft tissue profile was similar to the contralateral tooth.

An alignment drill was then used to initially prepare the implant site and begin to develop the path of insertion for the implant drills (Figure 35-27, *C*). This drill was also designed to level the crest of the ridge 3 mm below the free gingival margin of the implant crown and allow the abutment head of the implant to be level with the bone. A radiograph was taken with the alignment drill in place to evaluate the path of insertion (Figure 35-27, *D*).

A trial implant was then placed into the initial osteotomy site created by the alignment drill. The top of this device is the same size as the final implant abutment. The esthetic position and interocclusal clearance may be determined with this trial abutment. A periapical radiograph may also be taken of the trial implant to confirm the mesiodistal position and angulation. The position and/or angulation of the initial site may be corrected with the side-cutting feature of the alignment drill.

The depth of the osteotomy was established using a 2.0-mm-diameter depth drill of 12, 15, or 18 mm. A 15-mm drill was used in this patient (Figure 35-27, *E*). The longer the implant, the greater the initial stability. In addition, if the opposing dense cortical plate can be engaged, then a further benefit of rigid fixation occurs (Figure 35-27, *F*). A radiograph may be used to confirm the proper drill length and position (Figure 35-27, *G*). The osteotomy can be widened to 2.5 mm using the finishing drill when the bone is of a dense quality. Use of the final drill is not necessary in softer bone types, because the implant will condense the bone during insertion and provide greater fixation. A bone tap may be used when the bone is very dense (i.e., as is occasionally found in the anterior mandible).

The one-piece implant body-abutment was then inserted with a hand piece mount at 30 rpm (a hand wrench insertion with a ratchet adapter may also be used) (Figure 35-27, *H*). The implant was positioned so that the threads were 1 to 2 mm below the crest of the bone (Figure 35-27, *I*). A periapical radiograph confirmed the position.

A No. 702L preparation bur was used to modify the abutment as required, with consideration of the opposing teeth in occlusion. A transitional crown, without any occlusal contact, was then fabricated for the implant. The one-piece, small-diameter implant may use the same two options as previously presented for the single-tooth immediate-restoration implant (Figure 35-27, *J* to *L*). After a 4- to 6-month period, the transitional crown may be replaced with a final crown and regular implant-protective occlusion (Figure 35-27, *M*).

Limitations

Implants with smaller diameters have several limitations including less surface area, lower fatigue strength, and higher risk of screw loosening. Smaller-diameter implants have a smaller surface area for bone-implant contact, which could reduce the long-term survival of the fixture. The surface area of an implant is related to the amount of force the implant is able to resist when serving as a prosthetic abutment. The roots of posterior natural teeth have greater surface area than anterior teeth, and forces are greater on posterior teeth. Likewise, an implant with greater surface area is less likely to be overloaded during function.[78] A 1-mm decrease in width of an implant may decrease the surface area of

WWW.HIGHDENT.IR

an implant by more than 40%.[79] Therefore a 3-mm-diameter implant may have almost one-third less surface area of contact with bone as compared with a 4-mm-diameter implant.

The fatigue strength of an implant is affected by the diameter, the implant material, and the amount of force applied to the system.[80] The formula for the fracture strength of a circular implant is $\pi/4(R4)$. This means that a unit decrease in width decreases the strength of the implant by a factor of 4. For example, a 2-mm-diameter implant is 16 times weaker than a 4-mm-diameter implant. For this reason, clinicians may use a 2-mm-diameter transitional implant, but regular occlusal loads over an extended period of time would result in an unstable situation.

The fracture of the implant is also related to the metal of the implant. Regarding the materials from which implants are fabricated, the most common implant body is fabricated from titanium, because a direct bone-implant interface has been shown to develop.[81] Five grades of titanium are used for implants.[82] Grade 1 to 4 is 99% titanium, and grade 5 is titanium alloy (90% titanium, 6% vanadium, and 4% aluminum). The strength of each of these materials is different. Grade 1 titanium is four times weaker than grade 5 titanium. Although a few manufacturers have used this grade for 4-mm-diameter implants, it is inappropriate for use in a permanent small-diameter implant. Some manufacturers of transitional implants select a lower-grade titanium so that the clinician can bend the abutment post for parallelism. Several implant companies use softer grade 3 titanium for their implants, yet grade 3 is two times weaker than grade 5. Further, grade 4 titanium is 1.6 times weaker than grade 5. Thus when small-diameter implants are used to permanently replace a natural tooth, a grade 5 implant material should be used. The BIC is similar for all grades of titanium, because a similar oxide layer is formed regardless of the titanium grade.[82]

The fracture of an implant is also directly related to the amount of force placed on the implant component or body. Greater force is more likely to fracture an implant than lesser force. The maximum bite forces in the mouth are less in the anterior regions (25 to

50 lb/in^2) compared with the molar regions (200 to 250 lb/in^2).[83] Consequently, smaller-diameter implants should be limited to the anterior regions of the mouth to reduce the occurrence of fracture.

The prosthetic platform of a two-stage small-diameter implant is more likely to have screw loosening.[84] The narrower the abutment to implant attachment diameter, the more force applied to the abutment screw during occlusal loading. When the abutment screw becomes loose under a cemented crown, the crown may need to be cut off to gain access to the abutment screw. Abutment screw loosening is the most common prosthetic complication of single-tooth implants and has been reported to occur in 7% to 40% of cases (depending on patient factors and the implant system used).[85] A one-piece implant body and abutment has a distinct advantage because abutment screw loosening does not occur.

The one-piece small-diameter implant has several advantages when used to replace maxillary lateral incisors and mandibular incisors. The one-piece design eliminates the risk of abutment screw loosening. Because no microgap exists between the abutment and implant, the amount of crestal bone loss may also be reduced.[78] The abutment-implant connection of two-piece implants is often at or below the crestal bone. With traditional implant designs, bone loss of as much as 3 mm from the microgap has been reported.[77]

The primary disadvantage for a one-piece small-diameter implant is the requirement of immediate restoration. Because the implant abutment is intraoral at the time of surgical placement (the implant body and abutment are a single component), an increased risk of overload is present during initial bone healing. Oral habits or activities such as gum chewing, tongue thrusting and playing some musical instruments (i.e., woodwinds) may overload the developing interface. The "open" transitional crown concept, whereby the premade crown is not relined with acrylic, reduces this risk.

Traditional implant sizes of 3.5 mm and greater at the crest module are often too large to replace a missing tooth in the anterior regions of the jaws. On the other hand, temporary implants of less than 3.0-mm diameter

WWW.HIGHDENT.IR

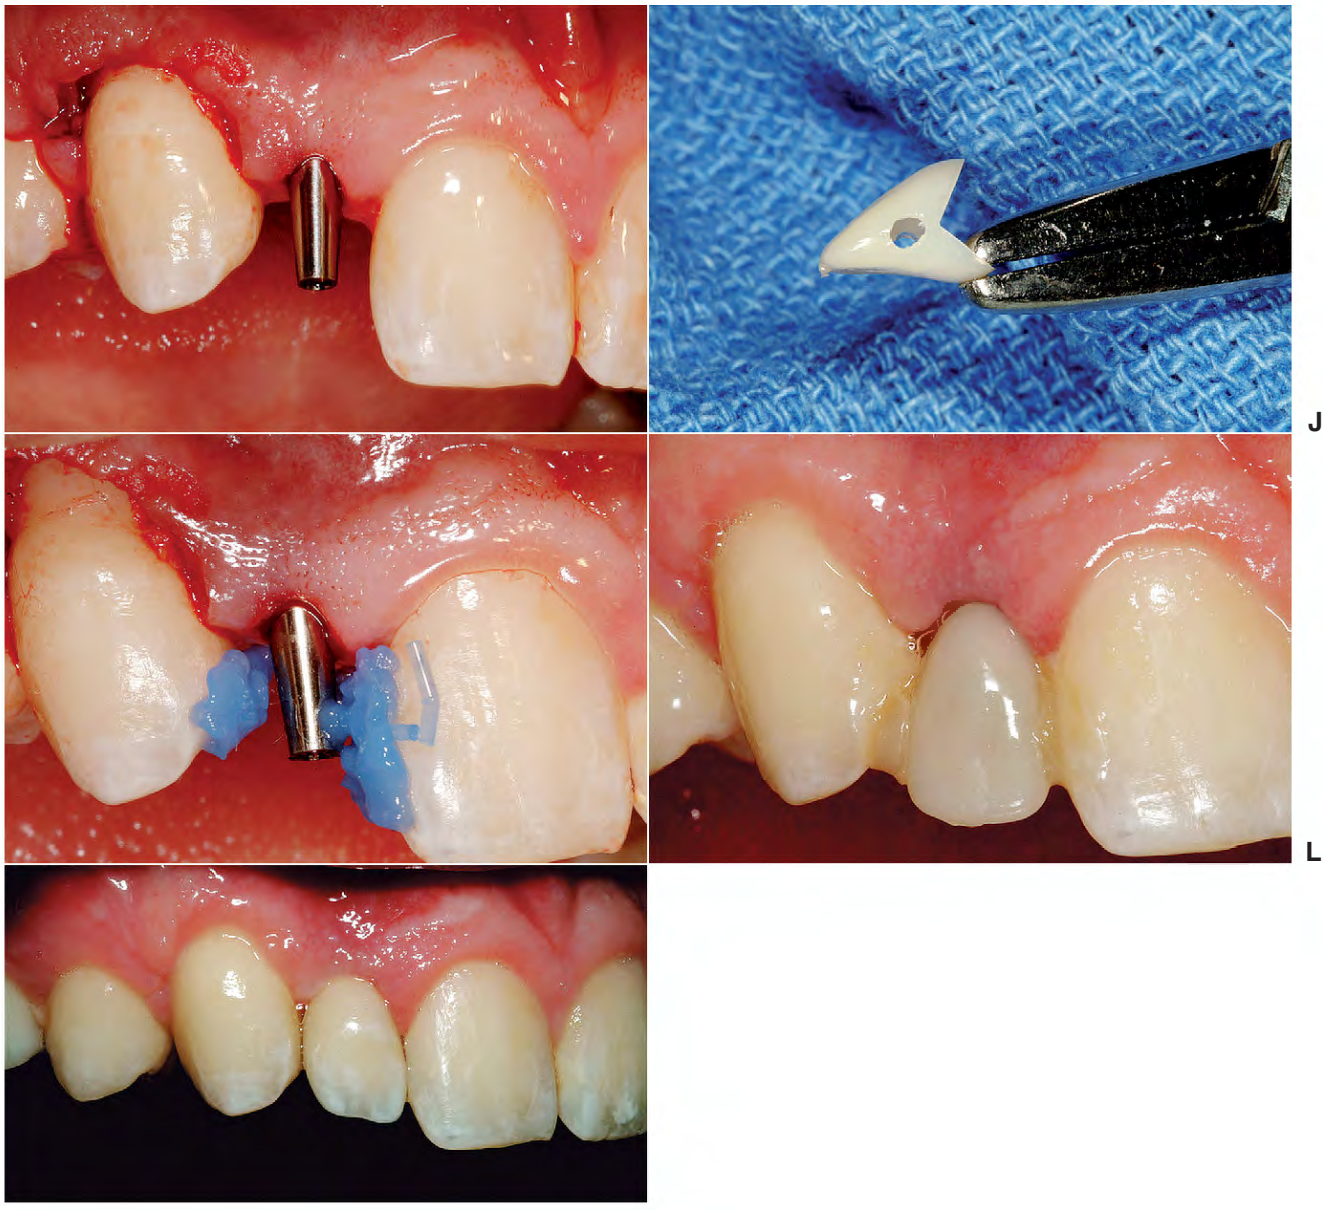

Figure 35-27, cont'd **I,** The implant in position. **J,** A hollow temporary crown with the interproximal contacts open is selected. **K,** The adjacent teeth are acid etched and bonded to the temporary crown. The temporary crown is not attached to the implant. **L,** Soft tissue healing is allowed to take place over several months. **M,** A porcelain-metal crown is fabricated and cemented to the implant 4 or more months after surgery. Esthetic crown lengthening on the canine increased the crown height to be comparable with the central incisor.

risk fatigue fracture. A fracture of an implant will also place the adjacent teeth at risk during implant removal. An integrated implant that is fractured must be removed from the bone using a bur, at the expense of the bone and the adjacent teeth.

The indications for small-diameter implants are primarily related to limited mesiodistal spaces in the anterior region of the mouth. In this way the occlusal forces are reduced to decrease the risk of fracture. The single-tooth replacement for maxillary lateral incisors, mandibular central incisors, and mandibular lateral incisors often require smaller implant dimensions. In addition, when adjacent mandibular incisors are missing, splinting two smaller-diameter implants together is a better option than cantilevers from one implant. Two small-diameter implants have greater surface area than one traditional implant, and the moment force is reduced when the cantilever is eliminated.

WWW.HIGHDENT.IR

RISKS OF IMMEDIATE OCCLUSAL LOADING

The concept of immediate occlusal loading with dental implants offers several advantages. The implant abutments are placed at the time of surgery or at the suture removal appointment. As such, a second-stage surgery is eliminated, along with a suture removal appointment. This saves the patient pain and suffering and saves the dentist overhead time and material. The patient does not need to wear a removable prosthesis during the healing time, which is often a significant advantage when patients are having problems with these devices. The soft tissue–borne restoration also may load the implant inadvertently through the soft tissue and cause bone loss or failure. When the clinician uses a one-stage surgical procedure, the implants are independent during healing. When immediately loaded, the implants are splinted together during healing, which is biomechanically superior. The soft tissue is allowed to mature for several months before the fabrication of the final restorations. Tissue maturation is most important in esthetic zones, where tissue shrinkage after second-stage surgery may compromise the soft tissue directly related to margins and papilla contour around the final restorations.

In the immediate-loading technique for the completely edentulous patient, more implants usually are inserted, which increases the fee and makes patient acceptance less likely.

The litigious risk is low in dentistry but increases as the fees increase. As such, because immediate loading of fixed prostheses is expensive, a failure may increase a malpractice case against the dentist, especially because the patient may need to wear a removable prosthesis and may be subjected to several additional surgeries and appointments.

The primary disadvantage of immediate loading is the risk of implant failure or greater crestal bone loss around the healing implants. When an implant failure occurs, several side effects follow. Implant overload failure most often is associated with bone loss around the implant. If the bone loss includes a lateral cortical plate, then the bone width does not regenerate on its own after the implant is removed. As a result, a bone graft often is required. The bone graft often is separated from the implant extraction procedure to improve the incision line healing and decrease the risk of infection. As a result, two or three appointments usually pass before diagnosis of the implant failure, two appointments are required to remove the implant (one surgery and one suture removal), and two appointments are required for the bone graft. The bone graft often is evaluated every 2 months over a 6-month period for three more appointments. The patient then has the implant or implants replaced, for two more appointments (one surgery and one suture removal). Therefore a total of 12 appointments are associated with the implant failure over 6 to 8 months. During this time the patient most often is wearing a removable prosthesis, the very thing that often is described as a disadvantage for traditional two-stage procedures. In addition, the second implantation procedure usually does not follow an immediate-load format because the doctor and patient are more aware of the risks of the procedure. The patient wears the removable device an additional 3 to 6 months after the bone graft, during a more traditional two-stage healing period of the implant reinsertion. After this time, another two appointments are used to uncover and remove the sutures. As a result, as many as 14 additional appointments may occur for each implant failure.

Usually the dentist does not charge a fee for the implant extraction, bone graft, implant reinsertion, suture removal, and tissue checks for the treatment of the complication because the doctor-patient relationship already may be strained after the failure, and patients do not feel the additional procedures are their responsibility. Therefore loss of production, time, and income of several thousand dollars results.

The overhead in a typical implant practice is greater than 60%. The implantation procedure is repeated at no fee, but the overhead remains. In addition, the doctor loses the income of the procedures redone. When the additional appointments and procedures are added to the implant failure, the doctor most often loses the profit of five or more successful cases for each implant failure. Therefore if immediate loading is 90% successful, then one of 10 cases may fail. The one of 10 cases that fails causes the doctor to lose the profits of five cases. Therefore 90% success means the doctor is paid for 50% of the cases performed. This is a considerable economic loss in an implant practice.

In addition to lost income, the implant practice is also at increased risk. In a referral patient, the referring doctor may lose confidence in the surgeon when failure occurs. As a result, the failure also may cause future referral loss from the restoring dentist.

Early crestal bone loss after implant loading may have a relationship to occlusal overload. Whether immediate loading increases the risk of early crestal bone loss is unclear but is strongly suspected. The early loading was speculated to interfere with the ability of necrotic bone (created by the surgical trauma) to be replaced by newly formed bone. Successful implants with greater than 5-mm soft tissue pockets may be more often a result of immediate loading.

SUMMARY

The delivery of care for patients missing one or all of their teeth very often requires implants to restore function, esthetics, bone and soft tissue contours,

WWW.HIGHDENT.IR

speech, and intraoral health. The delayed occlusal-loading protocol, either one- or two-stage approach, has been evaluated for more than 30 years by a number of clinical settings and situations. However, in some patient conditions, the delayed healing process can cause psychological, social, speech, and/or function problems. A full range of treatment options relative to the initial hard and soft tissue healing is available. Immediate restoration of a patient after implant surgery is one of these alternatives.

A benefit/risk ratio may be assessed for each patient condition to ascertain whether immediate occlusal loading is a worthwhile alternative. The greater the benefit and/or the lower the risk, the more likely that immediate loading is considered. A complete edentulous mandible restored with an overdenture supported by four or more implants is a very low-risk condition. If the patient cannot tolerate a mandibular denture and does not wear the device, then an immediate-load protocol would be a high benefit. The highest risk for immediate loading would be a posterior single-tooth implant. Implant number cannot be increased, and implant length cannot engage cortical bone. When the single-tooth replacement is out of the esthetic zone, very low benefit is obtained with the immediate-restoration approach.

Additional clinical studies to evaluate the associated risks, especially in the maxillary arch, are expected over the next several years. Until the profession has longer-term evidence and more multicenter studies, immediate occlusal loading will be a secondary treatment option, restricted on a case-by-case basis.

A biomechanical rational for immediate loading may decrease the risk of occlusal overload during initial healing. The stresses applied to the implant support system result in strain to the bone interface. The greater the stress, the higher the strain. Increasing implant area and/or reducing the forces applied to the prosthesis may reduce stress. The implant size, design, and surface condition all affect the area over which the occlusal forces are dissipated. The forces may be reduced by patient factors, implant position, reducing force magnifiers such as crown height or cantilever length, reducing the occlusal contacts, decreasing angled forces to the prostheses, and altering the diet. The mechanical properties of bone also affect the risk of overload, because the bone density is directly related to the strength of bone, its elastic modulus, and the amount of BIC. All these factors are important in the traditional two-stage approach. They are especially noteworthy for immediate loading, because the surgical trauma of placing the implant also modifies the mechanical properties of bone during initial healing.

The majority of clinical reports reveal similar survival rates between immediately loaded and two-stage unloaded healing approaches in the completely edentulous patient. Nonetheless, these findings do not imply that a submerged surgical approach is no longer necessary or prudent in many cases. Future studies may find indications based on surgical, host, implant, and occlusal conditions more beneficial for one versus the other. For example, the strength of bone and the modulus of elasticity are related directly to bone density. The softest bone type may be 10 times weaker than for the densest types. The microstrain mismatch of titanium and the softest bone is much greater than the densest bone. As a result, higher implant failure and greater crestal bone loss seem likely but as yet are not reported in the literature.

The biomechanical treatment approach to increase surface area and decrease forces applied to the immediate restorations is most likely the major reason for the high implant survival.

Chapter 36

Keys to Bone Grafting and Bone Grafting Materials

Carl E. Misch, Francine Misch-Dietsh

To satisfy the ideal goals of implant dentistry, the hard and soft tissues need to present ideal volumes and quality. The alveolar process is affected so often after tooth loss that augmentation is usually indicated to achieve optimum results, especially in the esthetic zones. Augmentation is also required relative to functional conditions of the implant treatment plan, because a reduction of stress at the crestal bone region and a greater resistance to screw loosening and fatigue fracture occurs with larger-diameter implants. Therefore an improved understanding of biomechanical requirements for long-term prosthesis survival and the increasing use of implants in esthetic restorations often require ridge reconstruction before implant placement for complete or partially edentulous patients. This is especially true in the surgical placement of maxillary anterior implants, which is usually critical for ideal esthetics, phonetics, and function. As a result, treatment methods to improve the recipient bone dimensions to optimize success should be considered, especially in the premaxilla.

ALVEOLAR RESORPTION

In the anterior regions of the mouth, the labial cortical plate over the natural teeth is much thinner than its lingual counterpart. Periodontal disease creates infrabony defects on the lingual aspect of the supporting bone but often causes complete loss of the labial alveolar process. Dehiscence of the labial plate may also occur as a consequence of tooth eruption, orthodontic therapy, parafunction, trauma, vertical root fracture, apicoectomy, ill-fitting crown margins, subgingival tooth preparation, and extractions. The facial plate of bone is also first to remodel or resorb after tooth extraction, disease, or trauma, and it does so to a greater extent than the lingual cortical bone.

In the anterior maxilla, the alveolar bone is rapidly recontoured after the loss of the natural teeth, even in the presence of an intact alveolus after extraction. There is a 25% decrease in volume during the first year and a 40% to 60% decrease in width within the first 3 years after tooth loss.[1,2] This resorption is primarily at the expense of the facial dimension, as the lingual contour undergoes resorption only when more advanced atrophy occurs. As a result, an 8-mm-wide anterior ridge may remodel to less than 3 mm within 5 years after extraction.[3,4] In the posterior regions, the rate of initial bone loss is often greater than in the anterior regions. However, because the initial posterior ridge dimension is twice the width, even a 50% bone loss often leaves adequate volume to place 4-mm-diameter implants. As a consequence of these dimensional changes, the remodeled labial cortex is more medial than its original position.

SURGICAL KEYS TO BONE GRAFTING

Consistent bone grafting results for volume have been difficult to achieve, often because similar techniques are used, regardless of the patient's existing conditions, the volume of bone, and the region of the augmentation. Specific elements (keys) need to be present for successful bone grafting.[5] The doctor should evaluate the existing condition and alter the grafting technique and materials in function of each treatment performed. In other words, bone grafting is very much like opening a combination safe that requires at least seven of 11 different numbers. If only five or six numbers are correct, the safe will not open. The more numbers used to open the "safe" of successful bone grafting, the more predictable the growth of sufficient bone volume for implant placement.

The keys to bone grafting are local factors that affect the prognosis of the procedure and include: absence of infection, soft tissue closure, space maintenance, graft immobilization, regional acceleratory phenomenon (RAP), host bone vascularization, growth factors, bone morphogenetic proteins (BMPs), healing time, defect size and topography, and transitional prostheses. Several

WWW.HIGHDENT.IR

همیار دندانسازان

of these keys are interrelated; often, one key affects another and may form a cascade toward failure or success. The surgeon should attempt to provide all these elements, but especially those factors missing in the bone augmentation site.

Graft materials such as collagen, autogenous bone, demineralized freeze-dried allograft (DFDB), and calcium phosphate materials also are necessary elements for bone grafting procedures. The purpose of this chapter is to present these keys and materials as a basis for the methods presented within this book for predictable intraoral bone grafting for implant dentistry.

Surgical Asepsis/Absence of Infection

Bone and graft materials resorb at different rates under normal pH conditions, based upon porosity, size, and crystallization. However, all graft materials rapidly resorb through solution-mediated resorption in conditions of low pH (Figure 36-1). The hydroxylapatite crystal of bone (or enamel) is dissolved into calcium and phosphate components at a pH of 5.5 or less. For example, the enamel of a tooth is composed of 95% dense, crystalline hydroxylapatite.

Lactobacillus acidophilus bacteria produce a pH of 5.5, and when bacterial plaque and bacteria remain in enamel for more than 5 days, a solution-mediated resorption occurs, which is seen as a radiolucent zone on the radiograph. Infections within the bone often create a pH of less than 2. As a result, when a tooth becomes nonvital, a solution-mediated resorption occurs at the apex and a radiolucency at the apex of the tooth with an endodontic lesion may occur within a few days. Therefore bone grafting in the presence of infection, or infected bone grafts after surgery, increase the risk of insufficient volumes of bone formation and may even cause recipient bone loss (Figure 36-2). Before bone grafting, all evidence or potential causes of infection should be eliminated.

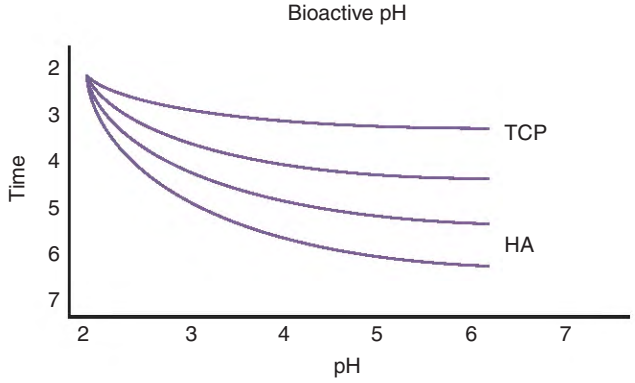

Figure 36-1 Bone graft materials resorb at different rates under normal pH conditions. However, when the pH is low, all graft materials (including bone) resorb rapidly through a solution-mediated resorption. *TCP,* Tricalcium phosphate; *HA,* hydroxyapatite.

Contamination of the bone graft may occur from endogenous bacteria, lack of aseptic surgical technique, or failure of primary soft tissue closure. Graft materials that fall into the oral cavity may be contaminated by saliva and should be thoroughly irrigated before use or discarded. The lack of primary soft tissue closure or incision line opening places the graft at significant risk. Barrier membranes or fixation screws that become exposed often become contaminated by bacteria. The bacteria invade the graft site and cause local inflammation with resultant decrease in bone formation.[6-10]

A blood supply within the graft is required for the normal distribution of an antibiotic to the site. Because no blood supply is present early on in the graft material, when bacterial contamination is a greater risk (i.e., sinus grafting), antibiotics may be added to the alloplastic material and autograft. Although tetracycline is often used in periodontal bone grafting to improve collagen formation, it chelates calcium and arrests the bone formation process.[11-13] Instead, parenteral penicillin, cephalosporin, or clindamycin may be mixed into the graft material, as these antibiotics do not affect the bone regeneration process (Figure 36-3). Tablets or capsules for oral administration of antibiotics are not used in

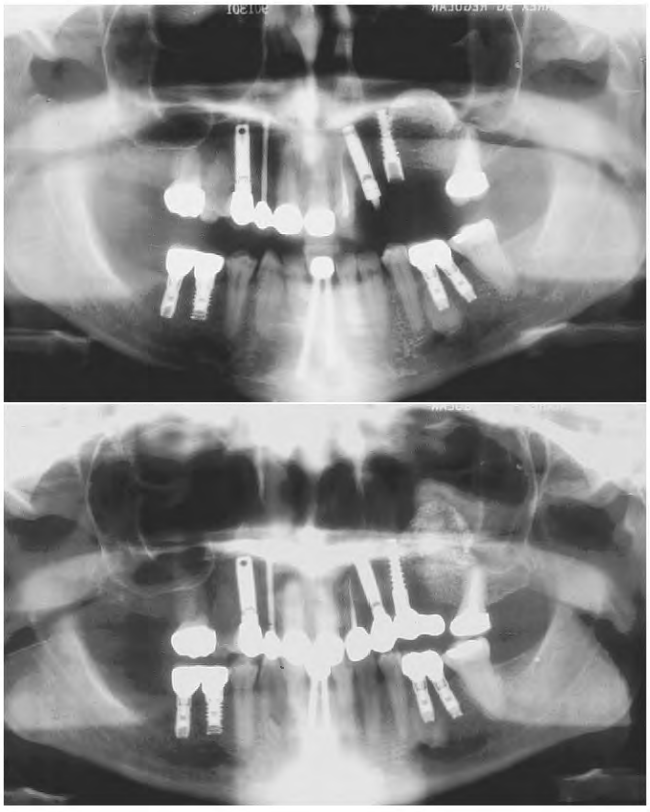

Figure 36-2 **A,** A panoramic radiograph of a sinus graft immediately post surgery. The radiopaque portion of the right sinus is from the mineralized, ceramic graft material which was inserted onto the maxillary floor. **B,** A postoperative panoramic radiograph of the same patient after a maxillary sinus infection, 2 weeks after the sinus surgery. The graft shows evidence of solution-mediated resorption of the graft material as a result of the infection.

WWW.HIGHDENT.IR

Figure 36-3 A parenteral form of cefazolin sodium (Ancef) may be added to the graft material when the site has been contaminated or become infected in the early healing process. This provides increased levels of the antibiotic at the site, even though vascularization is incomplete.

the graft site, as these often contain fillers of no benefit to the graft site.

Soft Tissue Coverage (Submucosal Space Technique) and Flap Design

Primary soft tissue closure is a mandatory condition for the success of grafting procedures other than socket grafting. It ensures healing by primary intention and requires minimal soft tissue collagen formation and soft tissue remodeling. It also minimizes postoperative discomfort. It is a necessary step for predictable bone regeneration. Even when socket grafting is performed without primary closure after extraction of a tooth, the epithelium covers the healing socket before bone forming in the crestal region.

Incision line opening during initial healing is the most common postoperative complication in intraoral bone grafting.[14-16] As a result, the graft is contaminated or lost, vascularization is delayed or eliminated, and bone growth is impaired.[8-10,17-20] The reason incision line opening is more common during bone grafting, compared with implant surgery, is that the overlying tissue must be advanced over a larger volume of bone and the tension on the incision line may pull the soft tissues apart. In addition, the soft tissues are poor in local growth factors under the reflected flaps that lie over a graft material or barrier membrane, rather than the host bone.

There are general guidelines to reduce the incidence of incision line opening.[21] The primary incision should be in keratinized tissue whenever possible. Not only does this reduce the initial intraoral bleeding, but it severs smaller blood vessels and reduces postoperative edema, which may add tension to the incision line. The crestal incision is designed more lingual, especially in the maxilla, as this places a greater amount of keratinized tissue onto the thinner facial flap and minimizes tearing of the tissue during suturing. Vertical relief incisions are designed away from the graft site directly on the host bone and create a broad-based flap[21,22] (Figure 36-4, *A* to *C*).

The blood supply to the reflected flap should be maintained whenever possible. The primary blood supply to the facial flap, which is most often the flap reflected for a bone graft, is from the unkeratinized mobile mucosa. This is especially true where muscles of facial expression or functional muscles attach to the periosteum. Therefore these vertical release incisions are made to the height of the mucogingival junction, and the facial flap is reflected only 5 mm above the height of the mucogingival junction. Both these procedures maintain more blood supply to the facial flap. In addition, incisions and reflection in the mobile alveolar mucosa increase flap retraction during initial healing, which may contribute to incision line opening and may increase risk of scar formation and delayed healing of the incision line as a consequence of reduced blood supply (see Figure 36-4, *D*, *E*).

The soft tissue flap design should also have the margins of the wound over host bone, rather than on the bone graft or barrier membrane. The host bone provides growth factors to the margins and allows the periosteum to regenerate faster to the site. The margins distal to the elevated flap should have minimal reflection. The palatal flap and the facial tissues distal to the reflected flap should not be elevated from the palatal bone (unless augmentation is required), because the blood supply to the incision line will be delayed. In addition, the unreflected flap does not retract during initial healing, which could place additional tension on the incision line. The soft tissue reflection distal to the graft site is split thickness to maintain some of the periosteum on the bone around the incision line. This improves the early vascularization to the incision line and adhesion of the margins to reduce retraction during initial healing (see Figure 36-4, *F, G*).

Primary wound closure should be without tension. Past techniques to expand tissue primarily used a more apical tissue reflection and horizontal scoring of the periosteum parallel to the primary incision. This is usually effective for primary closure when less than 5-mm advancement of the flap is necessary.

A submucosal space technique, developed by Misch in the early 1980s, is an effective method to expand tissue over larger grafts (greater than 15 × 10 mm in height and width).[5] The full-thickness facial flap first is elevated off the facial bone for only 5 mm above the height of the vestibule. One incision with a scalpel, 1 to 2 mm deep, is made through the periosteum parallel to the crestal incision and 3 to 5 mm above the vestibular height of the mucoperiosteum. This shallow incision is made the full length of the facial flap and may even extend above and beyond the vertical release incisions (see Figure 36-4, *H*). Care is taken to make this incision

WWW.HIGHDENT.IR

همیار دندانسازان

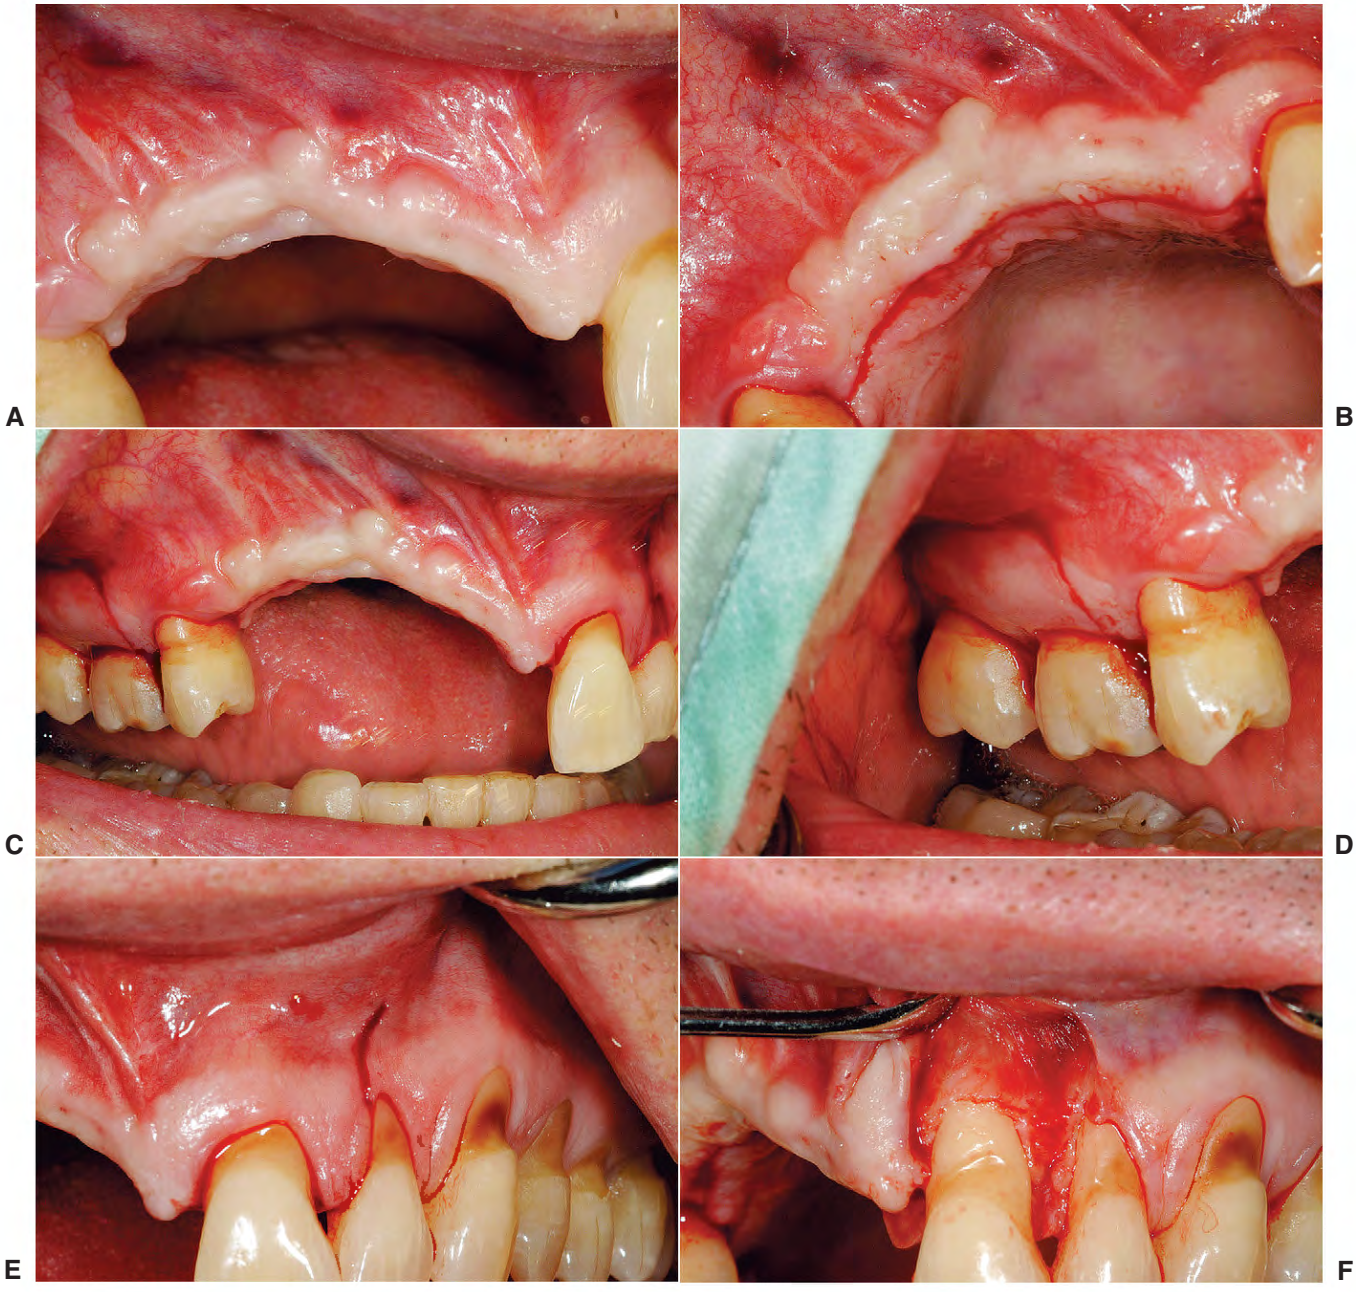

Figure 36-4 **A,** The site of the bone augmentation should ideally have adequate zones of attached keratinized tissue. **B,** The crestal incision is made in the attached keratinized tissue and slightly toward the palate. Incisions in attached keratinized mucosa minimize bleeding during surgery and edema post surgery, as smaller blood vessels are present compared with those in mobile, unkeratinized mucosa. A greater surface of keratinized tissue on the facial aspect provides a band of more tenacious tissue on the more mobile facial tissue flap. The risk of sutures tearing through the soft tissue during postoperative swelling or flap movement during function is therefore minimized. **C,** The larger the bone augmentation site, the farther distal the vertical release incisions. This increases blood supply to the reflected flap and minimizes tension on the incision line postoperatively. It also places the vertical release incisions on the split-thickness reflected sites away from the graft site. **D,** The vertical release incisions are made more distal from the augmentation site, as the size of the graft site increases. This gives more tissue to the reflected flap and improves the blood supply. The more distal incisions also ensure the wound margins will be on host bone, not over the graft site. **E,** The vertical release incision does not extend beyond the mucogingival junction and into the mobile alveolar mucosa, as larger blood vessels would be severed, increasing bleeding, flap retraction during initial healing and scar formation at the incision line. **F,** The reflection of the flap is split thickness away from the graft augmentation site, to improve early vascularization and reduce retraction of the flap.

Continued

above the microgingival junction; otherwise, the flap may be perforated and delay soft tissue healing. Soft tissue scissors (i.e., Metzenbaum) are used in a blunt dissection technique to create a tunnel apical to the vestibule and above the unreflected periosteum. The scissors are closed and pushed through the initial scalpel incision approximately 10 mm deep, then opened. This submucosal space is parallel to the surface mucosa (not deep toward the overlying bone) and above the unreflected periosteum. The thickness of the facial flap should be 3 to 5 mm, because the scissors are parallel to the surface (see Figure 36-4, *I*, *J*). This tunnel is

WWW.HIGHDENT.IR

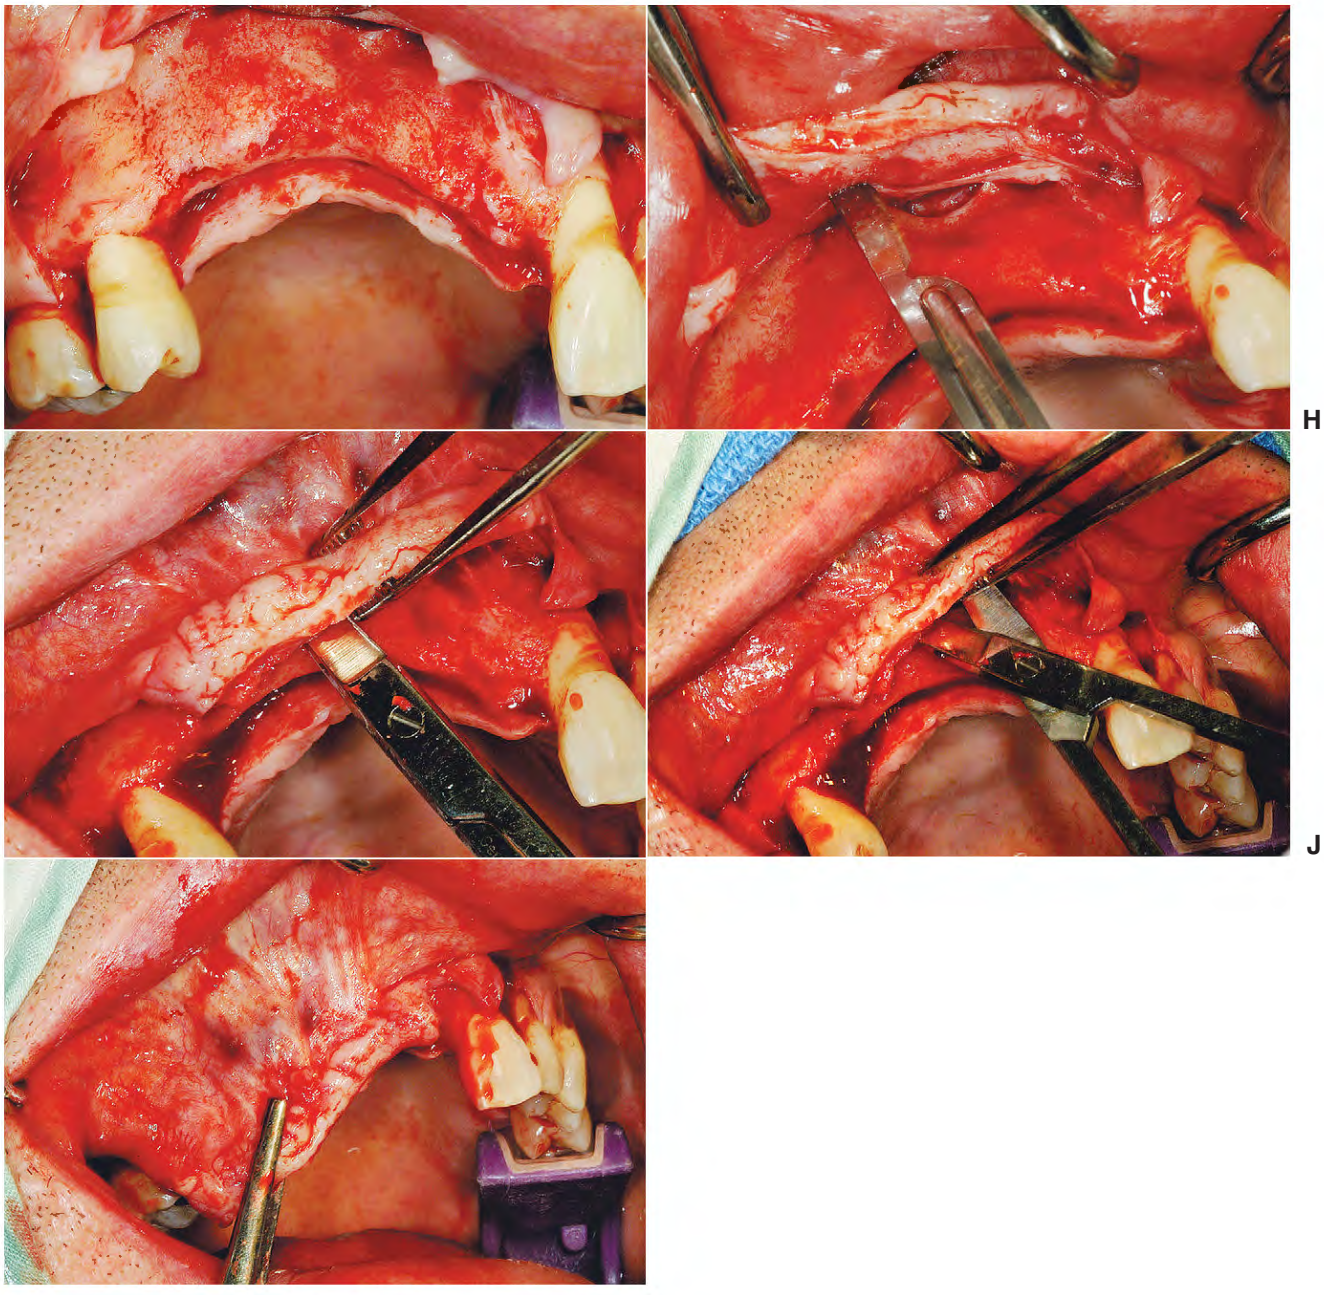

Figure 36-4, cont'd **G,** The full-thickness facial flap is reflected from the host bone 5 mm above the height of the mucogingival junction. **H,** A scalpel makes one incision parallel to the crestal incision, 1 to 2 mm deep, and extends the full length of the flap, 3 to 5 mm above the MGJ. **I,** A tissue pick-up may be positioned on the facial flap, with the end of the beak at the height of the mucogingival junction. When the flap is reflected, the lingual aspect of the tissue pick-up transfers the height dimension to the internal aspect of the flap. A soft tissue scissors (i.e., Metzenbaum) is pushed into the facial flap for approximately 10 mm with the blades closed, parallel to the surface mucosa. The thickness of the facial flap is approximately 3 to 5 mm. **J,** The tissue scissors are opened, once at the proper depth. This blunt dissection does not sever any blood vessels or nerves to the facial flap but does create a submucosal space or tunnel. **K,** Once the submucosal space or tunnel is created over and beyond the vertical release incisions, the facial flap may be advanced over the graft for primary closure, without tension.

expanded with the tissue scissors several millimeters above and distal to the vertical relief incisions.

Once the submucosal space is developed, the flap may now advance the distance of the "tunnel" and drape over the graft, to approximate the tissue for primary closure without tension (see Figure 36-4, *K*). In fact, the facial flap should be able to advance over the graft and past the lingual flap margin by more than 5 mm. Then the facial flap may be returned to the lingual flap margin and sutured. This soft tissue procedure is performed before preparing the host region and harvesting the donor site. Access to the facial tissues is easier before graft placement, and particulate graft and membranes barrier are not dislodged during the soft tissue manipulation when it is performed before bone grafting.

WWW.HIGHDENT.IR

همیار دندانسازان

The submucosal space technique is very effective to achieve tension-free closure over large graft sites. However, a side effect of the procedure is the loss of vestibular depth, especially when grafting for residual ridge height. In addition, a lack of keratinized tissue also may exist on the facial region of the grafted site, because the original facial tissue is now part of the crestal region after bone augmentation. As a consequence, soft tissue grafts or vestibuloplasties may be required after bone grafting when within the esthetic zone. It is suggested that these procedures be delayed for at least 4 months to allow regeneration of the blood supply to the soft tissue and the underlying bone. When necessary, these soft tissue procedures can be associated with implant placement or implant uncovery procedures, or even prior to the bone graft. To have mature tissue for the soft tissue advancement procedures, the soft tissue graft should be done 3 months or longer before the bone graft .

Platelet-rich plasma (PRP) may be placed over the bone graft to provide an additional source of transforming growth factor beta (TGF-β) and vascular endothelial growth factor (VEGF), which promote collagen formation and blood vessel growth (Figure 36-5).

Suture material selection should be made in function of the type and size of the bone grafting.[23-30] Silk has been shown to release less tension during early retraction of the flap from healing and to elicit greater inflammation and may contribute to incision line opening more often than synthetic materials.[26,27] Therefore it is not recommended for bone augmentation procedures. Chromic gut causes inflammation, loses tension, and resorbs too quickly to maintain soft tissue approximation over an augmented site. Therefore it is not recommended when the tissues are advanced for a bone augmentation.[29] Polyglycolic acid (PGA, Vicryl) shows the mildest tissue reaction and maintains sufficient tension over the first 2 weeks to be used for most bone graft procedures.[28] In larger-size bone grafts, the soft tissue is often approximated for primary closure with nonresorbable sutures (e.g., Prolene, Gore-Tex). Resorbable sutures usually lose 50% of their tensile strength after 14 days and may be associated with a delayed incision line opening (Figure 36-6). Each penetration of the tissue by the suture causes an approximate 1-mm devital zone and the need for repair. When the sutures are too close to the margin, the devital zone may include the incision line. The nonresorbable sutures remain in place for 2 or more weeks to enhance soft tissue maturation.[30]

The selection of a specific suture design also follows basic principles.[23,24] Interrupted sutures should be used 3 to 5 mm from each side of the tissue margin and 3 to 5 mm apart, and are appropriate in short spans of edentulous spaces (Figure 36-7). Too many sutures or too much tension impair the blood supply to the incision line and increase the risk of incision line opening.

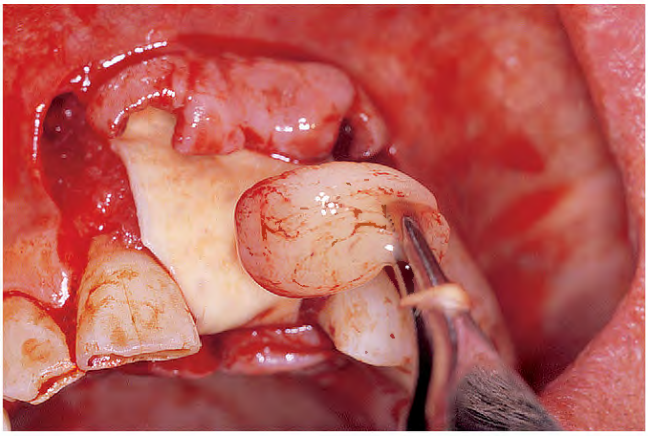

Figure 36-5 Platelet-rich plasma (PRP) may be applied to the graft site prior to soft tissue closure. TGF-β and VEGF are released from the PRP and may contribute to vascularization and early soft tissue healing.

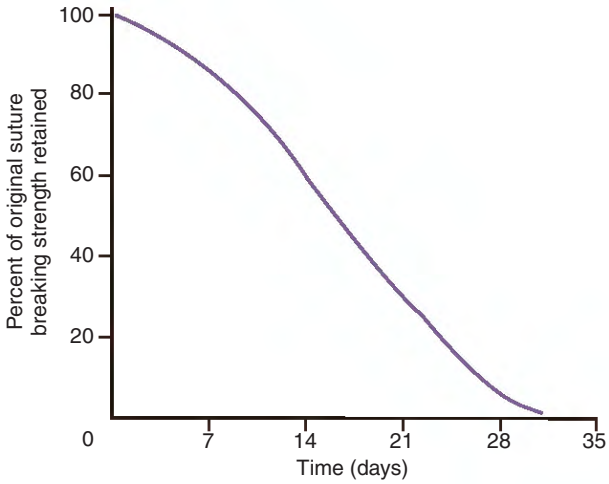

Figure 36-6 Vicryl sutures lose 50% of their strength 2 weeks after the initial surgery. As a result, a delayed incision line opening may occur if tension on the incision line from flap retraction during initial healing or from muscle pull during function/parafunction is present.

Because the tissues are passive while in place, sutures are not required to obtain the soft tissue closure. Soft tissue spans necessitating four or more interrupted sutures are best approximated with continuous nonlocking sutures. This suture design places less tension on the sutures and soft tissue and allows faster vascularization of the reflected soft tissue flaps.

Horizontal (or vertical) mattress sutures allow greater tension to be applied on the soft tissue closure without risk of tearing the soft tissue flap. It should be emphasized that they are not used to obtain primary closure when tension on the soft tissue flaps is present at surgery. The tissues should rest passively together before suturing. However, during function/parafunction movement of the tissues, the tension on the incision line may be reduced with a horizontal mattress suture. They are often used in the mandible when the floor of the mouth is in proximity to the lingual flap and the tissue is thin. They may also be used on a facial flap with a strong

WWW.HIGHDENT.IR

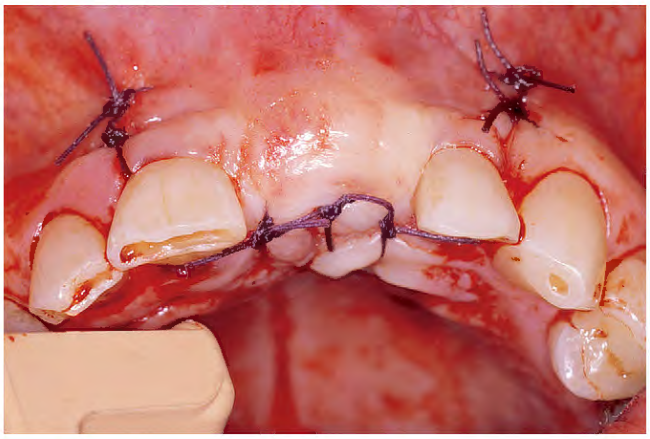

Figure 36-7 Interrupted (or continuous) sutures should be 3 to 5 mm from the incision line margin and 3 to 5 mm apart. They are used to passively approximate the tissues. Too many sutures delay vascularization to the flap and slow the healing process.

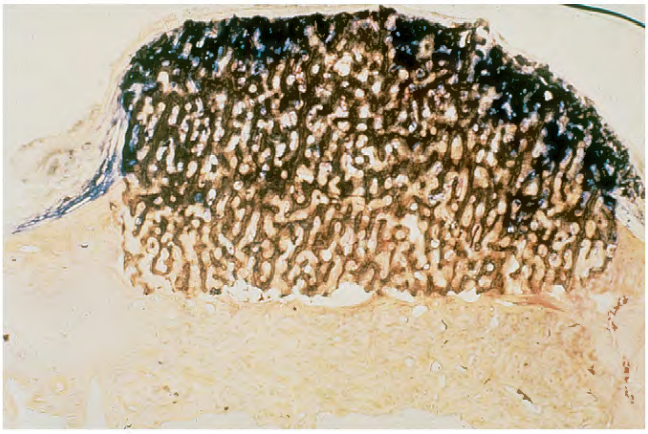

Figure 36-8 A "barrier by bulk" technique uses a graft material to maintain the space for a bone augmentation. In this picture, an alloplast (hydroxylapatite) block was placed on top of the bone and only soft tissue covered the site. After 4 months, the block biopsy was made and stained. The soft tissues stained blue and bone stained brown. Note the soft tissue invaded the block several millimeters, and bone grew into the porous block many millimeters. Removing the top layer of the graft material would remove the soft tissue and leave the rest of the site augmented with bone and the slowly resorbing graft material.

muscle pull on the soft tissue. In addition, horizontal mattress sutures avert the soft tissue margin and ensure primary closure without epithelium entrapment. A combination of a few horizontal mattress sutures with a continuous suture may be indicated to close large soft tissue spans.

No particulate graft material should be present in the incision line during initial primary closure, as this will delay soft tissue healing. Therefore, once the tissues are sutured, the incision line is inspected for any bone graft particles between the soft tissue margins.

Gentle pressure is then applied to the reflected soft tissue flaps for 3 to 5 minutes. This pressure may reduce postoperative bleeding under the flap, which may cause "dead spaces" and delayed healing. Any stagnant blood under the flap is "milked" from under the soft tissue by gentle pressure. This also allows the fibrin formation from the platelets to help "glue" the flap to the graft site.

Systemic corticosteroids may be administered before and after surgery to decrease soft tissue edema, as edema has been shown to contribute to incision line opening. Incision line opening has been associated with postoperative smoking[16,31-33]; therefore patients are instructed not to smoke until the incision line has healed. If a removable soft tissue–borne interim prosthesis is used, it should not contact the grafted area. When possible, a fixed transitional restoration is designed to reduce complications of incision line opening and graft micromovement during healing.

Space Maintenance

Space maintenance in the area of the bone graft site is paramount to the bone formation process. The *space* of the graft site refers to the anatomical size and contour of the desired augmentation, and *maintenance* refers to the fact the space must exist long enough for bone to fill the desired region. A barrier membrane is a sheet of material that covers the potential bone graft site and prevents the overlying soft tissue from growing into the graft site. A barrier membrane technique without graft material underneath has been suggested for ridge augmentation.[18,34-38] However, collapse of the space under the membrane may impair the desired size and contour. A fixation screw, elevated above the host bone level to the height/width of the desired bone volume, may support a barrier membrane and is called a *tent screw.* When the space under the barrier membrane is only air or blood, the initial quality of bone is poor for many months. Tent screws, titanium-reinforced membranes, and graft material beneath the membrane have been advocated to maintain the desired space during the augmentation process.[39-47] Space maintenance may be provided in a socket or sinus cavity by resorbable graft material. However, if the material resorbs too rapidly compared with the time required for bone formation, the site may fill with connective tissue rather than bone. Therefore the space or contour and size of the augmentation should remain until the bone graft has formed enough new bone to maintain the space itself.

The space for bone regeneration may also be provided by a graft material, as an autograft or alloplast "in excess."[48] The "barrier by bulk" concept by Misch applies to situations in which the graft site is over-contoured by several millimeters with a resorbable alloplast.[5] As bone grows below the alloplast, the invading fibrous tissue only invades the superficial alloplast layer. When the soft tissue is reflected to insert the implants, the top layer of fibrous tissue and alloplast is removed, and the new regenerated bone underneath remains (Figure 36-8). This technique works best when larger graft volumes still allow primary

WWW.HIGHDENT.IR

همیار دندانسازان

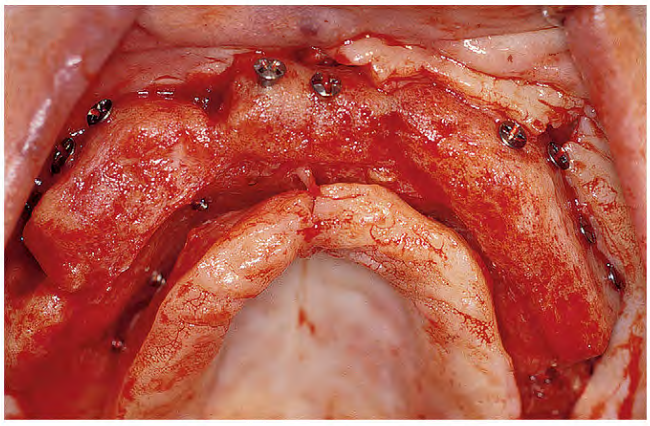

Figure 36-9 Block bone grafts from the iliac crest are fixated to the resorbed maxilla with fixation screws. These devices immobilize the graft during the bone modeling process.

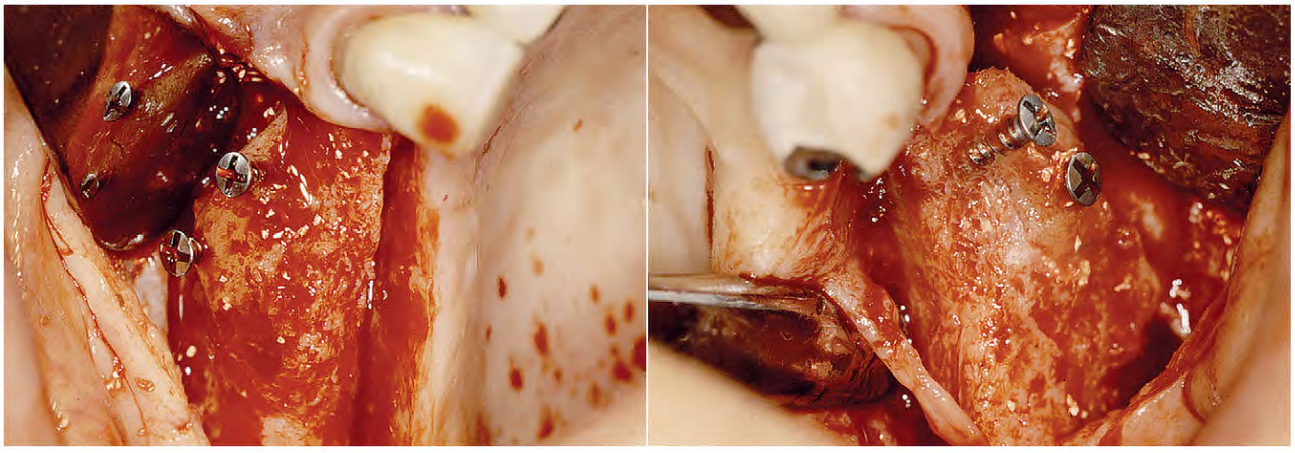
soft tissue closure and in the absence of pressure of the soft tissue. The use of soft tissue–borne provisional prostheses is discouraged for all augmentation procedures because the graft size may be modified and the graft may become mobile.

Graft Immobilization/Stability/Fixation

An implant with movement greater than 150 µm during healing does not integrate to the bone. A loaded implant may move as much as 100 µm during initial healing and develop a direct bone implant interface. However, this process occurs through bone remodeling and is less demanding on mobility. Even bone remodeling has its limits relative to micromovement. Changing the volume of bone is bone modeling and requires a more rigid interface during the bone formation process. Micromovement as low as 20 µm may be too much for bone modeling and may result in a nonfixated graft or fibrous encapsulation.

Graft stabilization is paramount to obtain a predictable bone augmentation. This ensures initial blood clot adhesion with its associated growth factors[49-56] (cytokines such as interleukin-1, interleukin-8, tumor necrosis factor, and growth factors such as platelet-derived growth factor [PDGF], insulin-like growth factor, and fibroblast growth factor [FGF]).[53-56] The granulation tissue that develops after blood clot stabilization is the initial mechanism for bone modeling and remodeling.[53,54] If pieces of a particulate graft material or block bone grafts are mobile, they cannot develop a blood supply for new bone formation. Instead, the graft becomes encapsulated in fibrous tissue and often sequestrates. Likewise, when barrier membranes or fixation screws become loose or mobile, fibrous tissue will encapsulate them. Therefore, for barrier membranes or particulate graft materials to work most effectively, no loads should be placed on the soft tissue over the graft, which may cause movement of the graft.

Barrier membranes may be immobilized to the graft site by bone tacks. As a result, when the soft tissue over the barrier membrane moves, the barrier membrane remains fixated. A tent screw placed under the barrier membrane can prevent movement to the graft site when the overlaying soft tissue is loaded. A block bone graft fixation with bone screws maintains a rigid interface more effectively than particulate grafts (Figure 36-9). A fixed transitional prosthesis, which protects the graft site, is the better option to limit graft movement during the augmentation process, especially with a "barrier by bulk" technique of particulate graft materials. When possible, soft tissue–bone removable restorations should have rest seats and clasps to prevent loading the soft tissue (Figure 36-10).



A B

Figure 36-10 **A,** Upon reentry, the particulate bone graft resorbed and provided inadequate volume for implant insertion. **B,** The other side of the patient underwent height resorption that included part of the block bone graft. Bone width was maintained because the fixation screw protected the inferior portion of the graft.

Regional Acceleratory Phenomenon

The RAP is the local response to a noxious stimulus and describes a process by which tissue forms faster than the normal regional regeneration process.[57-61] By enhancing the various healing stages, this phenomenon makes the healing process occur two to 10 times faster than normal physiologic healing. The RAP begins within a few days of injury, typically peaks at 1 to 2 months, usually lasts 4 months in bone, and may take 6 to more than 24 months to subside.[55-57] The duration and intensity of the RAP are directly proportional to the type and amount of stimulus and the site where it was produced. For bone injuries, the degree of remodeling activity varies depending on the extent of bone injury, the quantity of soft tissue involved in the injury, and the configuration of the bone fracture or trauma.

Noxious stimuli of sufficient magnitude, such as fractures, mechanical abuses, and noninfectious inflammatory injuries (including dental implant procedures), can evoke an RAP. Bone grafting surgery and internal fixation procedures also produce an RAP.[57] In animals, an RAP has been shown to exist after mucoperiosteal surgery on mandibular bone, with a clear correlation between quantity and quality of the noxious stimuli and degree of the RAP response.[62-64] When bone graft augmentation is required on both the buccal and lingual aspects, the RAP is created on both sides of the ridge. The host site during a bone graft procedure should be decorticated by drilling holes in the cortical bone. These holes provide access for trabecular bone blood vessels to the graft site, expedite revascularization, and bring growth factors to the graft site.[65,66] The marrow provides differentiated cells that evolve into osteoclasts and osteoblasts. The surgical trauma increases the RAP process, which, among other factors, includes the platelets released from the damaged vessels, which release PDGF and TGF, and increase the availability of osteogenic cells in the graft site. The penetrating holes in the cortical plate also improve graft union to the host bone, which is important when implants are placed within the seam of the donor and host site region.

The host bone decortication process may use a 20:1 low-speed hand piece at 2500 rpm with a bone drill designed for fixation screws to perforate the host bone with holes 3 to 5 mm apart and should be performed under copious amounts of saline irrigation to prevent surgical heat trauma, which delays healing (Figure 36-11). Excess heat transfers several millimeters within the bone and causes thermal necrosis, which could

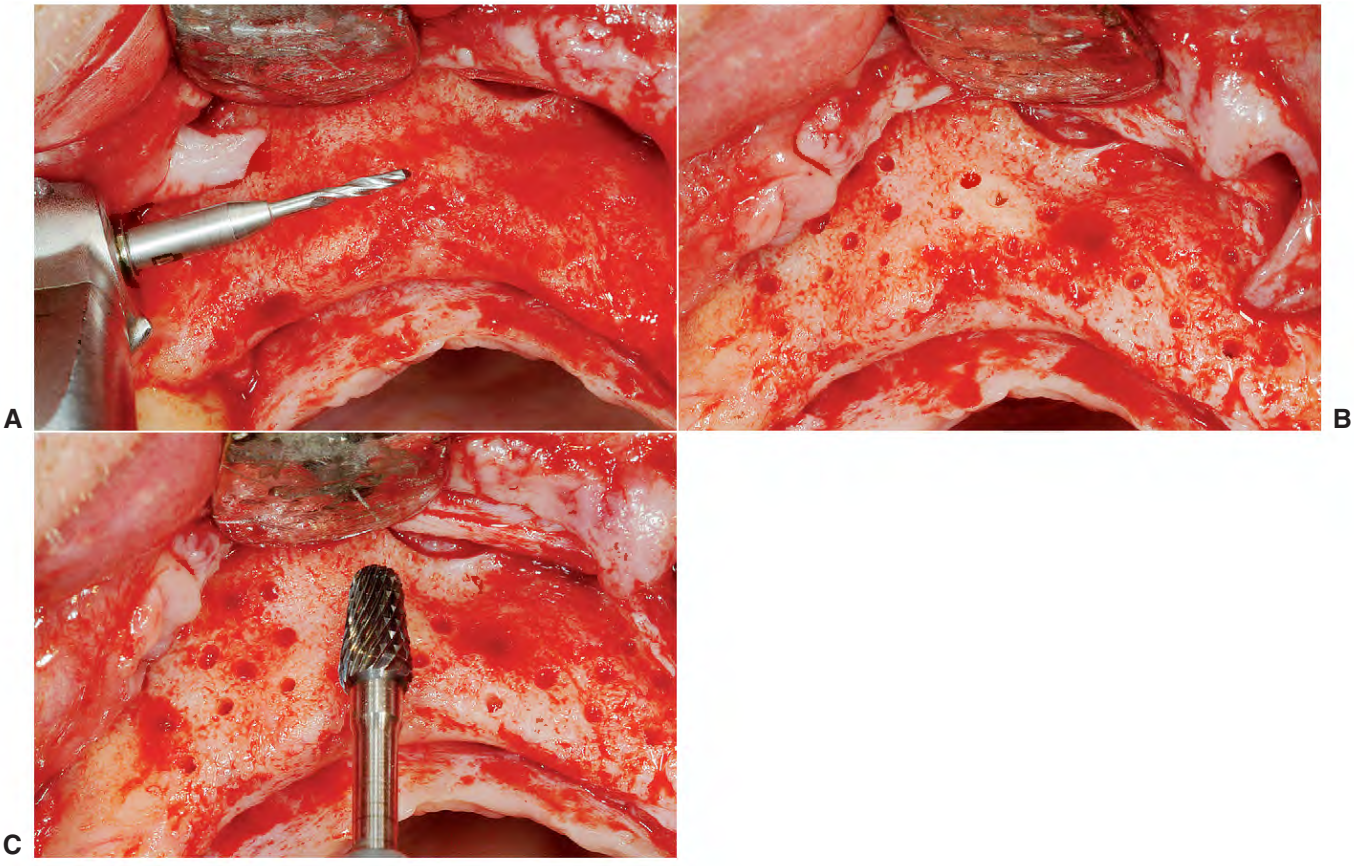

Figure 36-11 **A,** A low-speed hand piece (2500 rpm), similar to a root form osteotomy, may use a bone drill designed for fixation screws, with copious amount of saline irrigation. **B,** The holes perforate the labial plate every 3 to 5 mm to set up a regional acceleratory phenomenon (RAP) for bone repair at the graft–host bone interface. **C,** After the holes prepare the surface, a large pear-shaped drill may be used to recontour the host site to receive the graft and ensure no fibrous tissue remains on the host bone interface to the graft. This also increases the RAP.

WWW.HIGHDENT.IR

همیار دندانسازان

damage bone and blood vessels needed for repair. When injury to the bone is due to a pathologic process (e.g., arthrofibrosis, neuropathic soft tissue problems, rheumatoid phenomena, secondary osteoporosis, excessive heat), the RAP is either delayed or not initiated, and a complete healing process may not occur. When the RAP is inadequate, the result is a slow callus formation that is replaced by lamellar bone. This process contributes to the formation of biologically delayed unions and nonunion.

The increased rate of new formation of bone caused by the RAP does not result in a change in bone volume. In other words, the RAP in and of itself is usually restricted to bone remodeling.[67] In addition, RAP is more evident in cortical bone because the normal turnover of bone cells is 2% compared with 18% for trabecular bone. Biochemical agents, such as prostaglandin E_1 and bisphosphonate, also appear to facilitate the RAP.[62,68]

The RAP is usually accompanied by a systemic response, defined as the systemic acceleratory phenomenon (SAP), that demonstrates a metabolic response similar to the local response.[69] Inadequate RAP is also associated with several systemic medical conditions, including diabetes mellitus, peripheral neuropathies, regional sensory denervation, severe radiation damage, and severe malnutrition.

Host Bone Blood Vessels

Nutrient blood vessels must provide nourishment to an autologous bone graft to keep the transplanted cells alive. These vessels may arise from two primary sources. The host cortical bone contains very few arterioles, whereas cancellous bone has an intensely vascular network. For the blood vessels to penetrate into the autologous bone graft site, the cortical bone should be perforated or removed. This is especially important in the mandible, where the cortical plate is thicker compared with the maxilla.

The host bone blood vessels that grow into a bone graft are of primary importance for predictable bone augmentation.[70] These arteries can grow rather rapidly, compared with other tissues. Fibrous tissue may grow 1 mm each day, whereas woven bone grows at a rate of 60 µm each day. It would appear then that fibrous tissue would always win the race to fill a bony void. Yet, bone forms in an extraction socket when surrounded by walls of bone. One primary reason is that the blood vessels from the surrounding walls grow rapidly into the void and determine what type of tissue will form in the extraction site. The maxillary sinus region forms bone predictably, almost regardless of the type of alloplast or allograft material. This is in part because the antrum is surrounded by bone, and the primary source of revascularization of the graft comes from the adjacent bony walls.

Blood vessels from bone that enter the graft site provide pluripotential perivascular cells that have the capability to become osteoblasts. Monocysts in the blood form osteoclasts, which precede the blood vessel into the bone graft site by forming cutting cones, which resorb devital bone and graft material. As the osteoclasts resorb the graft material, the blood vessel can grow into the site. As importantly, the sides of the blood vessel carry osteoblasts, but only when the vessel comes from the host bone (Figure 36-12). Not only is the blood vessel needed to help the autograft maintain vitality, it is also needed to repopulate the area with osteoblasts to grow new bone. It has been postulated that the surface fibroblasts, if left to migrate within the graft, not only invade the space, but also may inhibit osteogenesis by contact inhibition.[56]

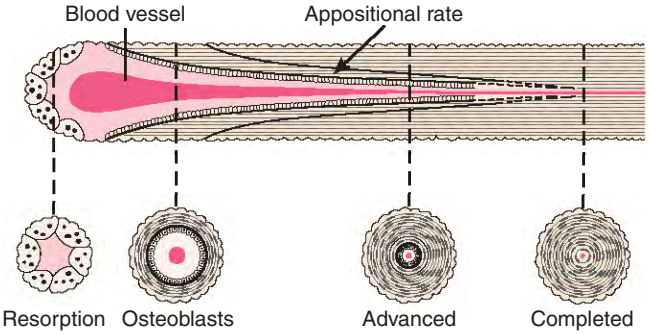

Figure 36-12 When a blood vessel grows into the graft site and comes from bone, several favorable factors occur. The osteoclasts precede the blood vessel, resorb the graft, and allow the blood vessel to grow into the space. The blood vessels from bone bring osteoblasts along the sides to repopulate the graft site with bone-forming cells. Blood vessels from the soft tissue do not populate the graft site with osteoblasts.

A tooth extraction socket fills with bone because the blood vessels from bone form granulation tissue in the site and prevent the epithelial cells from migrating into the site. Four to 6 months are then needed for the socket to replace the area filled with the blood clot (initially) and granulation tissue (later) with bone.[71]

One effective method to increase the amount of host blood vessels in a graft site is to decorticate the host site with a rotary drill.[72] The blood vessels from the trabecular bone are then able to invade the graft site from below and bring pluripotential cells. To permit blood vessels from the bone to enter the graft site, there should be spaces available between the graft particles. When autogenous bone is used as a graft material, the trabecular bone graft provides these open spaces, whereas cortical bone, which presents a denser surface, takes longer to revascularize. Spaces are also necessary when alloplasts are included in the bone graft site.

When an alloplast is placed upon a decorticated ridge and covered with soft tissue (without a barrier membrane), the bone from below the graft grows four times faster into the graft voids than the fibrous tissue grows down into the graft (Figure 36-13). This is because the blood vessels from bone grow rapidly into the region, and once they invade the site, bone follows.

WWW.HIGHDENT.IR

Figure 36-13 A bone graft site is decorticated and a "barrier by bulk" technique is used with an alloplast (in this case particulate hydroxyapatite) and covered with fibrous tissue. After 4 months, a block section was obtained and stained. The soft tissue is stained blue and the bone red. Note the bone grew up into the graft material four times farther than the soft tissue grew down into the graft. This is because the blood vessels grow faster than the fibrous tissue, and when the vessels come from bone, bone cells repopulate the graft and form bone. (NOTE: The same mechanism occurred in Figure 36-8.)

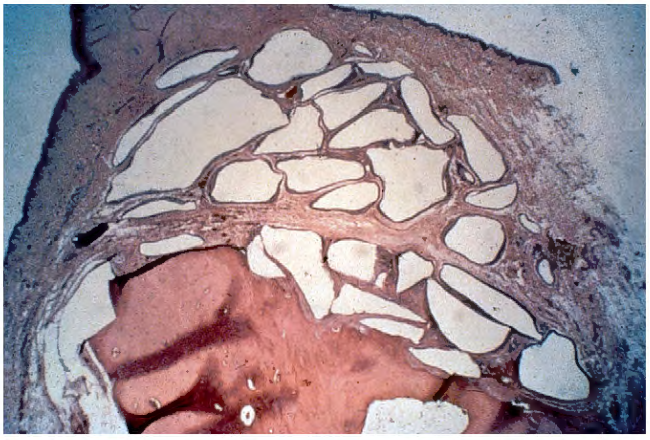

Figure 36-14 An alloplast (hydroxyapatite) placed on top of the bone that is not decorticated was covered with soft tissue and allowed to heal 4 months. A block section reveals the particles are surrounded with fibrous tissue. Because the bone blood vessels do not grow into the graft site, no bone around the particles is observed.

Box 36-1 Growth Factors

1. Platelet-derived growth factor (PDGF)
2. Fibroblast growth factor (FGF)
3. Transforming growth factor (TGF)
4. Insulinlike growth factor (IGF)
5. Platelet-rich plasma (PRP)
6. Bone morphogenetic proteins (BMP)

An alloplast placed upon host cortical bone forms fibrous tissue around the graft, as no host bone blood vessels are able to grow into the graft material (Figure 36-14). The key to whether bone or fibrous tissue forms in the bone graft site is the host blood vessels.

Growth Factors

Bone growth factors can enhance formation and mineralization of bone, induce undifferentiated mesenchymal cells to differentiate into bone cells, and trigger a cascade of intracellular reactions and the release of a number of additional bone growth factors and cell-enhancing factors. These growth factors bind to specific receptors on the surface of target cells. More than 50 known growth factors have been identified and categorized, with some specific to the functions in bone healing (Box 36-1). These constitute a separate group of proteins because of the way they can be produced and their mode of action. They are, however, part of the large superfamily of TGF-β.[73] Bone growth factors are primarily present in bone matrix and released during remodeling or after trauma. They act on the local osteoprogenitor differentiated cells and therefore have limited areas of action.[74] In contrast, BMPs, although also found in extracellular bone matrix, are osteoinductive and can trigger the differentiation of mesenchymal cells into osteoblasts.[75]

Platelet-Derived Growth Factors

Platelet-derived growth factors are produced by activated macrophages and stored in platelets and bone matrix.[76] Platelets are the greatest source of this growth factor and may be further divided into different types, AA, BB (homodimers), and AB (heterodimers). These factors have the characteristics of a wound hormone, acting as a chemoattractant and recruiting mesenchymal cells into the wound.[77,78] The activated platelets also enhance hemostasis by attracting additional platelets to the site, which release thrombin, thromboxane A_2, and adenosine diphosphate. Howes et al. used demineralized bone powder with PDGF in older rats to generate an increased production of mRNA for collagen II, alkaline phosphatase activity, and calcium content of the demineralized bone compared with controls without PDGF.[79] PDGFs increased cartilage and bone formation in the graft site. They have also been shown to activate collagenase within the latter stages of wound healing, which remodels collagen to promote soft tissue wound healing.

The primary roles of PDGFs in bone modeling and remodeling are to (1) increase the number of cells necessary for bone formation (including osteoblasts) at the repair site; (2) trigger capillary formation through its potent mitogenic activity; (3) enhance site debridement;

WWW.HIGHDENT.IR

همیار دندانسازان

and (4) provide a continued source of growth factors for bone repairs.[80] PDGF mixed with autologous bone grafts can accelerate mineralization by as much as 40% during the first year.[79,81-89] PDGF combined with other growth factors (such as IGF)[90] have shown promising results in periodontal regeneration with guided bone regeneration (GBR).[91] Further research targets the use of PDGF combined with IGF to enhance the implant-bone interface.[92]

Fibroblast Growth Factors

Fibroblast growth factors are stored in the extracellular matrix of bone and have many of the same functions as PDGFs. FGFs can stimulate the proliferation of osteoblasts, resulting in the net formation of bone. In addition, they are a potent angiogenic factor.[93] However, FGF-β needs to be in the presence of bone to be effective and is more effective when used in combination with PDGF. Research on the potential benefits of FGF is ongoing but has yielded varied results, with some studies showing bone abnormalities[94] or no bone growth at all.[95]

Transforming Growth Factor Beta

The super family of growth factors is TGF-β, with more than 47 known varieties. TFG-β includes cytokines that contribute to connective tissue repair and bone regeneration. Bone is the body's most abundant storage site for TGF-β, which acts as a weak mitogen for human osteoblastic cells.[93] TGF-β also induces chemotaxis and stimulates extracellular matrix formation in osteoblastic cells and may inhibit osteoclast formation.[93]

TGF-β_1 activates fibroblasts to form procollagen, which deposits type 1 collagen within the wound[77,90] and is therefore credited with the enhancement of soft and hard tissue repair. PDGF and TGF-β_1 assist in soft tissue healing and bone mineralization; therefore they can be mixed with grafting materials into the bone graft site and applied to the top layer of the graft.

Insulin-Like Growth Factors I and II

Insulin-like growth factors I and II (IGFI, II) mimic insulin in several ways. They are fabricated in the liver and travel through the blood stream. IGF has been shown to act as a chemotactic factor for mesenchymal progenitor cells derived from bone marrow.[96]

PRP is a volume of autogenous plasma that has a platelet concentration above baseline[97] (1 million platelets/μL versus normal average of 200,000 platelets/μL). It is a concentrated autogenous source of seven growth factors that are "native growth factors in their biologically determined ratios"[88] (contrary to recombinant growth factors, which are high concentrations of synthesized growth factors in the laboratory) (Box 36-2). It is not osteoinductive by itself, cannot induce bone formation alone, and therefore needs to be in the presence of bone or DFDB. However, it is a benefit to soft tissue healing also, and because soft tissue closure and blood supply are important keys to bone grafting, it is also a secondary benefit even when autologous or DFDB bone is not present.

It has been observed that 90% of the growth factors of PRP are released within 10 minutes of clot activation and the remainder within $1^1/_2$ hours. This is a very short time in the scheme of bone augmentation, which is a 4- to 9-month process. It is to be considered primarily a "spark" that ignites a process of cell enhancement features, which are then able to continue the process.

On the other hand, soft tissue healing is a process that is 90% complete within several weeks. The PRP influence is more noteworthy in this shorter time frame. As a result, the use of PRP should not influence the time of implant insertion into a graft if applied to an implant, nor should not be a major factor is when the device is prosthetically loaded. A study by Gerard et al. in dogs found PRP increased the amount of bone formation in a graft site at the 1- and 2-month time in load.[98] However, at 6 months, the control and PRP bone grafts had similar vital bone percentages (Figure 36-15). However, PRP may decrease incision line opening and enhance soft tissue maturation at a clinical rate that is advantageous to the general scope of the implant procedures for a bone graft.

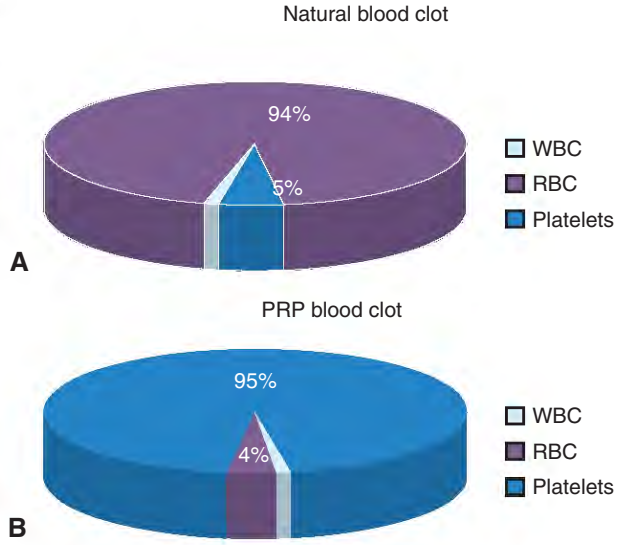

Figure 36-16 **A,** A regular blood clot that forms in the region of surgery is 94% RBC and 6% platelets. **B,** When a PRP concentrate forms a blood clot, 94% are platelets and only 5% are RBCs. *WBC,* White blood cell; *RBC,* red blood cell; *PRP,* platelet-rich plasma.

Preparation of Platelet-Rich Plasma

Specific steps and materials are to be used to produce PRP of a concentration of at least 1 million platelets/μL in a 5-mL volume.[86] Whole blood is primarily composed of red blood cells (RBCs) (almost 50%), white blood cells (WBCs), platelets, and serum. Red blood cells are needed for oxygen and nutrients to the cells. However, stagnant RBCs lyse and the pH is reduced, with the risk to kill vital bone cells.

In a study by Marx, iliac crest osteoblasts were stored in whole blood and in saline 9%. After 3 hours, 97% of the bone cells stored in saline 9% were still alive, whereas only 85% of cells in whole blood were vital. The stagnant RBCs in whole blood withdrawn from a vein or a normal blood clot are a deterrent to bone cell survival.[99] When a blood clot forms, 94% of the clot consists of RBCs, 6% platelets, and less than 1% WBC. In comparison, a PRP clot is 94% platelets, 5% RBCs, and 1% WBCs (Figure 36-16).

The first spin of the double centrifugation technique separates red blood cells from plasma containing platelets, WBCs, and clotting factors. The RBCs are separated from this first process and respun in the centrifuge. The second spin separates platelets and WBCs from the plasma and produces PRP. When the plasma is physically separated from the PRP, the plasma represents the platelet-poor plasma (PPP). One-spin techniques are ineffective at separating PRP from the PPP and produce too low a platelet count. The higher the number of platelets collected, the higher the concentration of growth factors (Figure 36-17).

The PRP factors have a threshold prior to making a difference in the bone and soft tissue healing process. When the threshold amount is not achieved, no difference in clinical result is obtained. Unfortunately,

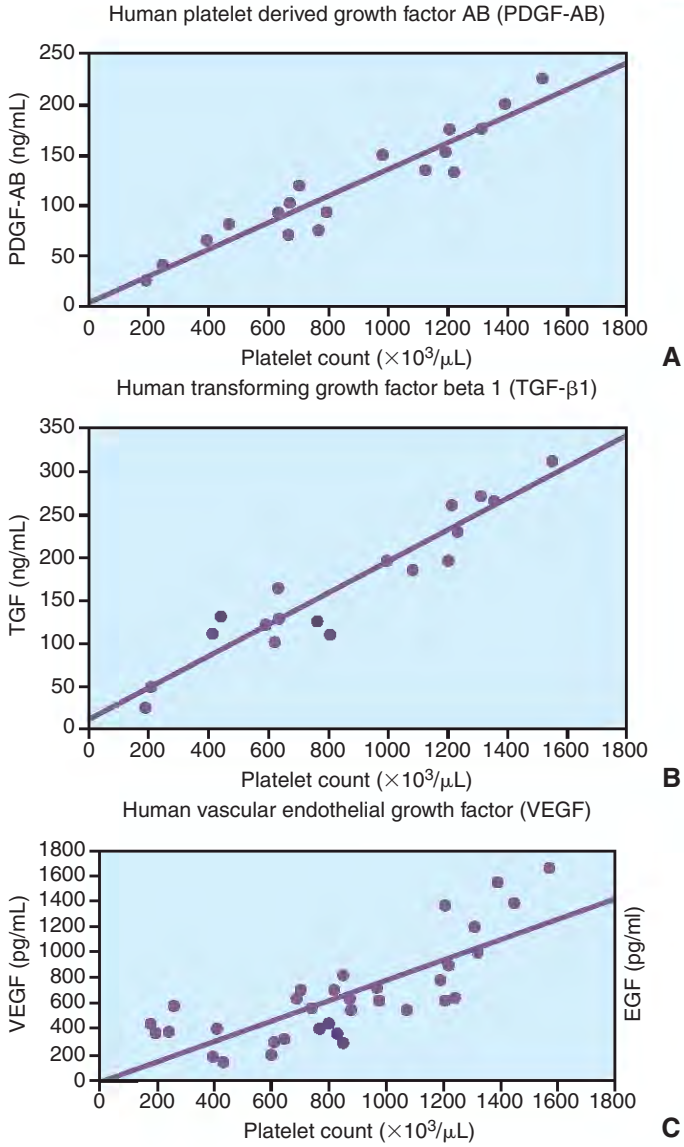

Figure 36-17 **A,** The greater the number of platelets/mL, the greater the amount of PDGF. **B,** The greater the number of platelets/mL, the greater the concentration of TGF-β. **C,** The greater the number of platelets/mL, the greater the concentration of VEGF.

the threshold of making a difference in the healing process is different from one person to the next. The higher the concentration, the more likely a difference will be observed in the rate of healing. The lower the concentration of platelets, the less likely a difference will be observed.

Typically 20 to 60 mL of blood is drawn from the patient to produce a sufficient PRP volume for dental use. Once the PRP is ready for use, it should be clotted (which activates the platelets) at the time of use, because once activated, platelets start secreting growth factors immediately (90% within the first 10 minutes, 100% in 30 minutes). Therefore, an anticoagulant (such as citrate dextrox-A [ACD-A]) is incorporated into the blood at withdrawal from the vein, which may keep the PRP uncoagulated for as long as 8 hours. However,

WWW.HIGHDENT.IR

همیار دندانسازان

PRP is best used when produced and then within 1 to 3 hours.

PRP is not a barrier membrane. Barrier membranes prevent soft tissue from invading the bone graft site for at least several weeks or months. PRP does not prevent fibroblasts from invading a bone graft site over an extended time frame. However, it may be applied to a barrier membrane. Because it also has fibrinogen, it provides added benefits to soft tissue, acts as a hemostatic agent, and has the ability to reduce postoperative pain and edema. Bone formation where PRP is added to the graft may increase in rate, quality, and volume (Figure 36-18).[80-102]

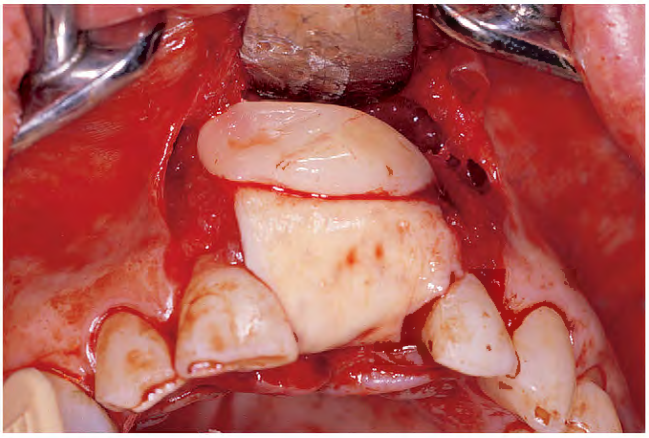

Figure 36-18 Platelet-rich plasma (PRP) is not a barrier membrane, as it does not prevent soft tissue from growing into a bone graft site for several weeks to months. However, it may be applied to a barrier membrane (e.g., Alloderm) and assist in the soft and hard tissue healing process.

Bone Morphogenetic Proteins

Bone morphogenetic proteins are distinct from growth factors in that they can be found in extracellular bone matrix and can induce mesenchymal cell differentiation into chondroblasts or osteoblasts.[75] However, they do not have mitogenic properties.[103] Urist first identified BMPs and showed their role in inducing ectopic bone formation with DFDB.[104-106]

BMP represents a collective term that now regroups more than 15 proteins (BMP-1 through BMP-15), many of which have been purified and cloned. For example, recombinant (concentrated) human BMP-2 (rhBMP-2) and others have been produced and have been shown to induce a complete sequence of endochondral ossification in decreased time, even for large defects.[107-113] Recombinant technology permits the synthesizing of BMP-2 and BMP-7 in larger quantities. A primary advantage is that although isolating BMP from cadaveric bones yields only 0.1 mg BMP per kilogram of bone, rhBMP-2 can be readily produced for widespread use. Areas of application that are being developed for the use of recombinant human BMP include large bone grafting sites, such as the maxillary sinus,[114,115] large periodontal defects,[116-118] and the bone-implant interface.[119,120] Giannobile et al. have reported on novel delivery systems for these BMPs to enhance periodontal and oral rehabilitation.[121,122]

Recombinant BMP-7 (OP-1) has been developed in the orthopedic field for very large bone defects. Most of the literature has concentrated on long bones of endochondral origins, and dental applications appear remote.[123]

In conclusion, there are four methods to increase bone and tissue growth factors during bone augmentation:

1. The PRP collected from the patient's blood may benefit the bone formation process and/or laid on top of the graft and membrane to promote soft tissue healing.
2. The use of autologous bone in the graft site can increase PDGF, FGF, TGF-β, IGF, and BMPs, as all are stored in the bone and released during the augmentation process. The BMP in an autograft primarily has an effect to provide growth factors at 2 weeks and with a peak at 6 weeks.
3. A third method to introduce growth factors at a bone graft site is to use an allograft in the graft site.[90] The DFDB from cortical bone contains a higher percent of BMP than trabecular bone, and therefore is the material of choice. However, the amount of BMP in commercial bone bank allografts is very small (0.001 mg) and is not a very significant factor.
4. A fourth method to increase the growth factors in the graft site is by the RAP process, which triggers a release of growth factors into the site.

All four of these methods are typically used in the bone augmentation process, especially when other key elements are scarce.

Healing Time

Adequate time must be provided for the graft to resorb and regenerate new bone volume. The amount of time required is variable and depends on local factors, such as the number of remaining walls of bone, the amount of autogenous bone in the graft, and the size of the defect. Larger grafts, less autogenous bone in the graft, and fewer bony walls surrounding the site increase the amount of healing time. In addition, systemic diseases such as diabetes, hyperparathyroidism, thyrotoxicosis, osteomalacia, osteoporosis, and Paget's disease may all affect the healing response. It is usually best to err on the side of safety. As a general rule, 4 to 6 months are recommended when graft volumes are less than 5 mm in dimension. Graft volumes more than 5 mm in dimension often require up to 6 to 10 months.

Often, a premature reentry gives the impression the bone graft did not work, and alloplast materials still represent the majority of the graft. Although this may

WWW.HIGHDENT.IR

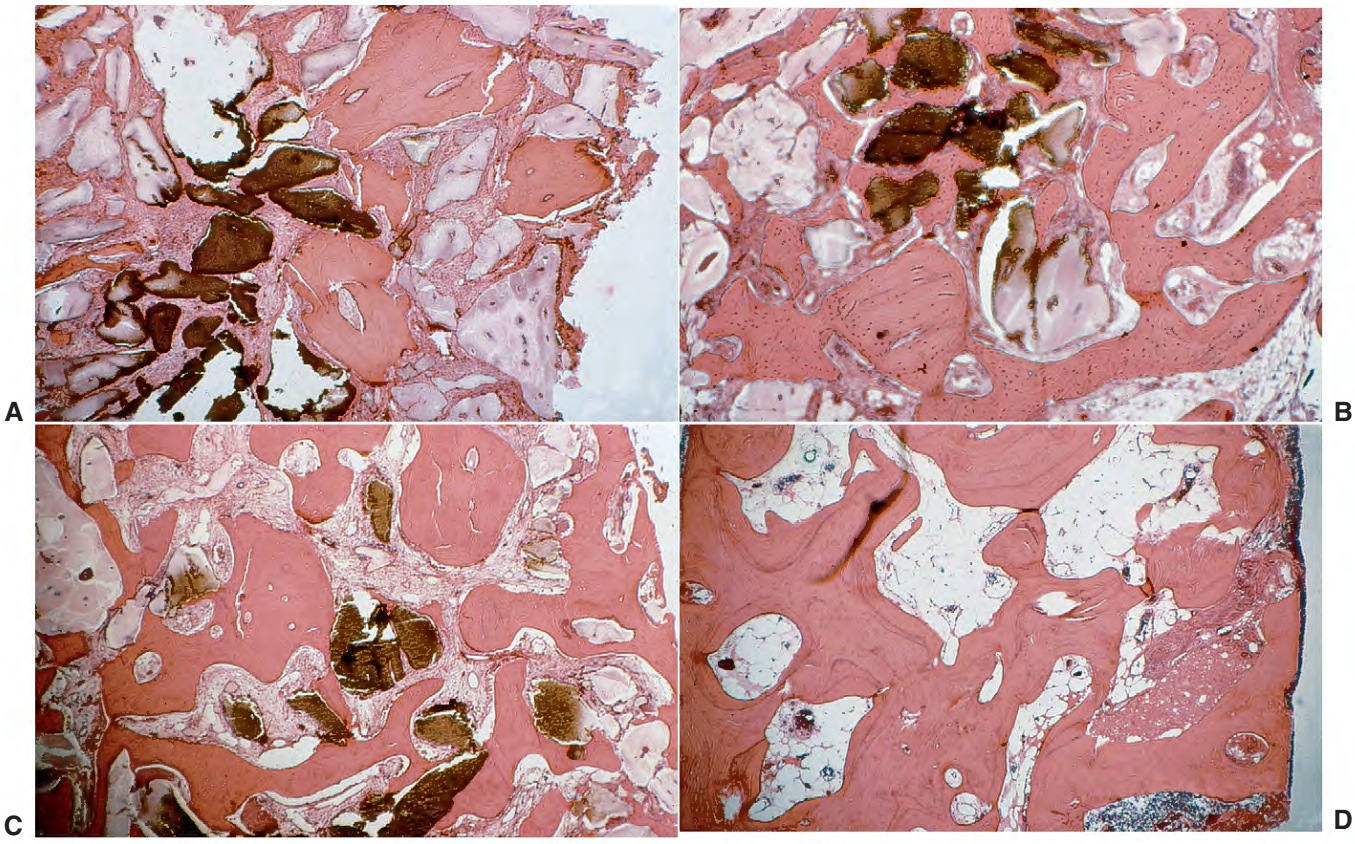

Figure 36-19 **A,** A combined autologous, demineralized freeze-dried bone (DFDB), and alloplast (bovine hydroxyapatite [HA]) graft, was placed as a sinus graft, and a biopsy was taken at 2 months. Most of the core biopsy is allograft and alloplast. **B,** Another core biopsy from the same patient after a 4-month healing period. Note most of the DFDB has been resorbed, and more vital bone is present. **C,** The same sinus graft patient had another core biopsy taken at 8 months. Almost all the DFDB and most of the bovine HA has resorbed and been replaced by vital bone. The bone is beginning to form a trabecular pattern. **D,** A core biopsy taken at 12 months in the same patient and graft site. All the sinus graft has been replaced by vital bone, and the bone structure is similar to a normal posterior maxilla. *(Courtesy S. Wallace.)*

be correct, it is not unusual that an additional healing period of several months would have allowed reentry in a successful graft site (Figure 36-19). Time frames may be shortened when additional keys to bone grafting are incorporated. As a general rule, the surgeon should provide enough keys to bone grafting to permit reentry in less than 8 months. If more than half the graft is from autogenous origin, a prolonged healing period of more than 1 year is often not beneficial and may result in bone resorption of the newly grafted site. On the other hand, some dense bovine calcium phosphate materials may require more than 2 years to be resorbed and replaced by bone.

Defect Size and Topography

The size of the defect is a factor in the healing time, the vascularization, and the transitional prosthetic options. It is also a factor for the graft material selection. The larger the bone defect in width and height, the longer the period of bone maturation before implant insertion. The larger the bone defect, the more autologous component needed in the graft. This relates to the creeping resorption and vascularization requirement for a larger graft site. The larger graft sites may require a removable restoration, as fixed transitional spans of four or more teeth are very prone to fracture and uncementation.

On the other hand, when a graft site is small, it is not unusual to insert the implant in the correct position and graft the site at the same time as implant insertion. When this is considered, the implant most often is not placed in function but is left to heal with an alloplast and primary soft tissue closure. When an implant is uncovered and a small defect is present, most often the graft site is augmented and the permucosal element or abutment is added. The implant may be restored with a transitional prosthesis out of occlusion, if it is rigidly fixated and fulfills all other requirements. The implant should not be loaded because crestal marginal stresses are greater under load. A bone graft at the crest of the ridge will not perform as predicted during the modeling/remodeling process that occurs during early bone formation.

The topography of the graft site is also a key for predictable bone augmentation, as it affects soft tissue closure, space maintenance, graft immobilization, vascularization, growth factors, BMPs, and healing time—in other words, almost every aspect of the equation. When

WWW.HIGHDENT.IR

همیار دندانسازان

the vital bone of an extraction socket is 1.5 to 2 mm thick or greater on the facial, lingual, mesial, distal, and apical regions, a 5 bony wall defect is present. This is an ideal environment for bone growth, as most all the keys are already present. The space will be maintained by the surrounding walls of bone and the graft is immobilized by the bony walls. Growth factors, BMPs, and RAP are released from the periodontal complex and walls of bone as a result of the extraction. As a result, bone grows in the site, even without initial soft tissue closure over a graft material.

On the other hand, when a bone augmentation for height and width is necessary, as for an onlay graft in a Division D bone volume host site, almost no keys are present for the augmentation. This condition represent a one-wall bony defect that needs 12 mm in height and 6 mm or greater in width and requires the surgeon to provide as many key factors as possible. In addition, the bone graft material in these unfavorable conditions must be primarily autologous cortical and trabecular bone—in other words, the number of walls of host bone and the size of the defect combine to affect almost all aspects of the bone augmentation process.

In the periodontal literature, it is well documented that a three-wall bony defect next to a tooth root can be restored more predictably than a two-wall bony defect. Likewise, a three-wall bony defect in an edentulous site can be augmented better than a two-wall defect. Most often, a three- to four-wall defect in implant dentistry corresponds with a lack of facial bone. The bone is present on the lingual, mesial, distal, and apical regions (four-wall defect), the apical region is too narrow or compromised (three-wall defect), or the bone defect is next to a tooth root (Figure 36-20). Under these conditions, soft tissue closure, space maintenance, and graft immobilization become more critical. A barrier membrane and longer healing time are often necessary. The graft material in a three- or four-wall defect does not require only an autograft as the major component, although it is of benefit. The number of bony walls remaining around the defect is a key to predictable augmentation (see Chapter 37).

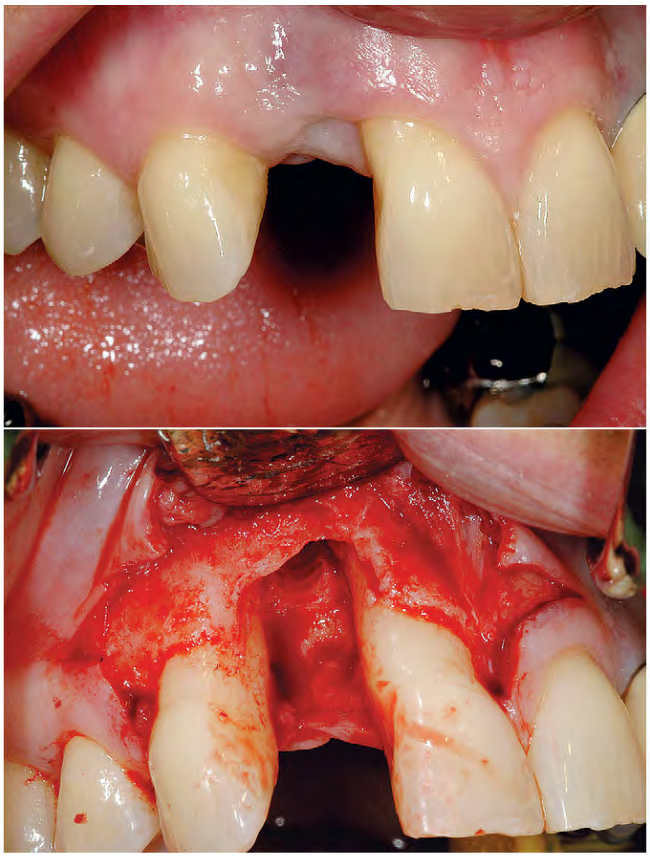

Figure 36-20 **A,** A bone defect is observed between two teeth. **B,** A bony wall is present on the palatal and apex. No bone is on the mesial, distal, or buccal. This two-wall bony defect will be difficult to cement because few keys are present.

Transitional Prostheses

The transitional prosthesis worn during the soft tissue healing and maturation of the bone is a critical component of predictable bone grafting. The transitional restoration affects the keys of soft tissue closure, the maintenance of space for the augmentation, and the immobilization of the graft during healing. In addition, the restoration often restores some esthetic and functional components for patients during the many months required for the maturation of the bone. It may also help contour the soft tissues and allow maturation before the final fabrication of the prosthesis. The value of transitional restorations should not be underestimated from either a patient management or a predictable outcome perspective.

Whenever possible, a fixed restoration that does not rely on soft tissue support in the area of the bone graft is preferred. There are several options to accomplish this goal. When natural teeth are in position around the graft site and require restoration, a transitional acrylic fixed partial denture may use the natural abutments and pontics span the site of the augmentation (Figure 36-21). Whenever the pontic span is greater than two teeth, consideration is given to metal reinforcement, as the risk of fracture exponentially increases. Other options include increasing the bulk of acrylic (twice the thickness decreases fracture risk by half) and eliminating occlusal forces over the pontics.

When natural teeth are present adjacent to the augmented sites but do not require restoration, a resin-bonded prosthesis may be fabricated. These are designed gingival to the occlusal contacts, so the teeth do not require preparation. However, this increases the risk of debonding, so a secondary removable device may be delivered and used as an emergency until the patient is able to return to the office for rebonding of the restoration. These resin-bonded prostheses should use

WWW.HIGHDENT.IR

Figure 36-21 **A,** A provisional prosthesis with a pontic was used to restore the missing tooth over the grafted site to provide an undisturbed healing environment. **B,** A fixed transitional prosthesis is the best treatment option during graft maturation.

acrylic denture teeth so that they may be modified (add or subtract) at the time of surgery and during the healing process.

When natural teeth are not present adjacent to the bone graft site, a fixed temporary may be fabricated on a small diameter and temporary implants placed in the lingual plate or in sites away from the bone graft. These implants are often inserted at the same time as the bone graft and immediately restored with an acrylic, fixed, transitional prosthesis. These restorations should be out of occlusion in partially edentulous patients and have no posterior cantilevers out of the esthetic zone in completely edentulous patients (Figure 36-22).

The transitional implants should engage as much cortical bone as possible and therefore are usually longer than implants with a delayed loading protocol. At the reentry and final implant placement, the transitional implants are often removed. At this point, the final implants may be immediately loaded to support a modified transitional restoration, or a removable prosthesis may be fabricated. The risk of micromovement on the soft tissue over the graft site is less, as the graft has already matured 4 to 8 months before the implant placement. There is a higher risk of implant failure with transitional implants, which, as a consequence, may cause loss of graft volume. Therefore other transitional methods, when possible, are suggested.

A removable restoration may be fabricated over the bone graft but should be designed to not load the soft tissue over the graft site. When teeth are present, a cast metal framework with direct and indirect retainers and rest seats may be fabricated. Before the removable partial denture framework design, a stone cast of the patient's mouth is augmented with clay or wax in the laboratory in the sites of the future bone graft. In addition, the framework does not have metal mesh over the bone graft site. Otherwise, the surgeon most often must remove the chrome cobalt mesh, as the laboratory often does not provide enough relief between the augmented site and the metal framework (Figure 36-23).

- Xenografts (osteoconduction)

BONE GRAFT MATERIALS

In addition to the keys needed to develop a predictable bone augmentation site, there are materials necessary to augment the location. Bone graft materials and their mechanism of action are not all the same. The materials most often used in implant dentistry to aid in bone augmentation include: (1) collagen, (2) human DFDB, (3) human freeze-dried allograft (FDB), (4) xenograft bone, and (5) autogenous bone (Box 36-3).

Collagen

Several types of collagen are found in the human body. Type I collagen is among the first products synthesized by the body when bone formation occurs.[124,125] The irregular pattern of initial bone formation (woven bone) is a result of the rapid, unorganized response of the body to lay down collagen, which is then invaded and mineralized with HA along the direction of the collagen fibers by osteoblasts. The haphazard organization of collagen results in unorganized bone formation, called *woven bone*, which forms first and at a faster rate and is less strong. The most common source of collagen in implant dentistry is bovine collagen from the "Achilles" tendons in the leg. Another source of type I collagen is DFDB, which can provide the space necessary for blood vessel ingrowth into the graft and may contribute to the bone formation process. However, DFDB alone has not proven an effective graft material and should

be combined with other categories of bone-grafting materials.

Collagen also is an integral part of the soft tissues with chemotactic and hemostatic properties. It can bond and activate platelets to form a platelet plug within the vessel. It may also act as a scaffold for migrating cells of the epithelium. In the application of bone regeneration, collagen may be used at the level of the soft tissue to accelerate healing over an extraction site or to promote coagulation of a bleeding surgical site.

Over the last decades, several collagen barrier membranes have been introduced for guided bone regeneration. Processed bovine type I collagen membranes (from tendons and dermis) have yielded favorable results to decrease the invasion rate of epithelial cells or fibroblasts into a graft site. Resorption rates of collagen

WWW.HIGHDENT.IR

barrier membranes are variable, with ranges from a few months to 1 year, and are often intended to be maintained for the whole bone regeneration cycle.

Autologous Bone and Osteogenesis

An important key for predictable bone augmentation is the presence of autogenous bone as a component of the graft. Autogenous bone is the only graft material that directly forms bone from transplanted trabecular bone cells. The autogenous graft also contributes to bone growth with several growth factors (e.g., BMPs) that are released into the environment during incorporation of the graft and form bone through induction. The autograft, which becomes nonviable bone, acts as an osteoconductive matrix of calcium phosphate for bone growth by creeping substitution (Figure 36-24). The space requirements of grafting may also be fulfilled by the autogenous bone because its physical volume maintains the contours of the desired augmentation. The growth factors also help the soft tissue healing on the outside and accelerate blood vessel growth into the graft site of the host bone on the inside of the graft.

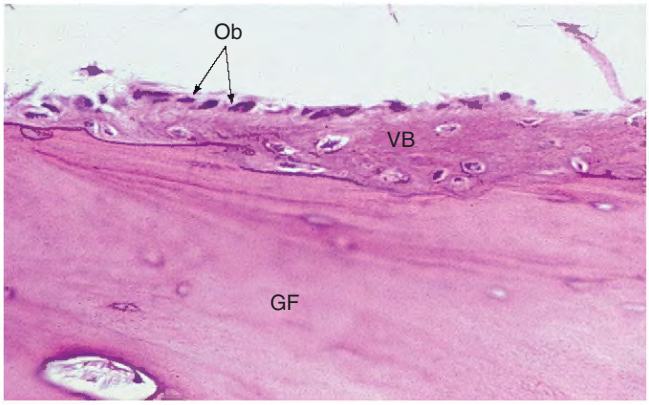

Figure 36-24 A bone biopsy of an iliac crest bone graft after 6 months of healing. Most of the autograft is devital. Bone is growing into the graft around the newly formed blood vessel. As the bone graft resorbs, it is replaced by new, vital bone (creeping substitution). *Ob,* Osteoblasts; *VB,* vital bone; *GF,* graft (autograft).

Osteogenesis

Osteogenesis refers to the growth of bone from viable cells transferred within the graft. Autogenous bone is the only graft material available with osteogenic properties. There are more osteoblasts in trabecular bone than cortical bone. New bone may be regenerated from endosteal osteoblasts and marrow stem cells transferred with the graft. This is not to say cortical bone is not an effective graft material. In fact, the author has observed that the cortical bone grafts from the mandibular ramus and symphysis and the cortical bone grafts from the iliac crest form more volume of bone than trabecular bone grafts from these regions. Apparently, cortical bone, although less rich in osteoblasts, has great osteoconductive properties and bone growth factors.

For the transplanted autogenous bone graft to produce osteoid, it must remain vital. Vitality of the graft may be improved in several ways. The recipient site is prepared first so that minimal time elapses between graft harvest and placement. It is then placed into an environment that provides for prompt angiogenesis to maintain its viability, rather than mixed with other synthetic graft materials, which impair blood vessels to reach the autogenous bone graft (Figure 36-25). As a result, the optimal place for the autologous graft is directly on the host bone after the cortical bone of the host site has been decorticated with a surgical bur (Figure 36-26).

Once harvested, the autologous graft should be used immediately (which is preferable) or stored in sterile saline, lactated Ringer's solution, or D_5W to maintain cell vitality. Distilled water is contraindicated as a storage media, as the hypotonicity results in cell lysis. Storing bone grafts in blood is also detrimental to cellular

Figure 36-25 The harvested autograft should not be mixed with other alloplasts or allografts, but should be placed on bone for early vascularization to minimize autograft cell death.

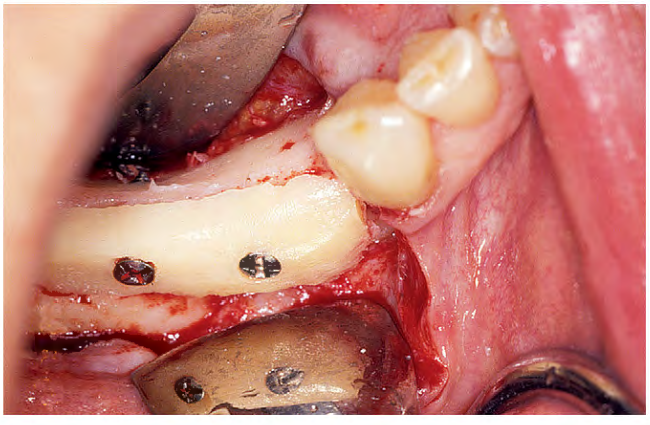

Figure 36-26 An autograft should be laid directly on top of the host bone. This releases growth factors, including those required for early vascularization, which is needed to maintain the vitality of the bone graft.

WWW.HIGHDENT.IR

همیار دندانسازان

survival, as red blood cells release several cytotoxic products once the cells lyse.[98] Because the autogenous graft material may require an additional operative site, it is usually selected when conditions for growth of bone are less ideal or in combination with other allografts or alloplasts.

The mechanism of bone growth within autogenous bone grafts includes three phases. Some transplanted osteoblastic cells survive the first 3 or 4 days through nutrition from the surrounding vascular tissue. The osteoblasts and stem cells at the surface of the bone graft from either trabecular or cortical bone that survive the transplantation process are responsible for proliferation and formation of new osteoid product.[126] This osteogenic process, referred to as *phase I bone*,[127] is related to the number of cells transplanted and initially dictates the amount of new bone that will directly form beyond the original dimension. Most of the osteocytes within the mineralized cancellous bone die because they cannot directly access nutrients (Box 36-4).

Blood vessels can grow into a graft site with almost the same speed as fibrous tissue, at approximately 1 mm per day. The graft success, therefore, depends on early vascularization.[128] In the hypoxic environment of the recipient bed and graft, macrophages secrete macrophage angiogenesis factor (MDAF) and macrophage-derived growth factors (MDGF). Platelet degranulation releases PDGF, which also initiates angiogenesis.[127] This process is directly proportional to the density of cells transplanted.[129] Therefore, to increase the transplanted cell volume when trabecular bone is harvested, the overall volume of the graft is packed into a syringe and compressed to provide as many bone cells per area as possible.[130]

The fresh autogenous trabecular bone that provides the survival of the maximum number of transplanted bone and undifferentiated cells for large grafts is usually harvested from the ilium. However, only osteoblasts within 300 microns of the blood supply within the first 1 to 2 weeks will survive, whereas all others die before adequate nutrition can reach them by diffusion.[127] Because blood vessels may grow 1 mm per day, only the autologous graft less than 7 to 10 mm thick will survive the transplantation.

Box 36-4 Autogenous Bone

Bone Blood Supply

Phase I: Osteogenesis—bone regeneration
Surviving cells 4 weeks (osteoid)
Phase II: Osteoinduction
BMP release 2 weeks to 6 months; peak at 6 weeks
Phase III: Osteoconduction
Inorganic matrix–space filler
Phase IV: Cortical plate, barrier membrane

BMP, Bone morphogenetic protein.

In the 3 to 7 days after bone grafting, stem cells and endosteal osteoblasts produce only a small amount of osteoid. Production increases as soon as oxygen and nutrients can be brought by the newly developed bloodstream. Therefore, initially, primary osteoid develops between the trabecular bone. New bone consolidation also occurs during this phase, which produces an unorganized woven bone.

Demineralized Freeze-Dried Bone and Osteoinduction

Osteoinduction involves new bone formation from osteoprogenitor cells derived from primitive mesenchymal cells under the influence of one or more inducing agents that emanate from the bone matrix.[131-133] When an osteoinductive material is placed subcutaneously in the absence of bone or within a muscle, it has been shown to induce bone formation in the ectopic site. Landmark work in this particular class of bone graft materials has been performed over the years by Urist et al. to identify the osteoinductive factors and their mode of action.[104,134-136]

The first phase of the bone formation process (osteogenesis) diminishes within 4 weeks. As the transplanted bone cells die, osteoclasts from the host tissue precede the invading blood vessels and remodel the graft by resorption. Inductive proteins and growth factors are then released from the transplanted bone and initiate the phase-II osteoinductive process. Stem cells in the graft and BMPs mostly from cortical bone also contribute to osteoblast differentiation and new bone formation and result in phase II bone, which is less cellular, more mineralized, and organized. This phase begins after approximately 6 weeks and lasts as long as 6 months.

The most commonly used osteoinductive materials for bone augmentation in implant dentistry are bone autografts and allografts. A bone allograft is an osseous, transplanted tissue from the same species as the recipient but of different genotype. Therefore, when performing grafts on humans, cadaver bone must be used. However, when using allograft for animal studies on dogs, dog bone must be processed. The main advantage of allografts is that they eliminate the need for a donor site. In addition, their unlimited availability permits their use in large quantities if necessary. However, larger grafts most often require other material to make the bone augmentation predictable. Osteoinductive materials are more contributory to bone formation during the remodeling process.[134] The tissue is processed and then stored in various shapes and sizes in bone banks for future use.[137] There are primarily three types of bone allografts: frozen, freeze-dried, and demineralized freeze-dried.

Frozen bone is often harvested, frozen, and stored for use on the same patient at a later date. It may also

WWW.HIGHDENT.IR

be irradiated to decrease the immune reaction when used for a different recipient. Allograft frozen bone is rarely used in implant dentistry because of the risks of rejection and disease transmission. It has often been used in biomechanical analyses to determine the physical properties of bone found in the jaws.

The most common allografts used in implant dentistry are DFDB and FDB. The process to form FDB and demineralized DFDB is different and specific, although some variations among laboratories exist.[136] In both allografts, cortical and trabecular bone is harvested in a sterile fashion from a disease-free donor. The bone is then washed in distilled water and ground to a particle size of 500 µm to 5 mm. It is then immersed in 100% ethanol to remove fat, frozen in nitrogen, then freeze-dried and ground to smaller particles (250 to 1500 µm), which has been shown to promote osteogenesis.[136] The desiccating step allows for long-term storage and decreases antigenicity. This bone process results with FDB. Solvent-preserved products have been developed instead of freeze drying to reduce antigenicity and still assure a minimal risk of contamination.[128-140] The inorganic and organic matrix is therefore maintained because the calcium and phosphate salts of HA remain.

The organic material in bone, which includes bone morphogenetic proteins, is found within the structure of the HA. However, osteoclasts are required to resorb the bone to release its bone growth factors. This delays the release over a longer period. Coupled with the fact that very little growth factors are present, this results in a graft material that is primarily an inorganic mineral source of HA, which serves as scaffold for bone formation. Therefore FDB acts primarily through an osteoconductive process, because inductive proteins are slowly released after resorption of the mineral and often found in only minute quantities (Table 36-1).

DFDB and FDB have a similar initial processing step, but DFDB is produced by an additional step, demineralizing the ground bone powder in 0.6-N hydrochloric or nitric acid for 6 to 16 hours. The BMP is not acid soluble, but the calcium and phosphate salts of HA are acid soluble and therefore are removed from the bone in the acid-reducing process. As a result, the demineralization of the freeze-dried bone more readily exposes the BMPs.[141,142]

Completely demineralized grafts have been shown to stimulate more bone induction than partially demineralized material.[143] Because the mineral salts are removed from the bone, the nonsoluble BMPs are available in the local environment earlier than with freeze-dried bone, which requires their release by osteoclastic activity. As a result, more undifferentiated cells may transform earlier into osteoblasts.[144,145]

Therefore FDB is primarily osteoconductive and DFDB is not osteoconductive (as it has no mineral) but is believed to be more osteoinductive.

After washing and dehydration of the DFDB after the acid bath, it is often either irradiated or sterilized in ethylene oxide (EO) to further decrease the antigenicity and to protect the host from disease transmission. The use of irradiation is controversial, and it is generally agreed that doses greater than 2.5 Mrad of irradiation are destructive to the BMPs and, therefore, to bone formation.[146] EO is also controversial, and it is recommended to limit it to a 5-hour EO sterilization process at 29° C to maintain osteoinductive properties.[147]

Several tests are performed to evaluate the safety of the allograft and to ensure that the acid demineralization process destroys all pathogens.[148-150] The probability that a particular graft of DFDB might contain human immunodeficiency virus has been calculated to be 1 in 2.8 billion,[151,152] and to the author's knowledge, no occurrence has been reported in the literature. Because some reports suggested that a dose of irradiation or EO sufficient to kill spores may render the BMP in the allograft unable to induce bone formation, it may be beneficial to use DFDB bone that is harvested from soft tissue donors with no history of disease transmission and no preparation history of radiation or EO.[148] Results of studies using DFDB for bone regeneration are conflicting. Several reports conclude that DFDB exhibits osteopromotive properties, whereas others question such benefits.[34,35,153-158] In particular, some reports raise the question of variability of BMP concentration and activity in commercially available allografts, and therefore

Table 36-1 Allografts

MATERIAL	COMMERCIAL SOURCE	COMPOSITION	BONE GROWTH METHOD	RESORPTION TIME/%

WWW.HIGHDENT.IR

همیار دندانسازان

qualify them as less predictable.[139,159] Product fabrication and formulation are critical in ensuring the quality and osteoinductive properties of the product.[160-164] The osteoinductive properties of DFDB are variable from one cadaver source to another. As a general rule, the younger the cadaver, the more BMPs available in the bone.[165] The demineralized cortical bone mineral contains a higher concentration of BMPs than trabecular bone and is recommended. In addition, membranous cortical bone exhibits greater concentrations of BMP than endochondral cortical bone, so the skull represents a better source of inductive proteins than the rest of the skeleton.

Some studies that substantiate the osteoinductive capacity of DFDB have been performed with materials enriched with rhBMP-2. These studies may have as much as 500 to 1200 mg of BMP compared with 0.001 mg found in a 5-g vial of DFDB from a bone bank; therefore the results may not be reproducible in clinical practice.[108,166,167] This explains some of the wide variability of the results discussed in the literature related to DFDB.

The particle size of DFDB may also affect its efficacy. Sizes smaller than 150 µm are less effective than those of 250 µm or larger. Fibers of cortical bone (e.g., Grafton) are more effective than particles. When a bone matrix fiber forms new bone, the osteoid material creeps along the length of the fiber. When a particle forms new bone, it appears localized to the particular spot (Figure 36-27). On a histologic slide, 1 DFDB particle out of 10 to 20 appears to form new bone, whereas more fibers appear to participate more often in the inductive process and act as a wick to promote bone formation along the entire length of the cortical fiber. More recently, putty consistency products have been introduced that facilitate delivery and use of the material intraorally. The fillers used to create the putty do not participate in the bone formation process and serve only to make the product more user friendly. The bone fibers in this preparation provide a scaffold for new bone growth and have been shown to be more inductive than particle forms of the DFDB.

Calcium Phosphate Minerals and Osteoconduction

It is postulated that the inorganic matrix of HA, which forms a scaffold in the autogenous graft, contributes the osteoconductive effect of bone formation as new bone forms by creeping substitution. This may be considered a third phase of bone formation by autogenous bone[48] (see Box 36-4).

Osteoconduction, which characterizes bone growth by resorption or apposition from the surrounding bone, has been called *creeping substitution*. Therefore this process must occur in the presence of bone or differentiated mesenchymal cells. Osteoconductive materials do not grow bone when placed into subcutaneous tissues, muscles, or fibrous tissue. Instead, the material remains relatively unchanged or resorbs. Osteoconductive materials are biocompatible, and bone or soft tissue can grow adjacent to them by apposition without evidence of a toxic reaction. The most common osteoconductive bone grafting materials used in implant dentistry are allografts, alloplasts, and xenografts. Allografts such as FDB already have been addressed. Recently, allografts that maintain the inorganic portion of bone (versus the organic components, such as in DFDB) have gained acceptance as the osteoconductive portion of the graft. Alloplastic materials are exclusively synthetic, biocompatible products developed to cover a broad range of indications. They come in a great variety of textures,

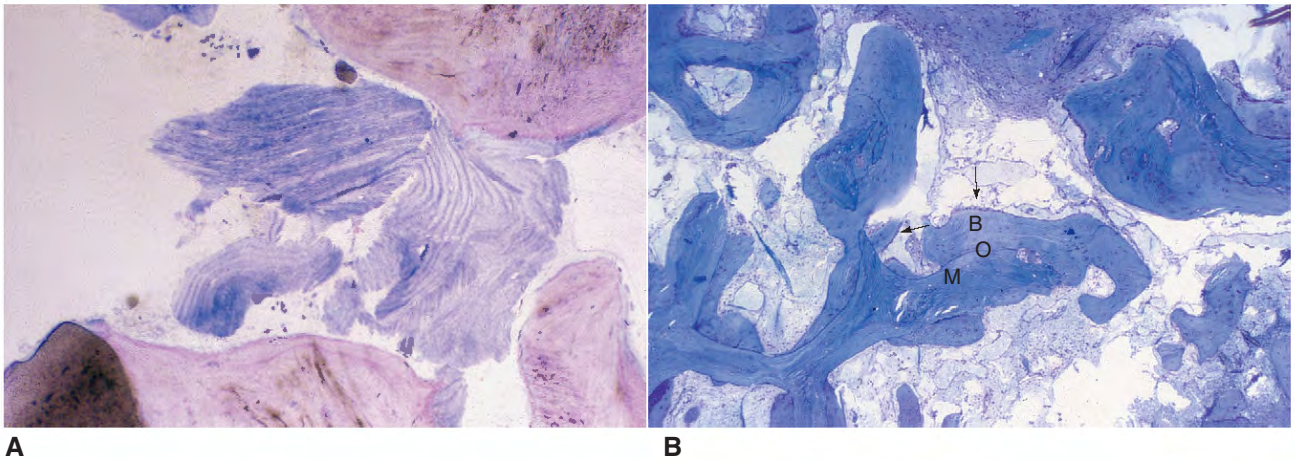

Figure 36-27 **A,** A particle of demineralized freeze-dried bone (DFDB) may be inductive and contribute to the bone graft. However, it has been observed by the author that very few particles participate in the inductive process, and marginal new bone formation next to a particle is observed. **B,** A cortical fiber of DFDB (Grafton) in a histologic section after a similar time frame elicits greater bone formation, more fibers participate in the inductive process, and greater new bone contact is observed along the length of the fiber. *B,* New bone formation; *O,* initial bone formed by induction; *M,* matrix of DFDB fiber (Grafton).

particle sizes, and shapes (Table 36-2). They may be separated into ceramics, polymers, and composites. The most frequently used are ceramics, which may be characterized as bioinert (e.g., aluminum oxide and titanium oxide) or bioactive (e.g., calcium phosphate). Bioinert ceramics exhibit direct bonding with the host bone (at the light microscopic level) and are mechanically held in contact to the bone. The healing of bone around a bioinert osteointegrated implant is an osteoconductive process, which follows typical phases of remodeling at the bone-implant interface.

Bioactive ceramics are the largest family of alloplasts used for bone augmentation and include calcium phosphate products such as synthetic HA and bovine-derived anorganic bone matrix, tricalcium phosphates, and calcium carbonates. Calcium phosphate materials display a complete lack of toxicity. Their ability to act as a substrate for bone growth makes them a popular material for osteoconductive properties, but they are not osteogenic or osteoinductive.[168]

Xenografts are fabricated from the inorganic portion of bone from animals other than humans and are also osteoconductive. Xenograft bone is reported as a good bone bank material, provided it is completely deproteinated and placed in a bed of bleeding trabecular bone or used with autologous red marrow.[169] It may also be used to augment soft tissue. Proponents of xenografts believe that the nonorganic bone of the animal most resembles the natural human bone mineral.

Osteoconductive materials for hard tissue maintenance or augmentation may be characterized as nonresorbable or resorbable, dense or porous, or crystalline or amorphous materials. Dense HA has become a popular bone substitute when living bone is not a requirement for the augmentation. This material has been described as nonresorbable when it is a highly dense crystalline structure.[170,171] In the presence of bone, a direct bone-HA interface may be observed.[170] This finding is more common when dense HA is placed within the bone and fibrous tissue is not in direct contact during healing.

WWW.HIGHDENT.IR

همیار دندانسازان

Fibrous tissue proliferates at a rate of 0.5 to 1 mm daily, compared with bone that forms much slower (approximately 50 µm per day). Thus the soft tissue has the capacity to reach and encapsulate the HA when it is placed on top of cortical bone. The contacting layer of HA may develop a bony interface, but the majority of material is surrounded by fibrous tissue.[173] The purpose of this type of augmentation is to serve as a denture support region or tissue augmentation to improve soft tissue contours around implants or teeth. When the material is placed into a bone preparation, tooth socket, or other cavity, such as the maxillary sinus, or covered with a barrier membrane (which prevents fibrous tissue from reaching the HA), the tissue developing at the interface is more likely to be bone. However, the material does not resorb to allow creeping substitution and new bone to replace the HA.

Dense HA is inorganic and, as such, cannot grow or integrate to an implant surface. It is also three times harder than cortical bone and is more similar to dentine than bone. Therefore when placed into bone, its primary purpose is to obtund a space and maintain bone contour and volume. If an endosteal implant is planned in the bone-dense HA region, a diamond and high-speed hand piece may be required to prepare the HA. Therefore this material is not recommended for placement into sockets that may receive dental implants in the future. A more common use for dense HA is its placement on the facial or crestal aspect of a ridge around implants to improve the soft tissue contour, or as a ridge augmentation material for denture support.[174] Its use was more widespread a few years ago when fewer bone augmentation products were available.

Highly crystalline HA is more resistant to cellular breakdown than the amorphous form. The crystalline structures of available graft materials present differences based on the origin of the product. It is felt that small crystals, such as observed in normal bone, are desirable. The different treatment (chemical or heat) results in different crystal sizes. It is argued that heat treatment (in excess of 1000° C) results in crystal growth, which does not change the basic structure but may cause altered surface characteristics. In vivo implantation studies in animals suggest that the resorption rate is somewhat proportional to the tricalcium phosphate (TCP) content of the material.[175,176] Therefore all HA may resorb, depending on the surrounding pH, porosity, particle size, volume, and crystallinity.

More porous or amorphous forms of calcium phosphate ceramics are osteoconductive materials, which are resorbable when placed into bone or soft tissue, and are replaced by a process similar to "creeping substitution" found in natural bone remodeling.[177,178] As the field of oral implantology grows, this category of products has been greatly expanded to assist in preservation of the alveolar ridge anatomy after tooth loss and before or in conjunction with implant placement. These materials are usually made of HA, beta-tricalcium phosphate (βTCP), the inorganic portions of a xenograft bone, or various combinations. This category of bone graft produces also includes human cadaver bone that has been freeze dried, but not demineralized (FDB).

Resorption primarily occurs through two different mechanisms: solution and cell mediated. Solution-mediated resorption of a material is a consequence of the pH of the surrounding media. As the pH decreases, mineralized materials such as HA dissolve. It should be noted that HA resorbs at these low pH levels at a similar rapid rate whether calcium phosphate, porous HA, or formulations of dense HA.[172] Solution-mediated resorption occurs too quickly to maintain a space and participate in bone formation. Therefore this category of resorption is to be avoided in most all augmentation sites.

In cell-mediated resorption, cells surrounding the grafted material resorb the material by phagocytosis and then intracellular degradation.[179,180] Osteoclasts and osteoblasts also have been shown to participate in this activity. It is suggested that cell-mediated resorption leads to the activation of protein kinase C, endocytosis, and intracellular dissolution of calcium phosphate materials, which then increases the intracellular calcium concentration, which in turn activates a "calcium-dependent pathway" leading to a mitogenic response.[180]

The resorption rate of calcium phosphates by cellular activity is affected by the particle size, volume of material porosity, and composition of the material. Larger particles require a longer time to resorb, if all other things are equal. For example, a 250-µm particle (a common size of bone substitutes) resorbs faster than a 750-µm particle. Resorption is also related to the volume of material implanted. Larger-size defects filled with HA take longer to be replaced by bone than smaller defects, with all other factors being equal.

The porosity of the material has a primary effect on the resorption time. Dense HA particles exhibit little to no porosity. A macroporous HA exhibits a larger, usually visible porous architecture with 15% holes or more by volume.[181] This type of topography may be produced by a hydrothermal exchange reaction with $CaCO_3$, found in the natural particles of the coral reef. A microporous HA (usually obtained from the inorganic portion of bone of xenografts or freeze-dried cadaver bone) exhibits in excess of 30% holes by volume with cortical bone and up to 70% pores when trabecular bone is used, thus leaving a large intraparticle volume of grafted area available for the regeneration of bone. Microporous HA will resorb by cellular activity faster than macroporous HA, and dense HA is the slowest to resorb, if all other factors are similar.

The tissue where the graft material is inserted also affects the cellular resorption rate. The rib has a cellular turnover rate of 2% per year; long bone, a 10% cellular turnover rate; and bone in the jaws, a turnover rate of 40% or more per year. The resorption process will be fastest in the jaws and slowest for a rib. The dense,

WWW.HIGHDENT.IR

crystalline HA particles may last a lifetime when large in size or volume and under stable pH conditions and in a slow turnover rate system. Amorphous forms of HA may resorb in several months when in small volumes and size and in a fast turnover rate region. Microporous materials are intermediate in resorption times but may require more than 1 year when in larger volumes, such as sinus grafts.

A synthetic 15 residue peptide (P-15) related to a biologically active domain of type I collagen has been identified. Reports suggest that P-15–coated anorganic bovine bone mineral may act as a matrix for bone repair.[182-184]

Prolific literature supporting the use of one alloplast versus another is available in the field of dentistry.[185-194] This may be confusing at times when selecting a specific product. An organized approach should consider the following elements:

- Does the product need to resorb and serve as a scaffold for new formation, or does it need to simply preserve the anatomy?
- If the product needs to resorb for bone growth, what time frame is appropriate for the type of procedure?

Short healing periods need a more readily resorbable product, which therefore should be more porous to facilitate cell-mediated resorption. However, if too easily removed by the recipient site, it may not maintain sufficient space to allow adequate bone formation. In contrast, a more crystalline, less porous product will maintain the space longer but will also take longer to disappear and form bone. Therefore, the choice of product should not necessarily always be from one family or another but is based on the application and the macromolecular and biochemical profile of the product.

Bioactive glass and bioinert ceramics can essentially be grouped with dense crystalline HA because their structure renders them practically unresorbable. Their use is limited to ridge maintenance in areas where no bone growth is needed (e.g., pontics, ridges under a denture).

Partially or slowly resorbable materials may be mixed with readily resorbable materials. In this way, the materials that resorb slowly maintain the space while the body invades the easily resorbed material. An example is in the sinus or membrane grafts with the layered approach of autograft in the host bone, DFDB (30%) and FDB (70%) in the middle layer, and a barrier membrane as a top layer. The material resorbs totally to allow the body to regenerate the whole grafted space, even though this may take years to accomplish.

Natural Barrier Membranes

A thick cortical plate on the graft may act similar to a barrier membrane in guided bone regeneration and prevent the infiltration of epithelium and connective tissue into the graft site. Misch has called this *phase IV* of bone grafting, which allows the cortical block to obtain large volumes of bone, even when the surface of the block has soft tissue covering the site. Autogenous bone is still the gold standard in grafting materials because it may form bone in all four mechanisms (osteogenesis, osteoinduction, osteoconduction, and barrier membrane) and is often readily available.

SUMMARY

The 11 keys of bone grafting are the necessary ingredients to predictable bone augmentation. Because bone modeling is more difficult than remodeling, more keys are required. Bone graft materials help provide several of these keys but are not the entire picture. Instead, the materials and keys are blended for an optimum result. A layered approach to bone augmentation has been developed by Misch. The first layer is the host bone, which has an absence of infection and a surgical RAP before the placement of the bone graft. The defect size and topography is a factor for subsequent consideration. An autograft is placed on the host bone and is immobilized with tent or fixation screws. The autograft and RAP encourage host bone blood vessels to grow into the graft site. Many host growth factors are presented to the graft site as a consequence. The next layer is a mixture of DFDB (30%) and mineralized bone (70%), mixed with PRP. This provides induction, growth factors, and longer space maintenance. A collagen barrier membrane (or cortical bone block) is the next layer, covered with PRP, PPP, or both. Soft tissue closure without tension on the incision line is the next consideration.

A transitional prosthesis, off the soft tissue, is the next step in the process. The last consideration is the undisturbed healing time. When in doubt, "wait longer" is a most important consideration for a successful graft. As a consequence, as many keys and bone graft materials are incorporated into the process as possible, all of which increase the predictable nature of the bone augmentation process.

Chapter 37

Tooth Extraction, Socket Grafting, and Barrier Membrane Bone Regeneration

Carl E. Misch, Jon B. Suzuki

Two fundamental concepts determine the position of an individual implant within a treatment plan: biomechanics and esthetics. Both of these concepts require adequate bone volume to accomplish their goals. Biomechanics requires key implant positions as the canine and first molar sites. When available bone is not present in those locations, bone augmentation is required. When the goal is an FP-1 restoration with ideal crown contour and soft tissue drape, abundant bone is necessary. If the available bone is inadequate, bone augmentation is indicated. Both factors of biomechanics and esthetics often require ideal available bone volumes.

The primary goal of this chapter is to present clinical guidelines to achieve adequate to ideal bone volumes for implant insertion. The process begins with the extraction of a hopeless tooth and socket grafting and continues to the use of barrier membrane (BM) guided bone regeneration (GBR).

ATRAUMATIC TOOTH EXTRACTION

At some point in time, the dental practitioner may decide to remove a natural tooth. Hopeless or unrestorable teeth may be related to periodontal, endodontic, prosthetic, or orthodontic failures. The concept of "treat or extract" was addressed in preprosthetic considerations in a previous chapter. Once the extraction of a natural tooth is indicated, methods to maintain or obtain the surrounding hard and soft tissues are indicated.

Over the last decade, interest has increased in atraumatic tooth extractions and socket grafting to maintain bone for implant insertion. Before extraction, exudates should not be present. Antibiotics, prophylaxis, scaling, and root planing may all be necessary before the extraction/grafting appointment.

The process of atraumatic tooth extraction and maintenance (or augmenting) of soft and hard tissues begins with the soft tissue. The cells of the inner layer of the periosteum are responsible for bone remodeling. Whenever the periosteum is reflected, the cells are injured and need to regenerate before the remodeling process begins. The cortical bone receives more than 80% of its arterial blood supply and faciliates 100% of its venous blood return through the periosteum.[1] When the bone volume is ideal, the periosteum should not be reflected. However, the periosteum also limits the volume of bone formation. When the periosteum is separated from the bone graft by a barrier membrane, more volume of bone is regenerated. The periosteum helps bone remodeling or bone repair, but it limits bone modeling and regeneration.

The soft tissue drape around the teeth is also affected by the reflection of the periosteum and often shrinks to adapt to the residual ridge form. In fact, the soft tissue is more labile to the trauma and reflection of the tissues than the hard tissues. Therefore the sulcular and surrounding soft tissue should remain undisturbed during tooth extraction to prevent further dimensional loss.

The extraction of a natural tooth begins with an incision within the sulcus, preferably with a thin scalpel blade rather than a blunt periotome, 360 degrees around the tooth, to cut the connective tissue attachment fibers above the bone (Figure 37-1). There are 13 different connective tissue fiber groups around a tooth, of which six directly insert into the cementum of the tooth above the bone. If these fibers are not cut before the extraction, trauma to the soft tissue is imminent; soft tissue tearing may occur as well. The tip of the interdental papilla is avascular and should not be incised when possible. The soft tissue should not be reflected, as soft tissue retraction and shrinkage during initial healing is more evident, especially in the interdental papilla region.

The next step in an atraumatic extraction process is to observe the crown and root anatomy, especially in multirooted teeth. When a tooth is extracted next

WWW.HIGHDENT.IR

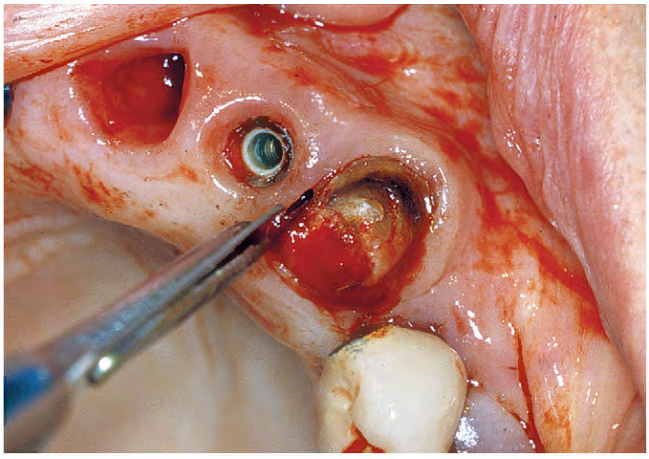

Figure 37-1 The extraction of the tooth begins with a scalpel to incise the sulcular connective tissue fibers above the bone, which are attached to the cementum of the tooth.

Figure 37-2 **A,** The maxillary lateral incisor requires extraction. The pathway of removal may restrict the extraction or chip an adjacent tooth. **B,** The distal portion of the lateral incisor was reduced to allow the tooth to move distal, which allows pressure to the periodontal ligament and bone. In addition, there is less risk of adjacent tooth damage.

to adjacent teeth, the pathway of removal is often obstructed by the position of the adjacent tooth. If the tooth to be extracted is not reduced (especially mesial and distal), instruments may chip the enamel (or restoration) of the adjacent tooth and may cause the extraction of the tooth to take an altered pathway of removal, which is more likely to fracture the roots,

Figure 37-3 **A,** The left central incisor with replacement resorption requires extraction. The single tooth root is reduced mesiodistal and separated in two. **B,** The separated central permits the unresorbed tooth root to be displaced to the mesial when the osteotome is inserted into the distal periodontal ligament space.

bone, or both (Figure 37-2). If the roots of the tooth to be extracted are divergent, they should be sectioned and removed as individual units, rather than risking fracture of the roots or surrounding bone (Figure 37-3). When the roots are fractured, there is an increased risk of bone fracture/removal to retrieve them. If bone removal around the tooth is necessary (because the tooth is fractured or decayed to the bony crest), it ideally should be at the expense of the lingual alveolus, not the more labial bone.

Biomechanic concepts have been used to extract teeth for thousands of years and date back to the days of Aristotle (384-322 BC),[2] who described the mechanics of the extraction forceps, including the advantages of "two levers acting in contrary sense having a single fulcrum." This was 100 years before Archimedes reported on the principles of the lever.

Pierre Fauchard (1690-1761) is credited with being the pioneer of scientific dentistry and gave specific instructions for extracting teeth using a dental elevator, a "pelican," or pincers (forceps).[2,3] He describes loosening the tooth with an elevator, then using the claw of the "pelican" (invented by Chauliac in the fourteenth century).[4] The pelican handle was positioned both on

WWW.HIGHDENT.IR

همیار دندانسازان

the tooth and on the gum below the tooth while it was rocked back and forth (which he called "shaking") before the extraction. Taft described a similar technique using the dental key, which had left and right claws that provided twisting and rocking in both directions.[5] This allowed the tooth to be loosened sufficiently to be pulled from the socket with "pincers" (forceps). Modern extraction forceps date from Tomes in 1840 with the development of the anatomical forceps, complete with a handle and beak to fit the neck of the tooth.

The principle of the dental elevator is also not a modern development. Abulkasim (AD 1050-1122) was the first to apply a single lever (elevator) under the tooth to force it from its "bed." It was improved by Ambroise Paré in the sixteenth century to lift out the tooth before using the pelican.[5] Although these biomechanical methods to remove teeth are effective, a review of the biomechanical principals is in order to decrease the trauma during the tooth extraction process.

The term "simple machine" is often used to describe basic devices that increase the amount of force applied (e.g., the lever, inclined plane, wheel, screw, pulley). They each transmit or modify force or torque. The most common devices used in the extraction of teeth include levers and inclined planes.

The wedge is technically a moving double inclined plane, which overcomes a large resistance by applying a relatively smaller force than the load necessary to move an object. The mechanical advantage of a wedge depends on the ratio of its length to its thickness. A short wedge with a wide angle moves an object faster; however, it requires more force than a long wedge with a smaller angle. Dental elevators and periotomes use the mechanical advantage of a wedge to initiate the luxation of teeth for their removal.

Periotomes are usually longer and thinner wedges compared with dental elevators and should be used to begin the atraumatic extraction process. Periotomes may be used in a similar manner for extraction of intact teeth or removal of retained root fragments. The long axis of the periotome blade should be inserted into the interproximal region along the root long axis (to protect the facial plate of bone), with the tip of the periotome blade located within the crest of the alveolar bone. The instrument is then pushed into the periodontal ligament space or tapped with a mallet into the periodontal ligament space along the mesial and distal root, severing the periodontal ligament immediately below the alveolar crest and wedging the tooth against the opposing cribriform plate (Figure 37-4, *A*).

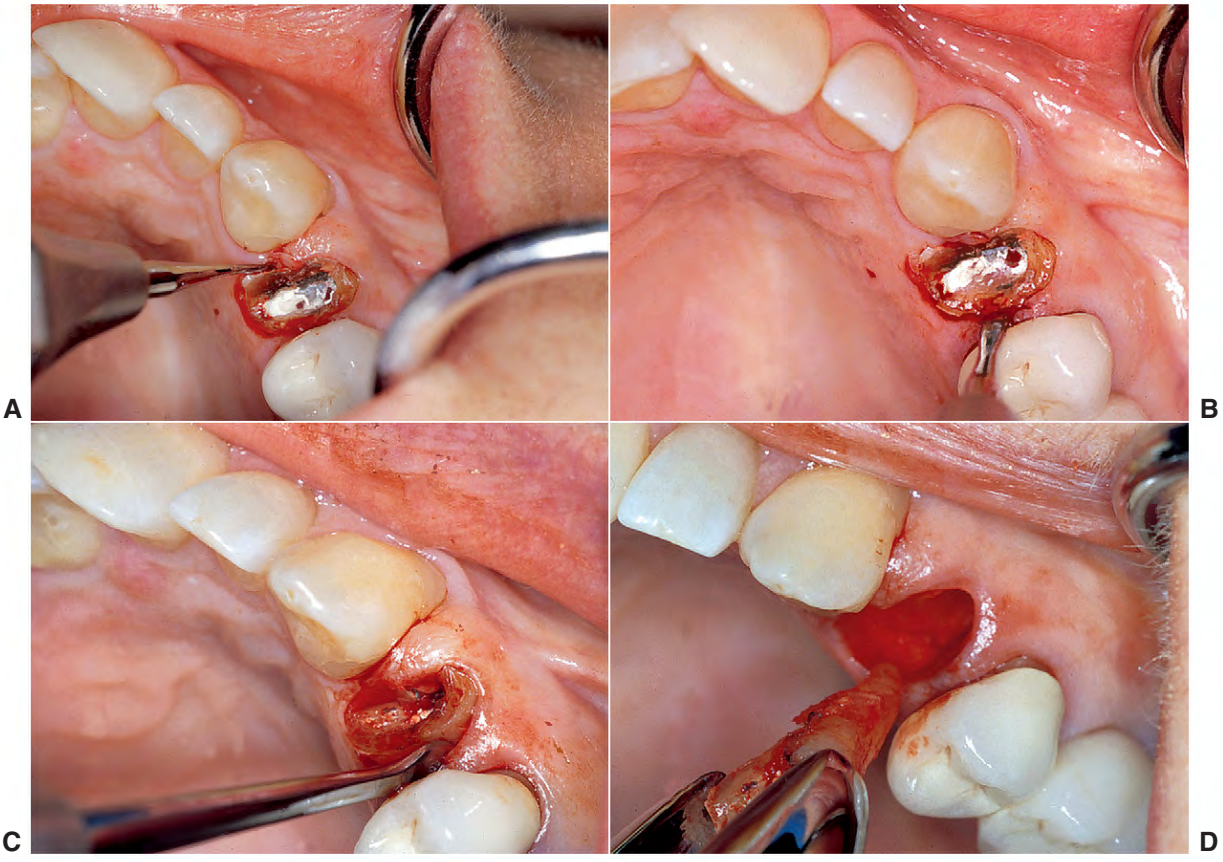

Figure 37-4 **A,** A periotome is inserted along the tooth root on the mesial and pushed (or tapped with a mallet) to wedge the tooth against the opposing cribriform plate. A similar process is performed on the distal interpositional region of the tooth root. **B,** Once the periotome acts as a wedge and is in place for 10 to 30 seconds, it is tapped (with a mallet) farther down along the mesial and distal interproximal root surface. **C,** The periotome is converted into a lever by rotating the handle several degrees, which magnifies the force against the root. The tooth becomes slightly mobile at this stage. **D,** A traditional dental forceps may remove the tooth after initial mobility is created by the periotome.

WWW.HIGHDENT.IR

A period of 10 to 30 seconds is allowed to elapse while the instrument is in place. This allows biomechanical creep to occur to the ligament and reduces its strength, and because the tooth is pushed against the opposing alveolus, it also begins to expand the bone. This process is much more effective when there is no adjacent tooth contact. Reducing the mesial and distal contacts of the tooth to be extracted not only decreases the risk of damage to the adjacent tooth crown, but also aids in the first step to extract the hopeless tooth. The periotome is then pushed farther down into the periodontal ligament toward the root apex, often using a mallet and light tapping force. This process continues along the crestal one third of the tooth. At the completion of this procedure, the tooth is often slightly mobile (see Figure 37-4, *B*).

Once the periotome is used as a moving wedge, it may then be converted to a lever (see Figure 37-4, *C*). The blade of the periotome is often 3 to 4 mm wide. When the handle is rotated, one side of the periotome is applied to the tooth root, the other side to the cribriform plate, and the width of the "wedge" is now the length of a lever, which magnifies the rotation force (moment). The rotation of the periotome handle increases both tooth mobility and the force against the opposite cortical plate to further expand it within physiologic limits.

A single-rooted tooth is most often tapered. As the periotome is tapped down to the cribriform plate and slightly rotated, the tooth often is pushed against the opposing cribriform plate. Because the socket is tapered, the lateral force on one side of the tooth is converted to a coronal direction force on the other side and the root is pushed out of the socket. As a result, the periotome may now be pushed farther apical,[1] toward the root apex. When time elapses between each force application, the tooth may even slide up and completely out of the socket. Additional time and elevation may be required if significant tooth mobility is not achieved.

A traditional dental forceps should not be applied to the tooth until significant tooth mobility is achieved. Once the wedge and lever action of the dental elevator is applied to a tooth, most often a dental forceps is used to ultimately grasp and deliberately rock the tooth back and forth and to rotate it as much as conditions will allow. The combination of these tooth movements expands the bony socket and separates the periodontal ligaments. As a consequence, the tooth may be removed (see Figure 37-4, *D*).

Conventional dental forceps are really two first-class levers connected with a hinge. The forces applied to the forceps handles are the long side of the lever and the beaks on the tooth are the short side of the lever, with the hinge acting as a fulcrum. The force on the handles is magnified to allow the beaks of the forceps to grasp the tooth with great force. None of the force on the forceps handles is used to extract the tooth. Rather, the increased force on the forceps beaks often crushes or fractures the tooth. The forceps hold the tooth, and the surgeon's hand, wrist, and arm are used to move and extract the tooth. This action would be similar to forcibly pulling a bottle cap off a bottle or pulling a nail from a piece of wood, using only a pair of pliers.

The principles of biomechanics are the basis for the development of a different type of dental forceps called *Physics Forceps* (Golden-Misch Instruments, Detroit, Mich.). A *moment of force* in physics represents the magnitude of force applied to a rotational system at a distance from the axis of rotation. The principle of moment *M* is derived from Archimedes's discovery of the operating principle of the lever and is defined as

$$M = rF$$

where *F* is the applied force and *r* is the distance from the force applied to the object. The concept of a moment arm is key to the operation of the lever, which is capable of generating mechanical advantage. This means that the force applied to an object is affected by the length of the lever arms. The lever arm is the distance from the force input to the fulcrum or from the fulcrum to the force output.

The Physics Forceps is a dental extractor that uses first-class lever mechanics. One beak of the device is connected to a "bumper," which acts as a fulcrum during the extraction. The bumper is placed most often on the facial aspect of the dental alveolus, at or above the mucogingival junction. The second beak of the extractor is positioned as low as practical on the tooth root, most often on the palatal (lingual) into the gingival sulcus.

Once the treatment is in position around the tooth root, no squeezing pressure is applied to the tooth. Instead, the handles, once in position, are rotated as one unit facially for a few degrees and stopped for approximately 60 seconds (Figure 37-5, *A*). The torque force generated on the tooth, periodontal ligament, and bone is related to the length of the handle to the bumper (8 cm), divided by the distance from the bumper to the forceps beak (1 cm). As a result, a force on the handle connected to the bumper will increase the force on the tooth periodontal ligament and bone by eight times. No force is required to be placed on the forceps beak, which is on the tooth. Therefore the tooth does not split, crush, or fracture. The 60 seconds of constant force cause biomechanical creep into the bone and periodontal ligament. Once creep has expanded and weakened the periodontal ligament and bone, the forceps handle may be slowly rotated another few degrees. This usually releases and elevates the tooth a few millimeters from the socket within an additional 10 seconds (see Figure 37-5, *B*). At this point the tooth is loose and ready to be removed from the socket using any pincer-like device (e.g., pick-ups, an extraction forceps, a hemostat) (see Figure 37-5, *C*).

The extraction of a tooth using the Physics Forceps is similar to the removal of a nail from wood with use

WWW.HIGHDENT.IR

همیار دندانسازان

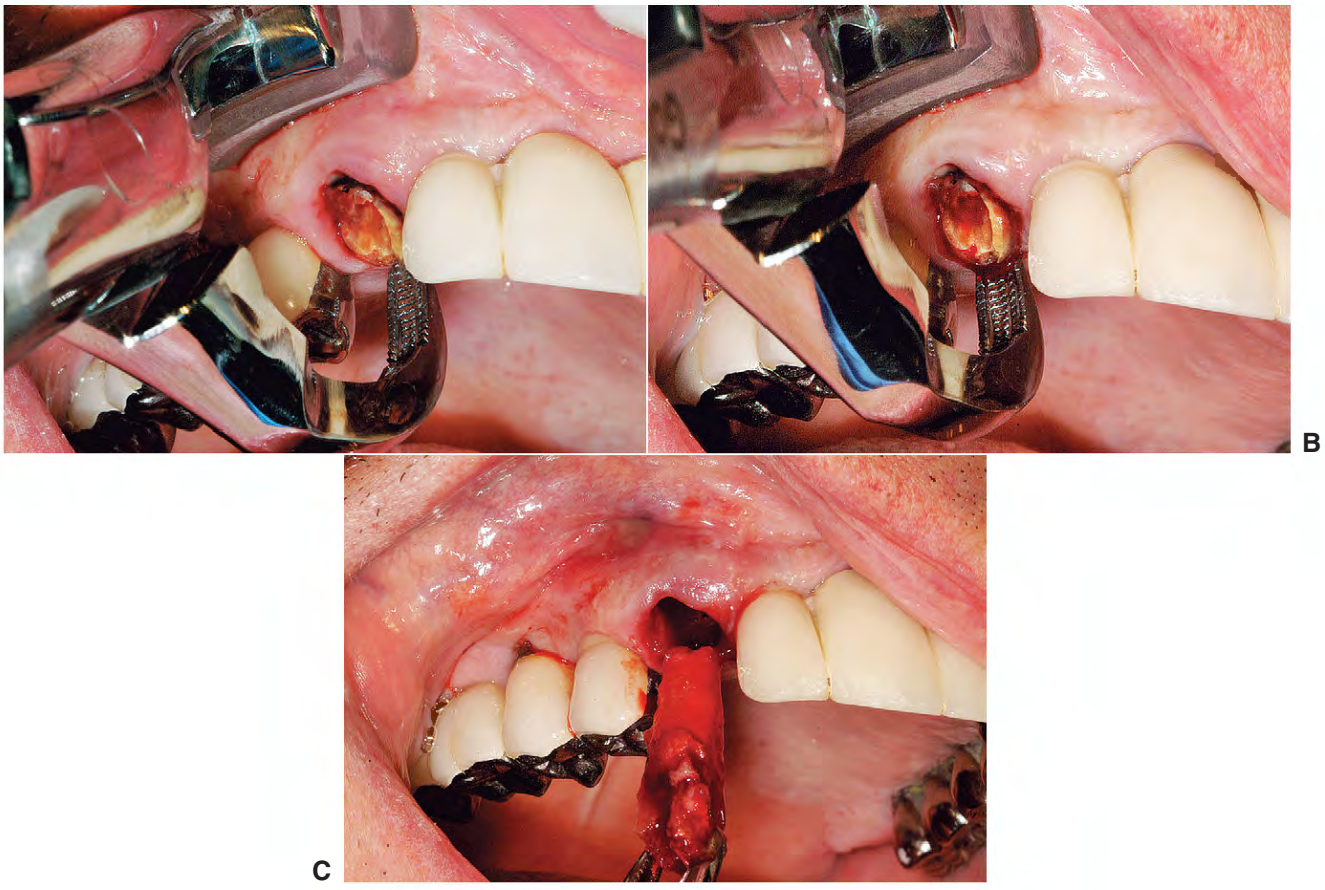

Figure 37-5 **A**, The Physics Forceps has a "bumper" on one beak, which is placed below the tooth and acts as a lever. The other beak is placed on the tooth root. The handles of the Physics Forceps act as a lever to rotate the tooth from the socket. The bumper is placed below the tooth, usually at or above the mucogingival junction. The beak is placed low on the tooth root in the gingival sulcus. **B**, Once in position on the tooth root, the Physics Forceps is used as one unit (no squeezing of the handles). A few degrees of rotation to the facial places moment force on the tooth, which is held for 60 seconds. Another few degrees of rotation are then applied, and the tooth releases and elevates. **C**, Once the tooth releases from the socket, it is removed with a pincer-like device (e.g., pick-ups, extraction forceps, hemostat).

of a carpenter's hammer (instead of pliers). The handle of the hammer is a lever, and the beaks of the hammer fit under the head of a nail (they do not squeeze the head). The hammer head acts as a fulcrum. A rotational force applied to the hammer handle magnifies the force by the length of the handle, and the nail is elevated from the wood.

Unlike a nail in wood, which is parallel and has friction for its full length, a tooth is tapered. Therefore, after it is elevated a few millimeters, the periodontal ligament fibers are broken and the tooth may be easily removed, without additional rotational force. This is important to note, as further rotational force on the forceps may fracture the facial plate of bone.

Creep is a phenomenon whereby a material continues to change shape over time under a constant load. In tooth extraction, creep may occur to bone and the periodontal ligament. Reilly established the creep curve of bone, whereby under a constant load of 60 Mpa, the bone over time responds in three different stages.[6] The majority of bone changes occur within the first minute, whereby the initial strain of bone (the change of length divided by the original length) is modified. The greater the force, the greater the deformation of the bone. This process allows the tooth socket to expand and the tooth to exit the socket.

A secondary creep curve allows the bone to further deform when the force is applied for 1 to 5 minutes. The longer the time, the greater the deformation. However, the secondary deformation is only a 10% to 20% difference compared with the initial strain over the first minute. Eventually, the bone will fracture if the load is applied over a longer time frame, representing creep rupture.

The creep curve of the periodontal complex is similar to the creep curve of the bone, whereby the constant load on a tooth over time increases the strain and decreases the strength of the periodontal complex. Therefore, the clinician should not underestimate the values of time and constant force to the tooth ligament and bone in the extraction process.

HEALING OF EXTRACTION SOCKETS

Once the tooth is extracted, the site may heal by repair or regeneration of the bone. All fibrous tissue

WWW.HIGHDENT.IR

from periodontal disease or endodontic origin should be completely removed, as these tissues impair bone formation and delay bone healing for extended periods. Repair occurs when there is injury or conditions of the bone that cause incomplete bone volume to form in the residual ridge. The most common conditions that cause repair are the absence of a labial plate before or as a consequence of tooth extraction. Other factors include a bony wall that is less than 1.5 mm thick (usually the facial), exudate, gross apical pathology, or excessive heat from a dental drill during root extraction. On rare occasions, bisphosphonate drugs or systemic conditions may cause a repair rather than a regeneration process.

The tooth socket with five bony walls regenerates bone by secondary intention, and bone healing in many aspects is similar to secondary intention soft tissue healing. The healing sequence in both hard and soft tissue includes inflammation, epithelialization, fibroplasia, and remodeling. However, socket healing presents unique microvascular features and a sequential pattern of bone formation before remodeling. The inflammatory stage of healing is initiated by the extraction trauma. Oral epithelium surrounds the crestal aspect of the socket and averages 3 mm in thickness in the absence of periodontal disease (the sulcus, junctional epithelial attachment, and connective tissue attachment accounting for approximately 1 mm each). The cribriform plate is composed of cortical-like bone and, after extraction, it is covered with the residual periodontal ligament. The vessels torn during the extraction fill the socket with blood, which coagulates and protects the bone during initial healing. The epithelium around the crest of the alveolus migrates down the socket walls during the first week. The migration continues until it reaches the bed of granulation tissue situated under the blood clot. It then migrates over this granulation tissue until it makes contact with the epithelium migrating from the other sides.

Ohta has proposed four stages of bone regeneration after a tooth is extracted with a healthy surrounding alveolus.[7] The time frames presented here have been modified from his dog study to reflect the human sigma of bone. The week following extraction is called the *initial angiogenic stage*. Initial angiogenesis develops from the broken ends of blood vessels in the residual periodontal ligament covering the cribriform plate. Blood plasma leaks from these broken vessels, and immature fibroblasts aggregate at the plasma-rich regions. The blood clot begins to shrink, and capillaries form sinusoids and granulation tissue, starting from the apex and the surrounding walls of bone. Fibroplasia begins early in the sequence during the first week as a result of the ingrowth of capillaries and fibroblasts. White blood cells kill bacteria and begin to dissolve foreign bodies and bone fragments. With few exceptions, the angiogenesis begins at the bottom of the socket because this area is not severely injured during the extraction and has the greatest source of blood vessels. Within 5 days of the extraction, early granulation tissue composed of immature capillaries and fibroblasts appears at the bottom of the socket and spreads upward along the socket walls. New bone trabeculae also form at the apical portion of the socket during this early stage.

The new bone formation stage begins as early as the third week after extraction.[7] At this time, the entire socket is filled with granulation tissue. This period demonstrates the greatest sinusoid formation activity. The forming trabeculae of woven bone first start from the bottom of the socket following the meshwork of newly formed anastomosing sinusoidal capillaries. Bone formation is more rapid at this point, creating a three-dimensional lattice pattern of woven bone. It has been observed that, during this time, the cortical bone of the marginal crest of the socket continues to resorb, especially in the interseptal regions and the thinner facial plate.

The bone growth stage starts 4 to 5 weeks after the extraction.[7] New bone trabeculae forming on the walls and apical region have thickened and fill the apical two thirds of the socket. The center of the socket is still woven bone because ossification occurs on randomly formed collagen fibers; hence its lattice appearance. The more organized lamellar bone starts to form from the lining of the socket toward the center of the socket.

The bone reorganization stage occurs at least 6 weeks after extraction.[7] The primary bone trabeculae remodel to form thicker secondary spongiosa. This process always begins at the apex of the extraction socket. The complete cortical lining of bone around the socket is not fully resorbed, and remodeling continues for 4 to 6 months after the initial extraction (Figure 37-6).

The timing for these four stages varies among individuals and clinical situations. The number of bony walls around the socket and size of the alveolus greatly influence the regeneration process. Molar sites take longer to completely form bone compared with smaller-diameter anterior sites. Although the period of regeneration for an extraction socket is variable, the clinical sign that the socket regeneration is complete is when the radiographic lamina dura (which represents the cribriform plate) is no longer present. This period is most often 3 to 6 months, dependent upon tooth size, root number, and trauma of extraction.

SOCKET GRAFTING

Multiple bone graft procedures and studies have been evaluated for socket augmentation at the time of extraction. However, variable results have been observed, not only among different reports, but also within each study.[8-11] Rather than use the same technique regardless of clinical conditions, when bone repair rather than regeneration is likely, the clinician should provide as many keys to bone grafting as possible to increase the socket.

WWW.HIGHDENT.IR

همیار دندانسازان

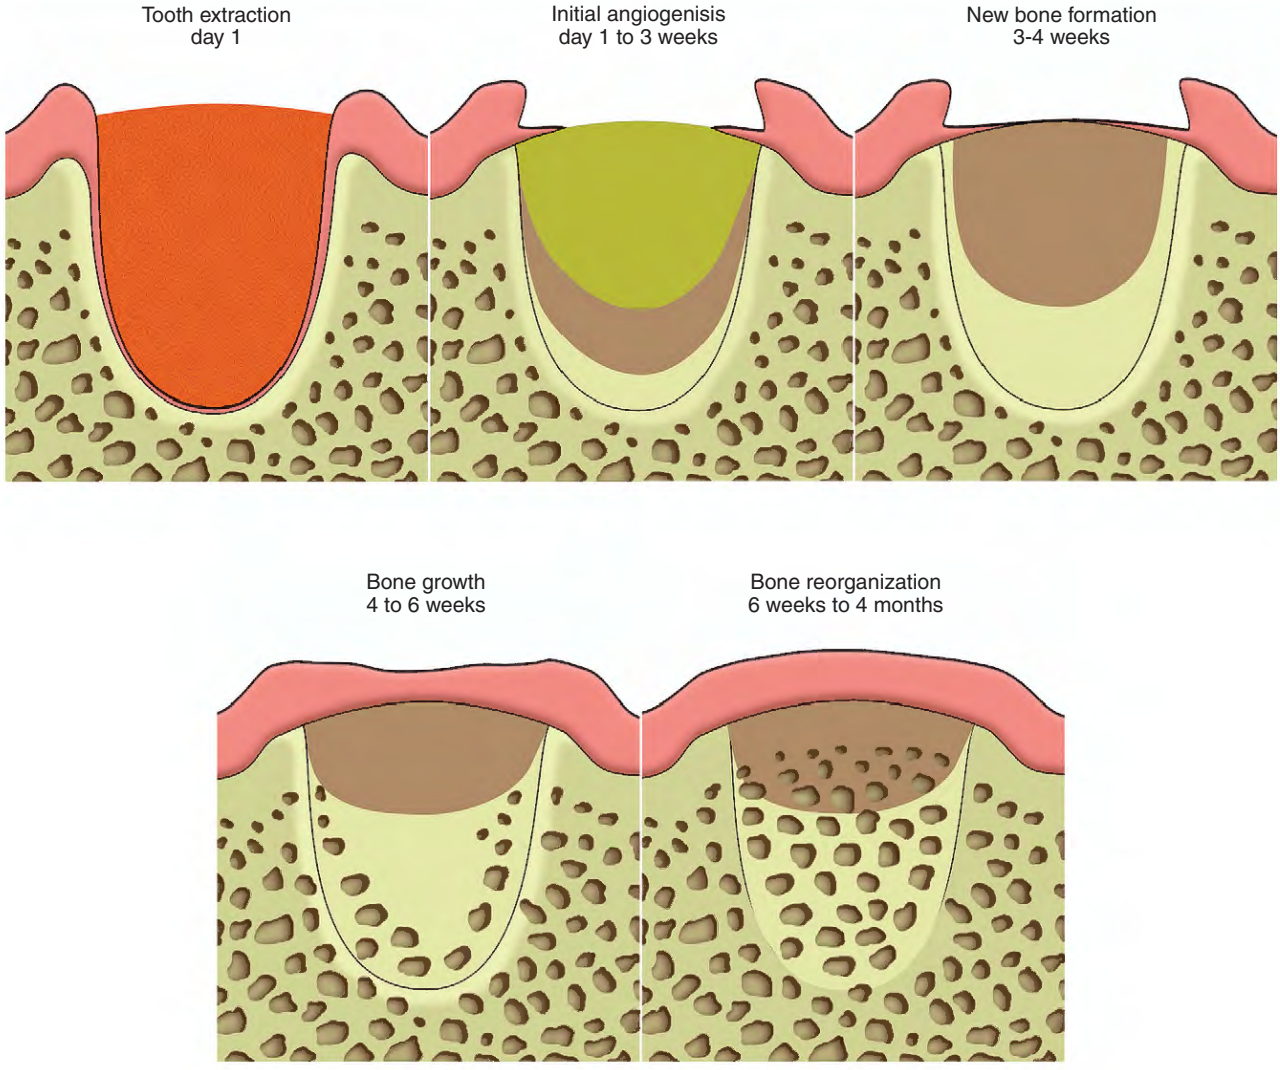

Figure 37-6 The four stages of healthy socket healing include: initial angiogenisis, new bone formation, bone growth, and bone reorganization. The complete process often takes 4 to 6 months.

In 1993, Misch and Dietsh suggested different graft materials and techniques based on the number of bony walls that remained after the tooth is removed.[12] A thick five bony wall defect will grow bone with almost any resorbable graft material (RGM); for example an alloplast, allograft, or autograft. When a wall of bone is less than 1.5 mm or a labial plate is missing (four bony wall defect), an autograft or an alloplast or freeze-dried bone (FDB) with BM and GBR increased the predictability of restoring the original bony contour. Becker et al. evaluated demineralized freeze-dried bone (DFDB) alone in extraction sockets, and no evidence of bone formation was observed.[13] It appears DFDB alone may be a poor choice for socket grafting. LeKovic et al. compared extractions alone to BM with extractions. At 6 months, crestal bone loss (0.38 versus 1.50 mm) and horizontal ridge resorption (–1.31 versus –4.56 mm) were found.[14] A two or three bony wall defect requires an RGM and, at least, some autogenous bone with a barrier membrane. A block graft of cortical autogenous bone fixated into the host bone position is suggested for one bony wall defect (Figure 37-7).

Thick Five Bony Wall Defect

Regeneration restores complete morphology and bone volume to the residual ridge. This most often occurs when there are five thick bony walls around the extraction site. Most of the keys for predictable bone formation are present under these conditions, and the socket often forms bone in the extraction socket without loss of width or height. The atraumatic extraction of a tooth without pathology provides many of the keys necessary for predictable bone regeneration. The extraction process sets up a regional acceleratory phenomenon (RAP) for healing (which increases the rate of repair and adds bone morphogenetic protein [BMP] to the site); the five bony walls protect the graft from mobility; the torn blood vessels in the periodontal complex leak growth factors into the region (platelet-derived growth

WWW.HIGHDENT.IR

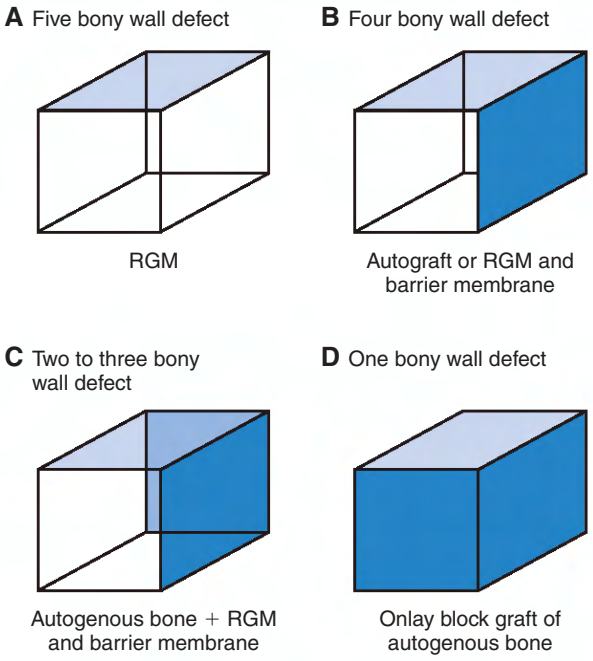

Figure 37-7 The graft materials and techniques for socket grafting are related to the remaining number of bony walls. A thick five wall bony defect may use any resorbable graft material (RGM). Four wall defects require an autograft or mineralized alloplast, allograft, and barrier membrane. A two or three wall bony defect may use some alloplast/mineralized allograft, but should use autograft and a barrier membrane as well. A one wall bony defect is most predictable with a cortical autograft fixated to the host bone.

factor [PDGF], transforming growth factor [TGF]); the space is maintained by the five walls of the bone; the bony walls provide blood vessels from bone into the site; and the defect size is small (i.e., one tooth). As a result, the only key initially missing is soft tissue closure (Figure 37-8). The soft tissue around the extraction site begins to grow over the clot and granulation tissue of the socket and within 2 to 3 weeks covers the site. For example, a mandibular third molar extraction site often has thick lateral walls of bone, and most often the bone area is regenerated in both height and width with no graft material or regeneration technique in the sockets.

Four to Five Wall Bony Socket

When a labial plate around a socket is missing, the absence of the wall prevents space maintenance, reduces host bone vascularization, and replaces it with soft tissue vascularization. The facial bone level will never grow above the height of bone on the facial cortical plate of the tooth. Bone augmentation procedures must be used to obtain an ideal volume and contour of bone. Sockets with a missing lateral wall are significantly compromised and heal by repair rather than regeneration.

When conditions of repair instead of regeneration are present, socket grafting for ridge augmentation at

the time of extraction is indicated.[12] Tooth extraction without grafting in these conditions results in residual bone loss as a result of resorption. The maxillary anterior region may be reduced 23% in the first 6 months after an extraction and another 11% over the following 5 years.[15] Within 2 years, an average of 40% to 60% of the original height and width of bone may be lost with multiple extractions.[16]

The first determination after the tooth extraction is complete is the assessment of the thickness of labial and palatal plates of bone and their relative height to the ideal volume desires. When one of the lateral plates of bone is thinner than 1.5 mm, or when height is desired, a socket graft is indicated, even in the presence of five bony walls. A similar socket augmentation procedure also may be used when the labial plate of bone is missing. The two techniques of choice are a BM with a mineralized alloplast/freeze-dried bone (FDB) socket fill or a modified socket seal surgery.

Barrier Membrane with Alloplast/ Freeze-Dried Bone

An acellular dermal matrix is selected for a BM when soft tissue augmentation is also desired, or a collagen BM is used when the soft tissue drape is not an issue. A periotome or thin periosteal elevator is used to tunnel under the final bone periosteum and lift the soft tissue off the bone over the thin bony wall. This tunnel should extend several millimeters beyond the desired augmentation site. A BM is then slid into the "pocket" created under the tissue and extends apical, mesial, and distal beyond the extraction site. Approximately 6 to 8 mm of the BM should extend above the marginal tissue.

When the facial plate is thin, the socket may be filled with FDB (e.g., MinerOss, Puros) or a mineralized hydroxyapatite (HA) source (e.g., BioOss, Osteograf-N). When the labial plate is missing, the FDB may be placed in the apical portion, but particulate autologous bone should be placed in the crestal half of the socket. The walls of bone on the mesial, distal, and palatal provide bone blood vessels to this autograft. The extension of collagen or AlloDerm then covers the top of the socket and is tucked below the palatal tissue. Sutures are then placed over the top of the BM. Primary closure of the soft tissues is not obtained, as the tissues would need to be reflected and advanced over the socket, which would affect the soft tissue drape (Figure 37-9, *A* to *H*).

The extraction site may be reentered after 4 to 6 months. The clinical time for reentry is determined by the absence of the cortical lining of the socket (cribriform plate) on a periapical radiograph. Once this has occurred, the implant may be inserted and a

regular protocol of healing and restoration used (see Figure 37-9, *I* to *N*).

Maxillary Tuberosity Donor Site

The tuberosity offers a variable amount of trabecular bone. This area is convenient for use in maxillary sinus grafting[12,17,18] and also may be considered for smaller areas of ridge augmentation[19,20] (Figure 37-10). The cancellous nature of the bone allows it to be molded into an alveolar defect, such as an extraction socket.[12] However, the trabecular graft will more often require the use of a barrier membrane in onlay grafting to minimize resorption and stabilize the graft.[21] The tuberosity autograft has growth factors for osteoinduction and to accelerate blood vessel growth in the host site.

The thicker soft tissue in the tuberosity region can mislead the assessment of this donor site. The tuberosity should be evaluated with panoramic or periapical radiographs. The anatomical limitations of this area include the maxillary sinus, pterygoid plates, adjacent teeth when present, and the greater palatine canal. A vertical incision is made posteriorly at the lateral aspect of the maxilla. It extends anteriorly across the tuberosity into the molar region. After reflection of a mucoperiosteal flap, bone may be harvested from the tuberosity with a rongeur or chisel. Removing the graft with a chisel will allow the harvesting of a larger piece of bone. Although the sinus may inadvertently be entered during removal of the graft, coverage of the perforation with the thick mucosa should preclude the development of an oroantral communication. If this is observed at suture removal, the patient is instructed to avoid creating high nasal pressures and should be placed on antibiotics and decongestants to prevent infection and ensure normal drainage. Most often, within 1 month, the oroantral opening will close on its own.

Socket Seal Surgery

A composite graft socket seal surgery has been developed by Misch et al.[22,23] composed of connective tissue, periosteum, and trabecular bone used to seal a fresh extraction socket. A connective tissue graft has the advantage over a keratinized graft by blending into the surrounding attached gingival regions, offering similar color and texture of the epithelium. This is most advantageous in the maxillary anterior region and

Continued

other aesthetic areas. The composite graft also contains autogenous bone. The major advantage of autologous bone is a more rapid and predictable bone formation via osteogenesis. This technique may be used any time a tooth is extracted and an implant is planned as replacement.

A 6- to 10-mm trephine bur corresponding to the extraction site diameter is used in a slow-speed, high-torque hand piece to harvest a gingival graft with underlying bone. The most common site for the intraoral composite graft harvest is the maxillary tuberosity region (see Figure 37-10). The trephine drill drills through the unreflected, keratinized, attached gingiva and into the bone of the tuberosity region at the prescribed depth related to the thickness of the tissue and the amount of donor bone available. Care should be exerted not to enter the antrum, but that is of little consequence if the antrum is healthy during the process. A trephine bur may be used as a lever to greenstick fracture the bone core from its base, once it is in position within the bone. A Molt elevator may also be used for this purpose. The bone core (usually 5 to 10 mm in height) and the attached soft tissue (about 3 mm in height) is trimmed of its epithelium with a tissue scissors, leaving 3 to 6 mm of connective tissue attached to the bone core.

If the bone core does not fill the extraction socket completely, a mineralized bone graft material (e.g., FDB, bovine bone) may be used in the apical portion of the socket, provided the labial plate is still intact. Because the new bone forms from the apical portion of the socket, this is the least important region to augment. If no bone plate remains in the apical half of the socket, additional autogenous bone should be harvested from an additional intraoral site to overfill the apical half of the socket. The bone of the composite graft (connective tissue attached to periosteum and bone) is compressed and fitted into the remaining portion of the socket. The tissue of the composite graft will seal the socket and remain above the surrounding gingiva. A mallet and blunt instrument should be used to tap it into place and compress the bony core to conform to the crestal contour of the socket. The connective tissue portion of the graft

is then sutured to the surrounding gingival tissue with facial and palatal interrupted 4-0 PMA or Vicryl sutures (Figure 37-11). A removable transitional prosthesis should not be permitted to load the tissue during the first few weeks after extraction; otherwise, the composite graft may become mobile and sequestrate. A fixed transitional restoration may use an ovoid pontic design to maintain the interdental papilla height and contour.

The benefits of the composite graft socket seal surgery technique permit the surrounding keratinized gingival tissues to migrate and form a similar color and texture of keratinized tissue over the socket. The blood supply to the composite graft is established from the surrounding soft tissue. In addition, because autogenous bone is used as the graft in the coronal half of the socket where the facial bone is most often very thin or

WWW.HIGHDENT.IR

همیار دندانسازان

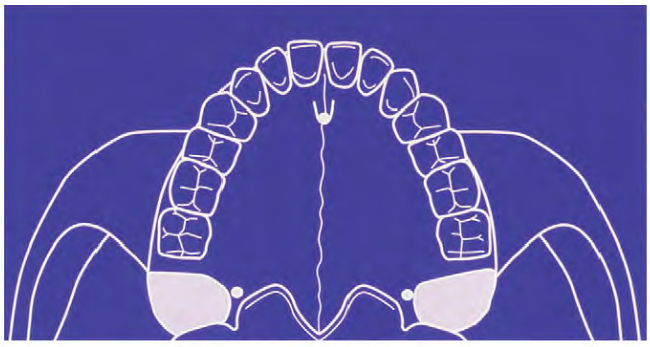

Figure 37-10 The maxillary tuberosity region is a common bone donor site for bone grafting, when trabecular bone is the desired product. Trabecular bone has growth factors for blood vessels and for regeneration of a bone defect.

absent, more predictable results will result than if an allograft were used. The transfer of the bone graft with an intact periosteal layer expedites revascularization and may decrease the healing time.[24,25] As a result, reentry may be in 4 to 5 months, and placement of an ideal implant diameter is often made possible (Figure 37-12).

Two to Three Bony Wall Defects

A two to three bony wall defect is treated very similar to a four bony wall defect. However, because the defect size is larger, more autograft is required in the bone graft. Rather than using the autograft primarily in the crestal region, it is of benefit that the entire first layer of the resorbable graft materials be an autograft. As a consequence, more often a donor site from the mandible is required.

The most common two to three bony wall defects are extraction sites missing more than the labial bony wall. Because the mesial distal bony walls are usually present, the host site is more predictable than a one bony wall defect. Incision line opening is less of a complication, as the residual ridge form has soft tissue support around the defect.

Trephine Bur Bone Harvest

Trephine burs are end-cutting devices of various diameters. Most often, a 6- to 10-mm trephine bur is selected. Once the bone harvest site is reflected, the trephine bur is used to harvest the autograft. When the ramus is selected, a larger trephine is usually selected. One half of the trephine bur is placed over the external oblique and bone, while one half is lateral to the bone and under the reflected masseter muscle, which is elevated off the anterior lateral aspect of the ramus. The trephine bur is used with a straight or angled hand piece at 2500 rpm with copious saline irrigation, 5 to 8 mm deep, making sure it is above and lateral to the position of the inferior alveolar nerve (IAN), artery, and vein. The IAN position may be evaluated on a panoramic radiograph or more precisely by computed tomographic (CT) reformatted images.

The next harvest site is above the half circle created by the first osteotomy and overlays the circle in the top third, or 3 mm from the top. This is repeated in the bottom third of the initial half circle, 3 mm above the bottom. Three interlacing semicircles are created along the external oblique of the ascending ramus. A large No. 8 round carbide in a straight hand piece then scores the lateral aspect of the ramus corresponding to the depth of the trephine bur semicircle cuts, 5 to 8 mm from the anterior border of the ramus. A chisel or surgical curette then may greenstick fracture the donor bone pieces from the ramus. These harvested pieces are usually the correct size to use in the graft site, as they are $5 \times 3 \times 5$ mm large. A collagen sponge (e.g., Avitene, Collatape) may be placed in the donor site and the tissues approximated for primary closure.

A trephine bur harvest over the apex of teeth or from a symphysis is usually with a 6- to 8-mm-diameter trephine. The trephine is used 5 to 8 mm deep, dependent upon the depth of the opposing landmark. Circular rings of the osteotomies are overlapped by 3 to 4 mm with a trephine bur. The first piece of bone is usually the most difficult to harvest. A wider slot is often drilled around the first segment to be harvested with a straight carbide drill (No. 557 surgical bur). The larger groove allows the curette or chisel to be introduced and leverage the piece of bone off the host site by greenstick fracture. Once the first piece is removed, the remaining pieces are tapped off the bone base with a chisel (Figure 37-13).

The two to three wall bony defect is filled with particulate autograft along the bony walls. When inadequate particulate autograft is harvested to completely fill the defect, a 30% DFDB and 70% mineralized bone (e.g., FDB) fills the remainder of the defect, preferably mixed with platelet-rich plasma (PRP). A barrier membrane is then placed over the site (Figure 37-14).

One Bony Wall Defects: Barrier Membranes and Guided Bone Regeneration

The concept of prosthetic-guided treatment plans has been presented as a method for achieving and maintaining predictable results when replacing the natural dentition. Because bone volume is often lost and the position of bone is modified rapidly after tooth loss, bone augmentation prior to or in conjunction with implant insertion is a common scenario when considering implant prostheses.

Several methods have been used to augment an edentulous site. There are advantages and disadvantages to each of the bone regeneration procedures. As a general rule, particulate grafts are easier to learn and to perform; they incur less incision line opening, have less postoperative discomfort from donor sites, have less altered nerve feeling from the donor site, may be more easily adapted to complex bone geometries in the host site, and may be used more easily at the same

The tissue thickness is reduced to 2 to 3 mm above the bone. The surface of the tissue is connective tissue (CT). **E,** The composite graft is inserted into the extraction socket and a blunt instrument (e.g., mirror handle) and mallet taps the composite graft into the socket so that the CT is level with the surrounding tissues. **F,** Sutures are positioned to maintain the composite graft in place.

time as implant insertion or for implant post-prosthetic bone loss. As a result, bone augmentation with GBR techniques is necessary to master.

There are disadvantages to using GBR procedures for all host defects or deficiencies. When bone augmentation is limited to only the GBR approach, limitations of treatment are observed. The larger the defect, the less predictable the graft. Bone height and width augmentation with BM are usually limited to less than 3 to 4 mm. Soft tissue contours are more difficult to predict. Extended healing times are necessary. The bone quality is often less than ideal. Full arches—GBR especially in the mandible—are not predictable. As a consequence, there is a place for both block bone grafts and GBR procedures when augmentation is required to fulfill the prosthetic-guided treatment plan.

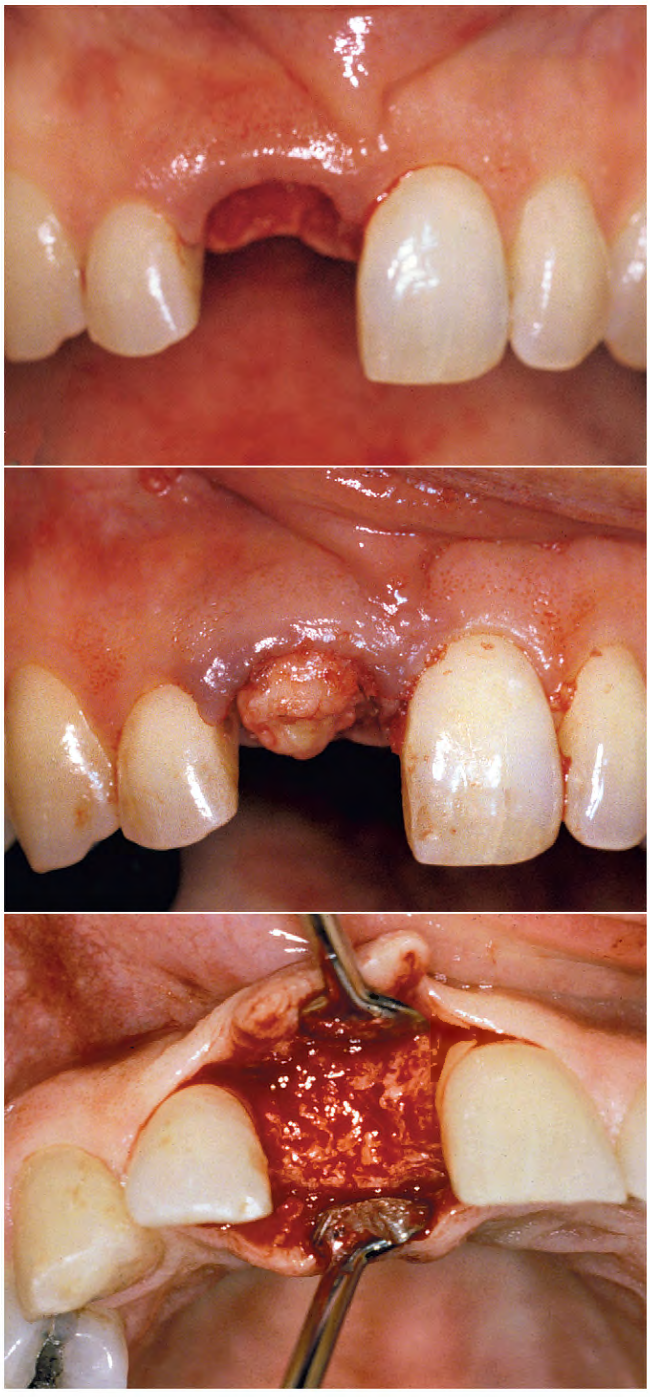

Figure 37-12 **A,** A maxillary central incisor is atraumatically extracted. **B,** A composite graft is positioned into the socket. **C,** After 4 months a reentry into the site observes the residual ridge has been augmented to the desired size.

The underlying concept of BMs has been used in medicine for more than 40 years.[26-33] The goal is to allow cell repopulation of a desired tissue to fill or regenerate a space and prevent unwanted cell types from entering the defect. The original concept for guided tissue regeneration was for nerve regeneration by leaving a tubelike chamber within a surrounding tissue connected to one end of the innervating nerve. The nerve could regenerate under these conditions and grow into the void to reinnervate the structures in the reconstructed defect.[26]

Tatum used a BM with particulate iliac crest bone grafts, placed in metal grids for jaw reconstruction before endosteal implant insertion in the early 1980s.[17] This technique was also used by Boyne with clinical success. The original clinical cases of BM and iliac crest particulate bone graft by Tatum and Boyne used nonresorbable cellulose filters (Millipore Filter, Millipore, Belford, Mass.).[34,35] However, both these clinicians abandoned the technique after several years because of a risk of increased incision line opening and associated risks of infection.

In the late 1980s, Gottlow et al. and Nyman et al. used Millipore, then expanded polytetrafluoroethylene (e-PTFE) (Gore-Tex, W.L. Gore, Flagstaff, Ariz.).[36,37] Most original clinical reports have used the nonresorbable e-PTFE membranes, and many reports have demonstrated predictable results.[36-39] Their research has led to a resurgence in guided tissue regeneration and GBR before or in conjunction with endosteal implants. However, the incidence of incision line opening is increased with this material, as the soft tissue does not readily adhere and attach. When incision line opening over a BM does occur, the amount of desired bone formation may be reduced as much as 60%. The cause of this decrease is often from bacterial contamination of the exposed membranes.[40-48]

The concept for GBR is to place a BM directly over a bone defect and under the soft tissue (including the periosteum) before primary closure. It has been accepted that the periosteum is a source of osteoblasts for bone formation and takes part in the bone augmentation process. However, this apparently is incorrect. When the periosteum is placed directly over a particulate bone graft, bone does not form under the periosteum. Instead fibrous tissue is observed on the surface. When a barrier membrane is placed over the particulate graft, bone is found. The new bone forms from the surrounding walls of host bone and follows the invading blood vessels from the host bone, which grow into the space provided by the membrane or particulate graft.

To create an ideal environment for bone modeling under the barrier membrane, the primary keys for bone grafting should be kept in mind. The GBR provides many of these, such as space maintenance, protection of blood vessels, clot with growth factors, graft stabilization, and exclusion of fibrous tissue in the graft. The barrier membrane should be placed over a particulate graft, rather than an empty or blood clot–filled space. A blood clot, in and of itself, does not participate in bone formation under the BM. Because a blood clot is 95% stagnant red blood cells and 5% platelets, the environment to grow bone is reduced, as red blood cells lyse and reduce the pH in the region.

A wide range of BM exists for GBR. The ideal properties of a BM include: (1) biocompatibility to hard

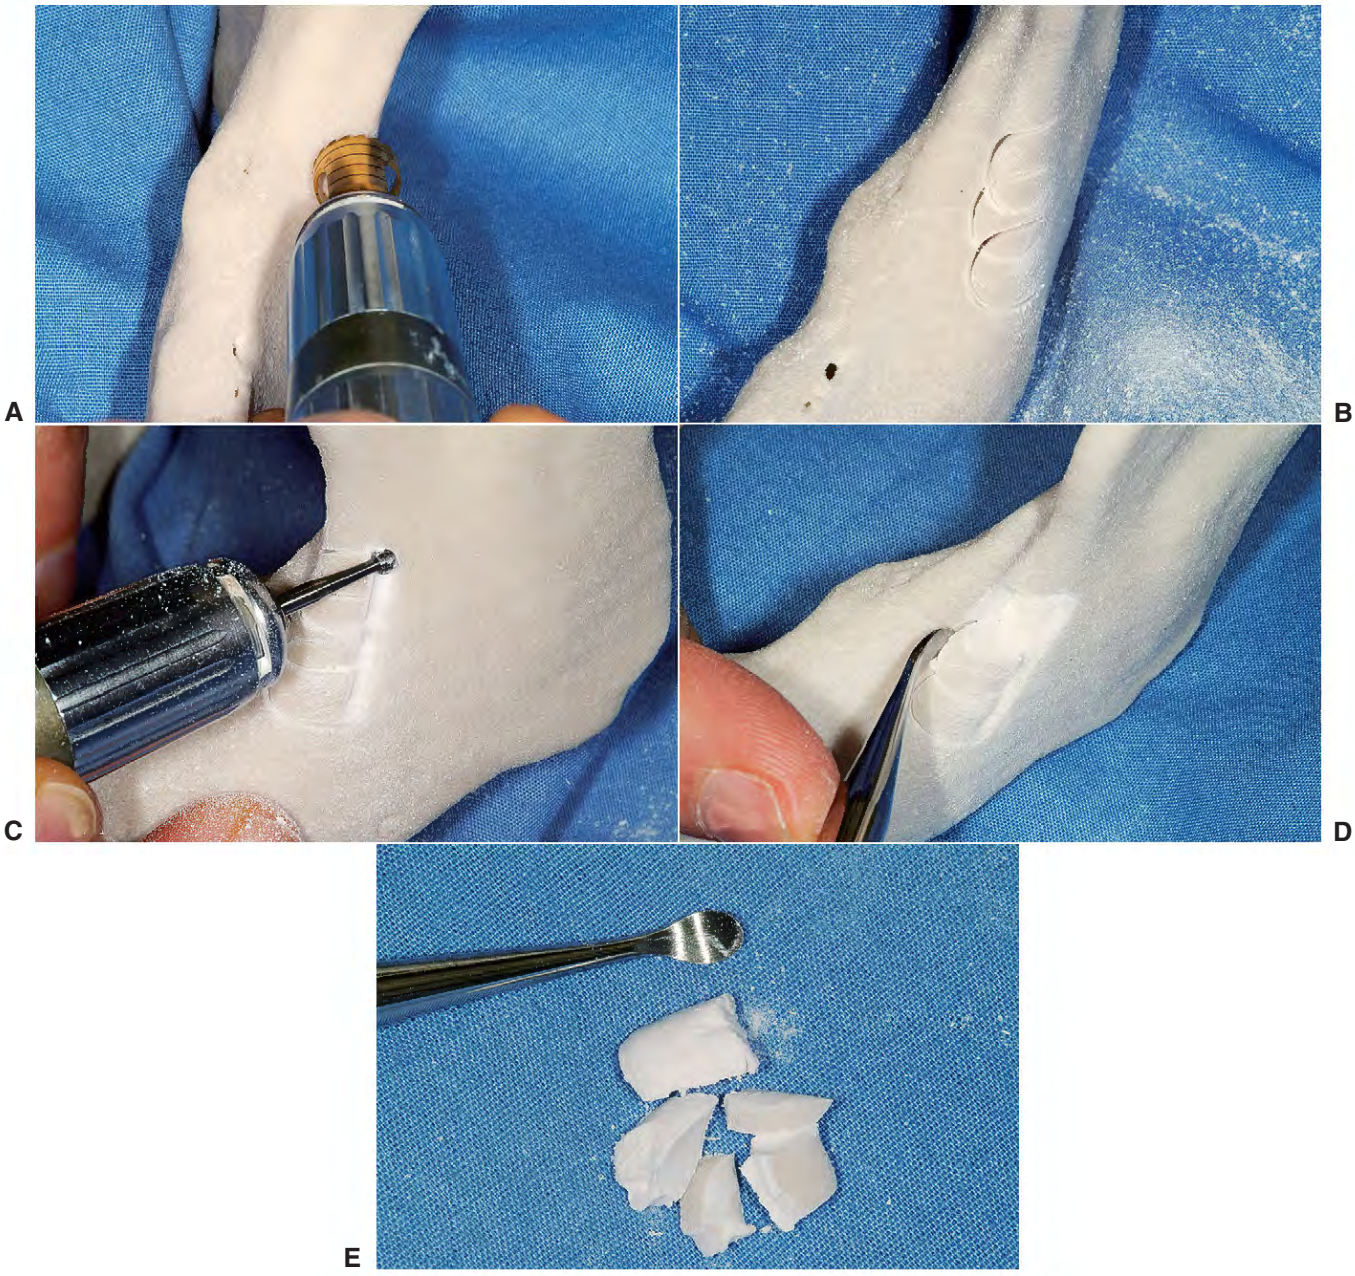

Figure 37-13 **A,** A trephine bur is used in the ramus to harvest autograft. Approximately half the trephine bur is placed on the lateral aspect of the ascending ramus, and penetrates the bone 4 to 8 mm. **B,** The osteotomy created by a trephine bur on the ascending ramus. Overlapping trephine bur osteotomies are made in the lateral aspect of the ascending ramus**. C,** A large round bur scores the lateral aspect of the ramus at the depth of the previous trephine bur osteotomy. **D,** A bone chisel is used to greenstick fracture the segment of particulate bone off the ascending ramus. **E,** The particulate bone pieces are 3 × 5 mm and used as the bottom layer of graft materials for the layered approach to BM GBR.

and soft tissues; (2) ability to occlude unwanted cell or tissue infiltration; (3) ability to maintain a space for the bone augmentation (4) ease of use to modify and place over the graft site; and (5) cost effectiveness.[40,41,46,48-54] In addition, the ideal BM should be absorbable but last long enough for predictable bone formation, decrease tissue movement and, when necessary, increase the tissue thickness over the bone graft. *Resorption* of a material describes the degradation of native tissues (e.g., bone). *Absorption* is the physiologic ability of tissues to degrade or reduce a foreign substance in the body. The absorption of the BM may be through a systematic activity called *biodegradation* or *bioabsorption* by hydroxylation from the surrounding soft tissues.

Although many BM fulfill most of these criteria, no single membrane is completely ideal. However, predictable results may be obtained when enough keys for bone grafting are present. The primary advantage of absorbable membranes is that a second-stage surgery is not necessary because it does not require removal. Although a secondary surgery is often used with GBR (unless the implant is placed at the same time), the

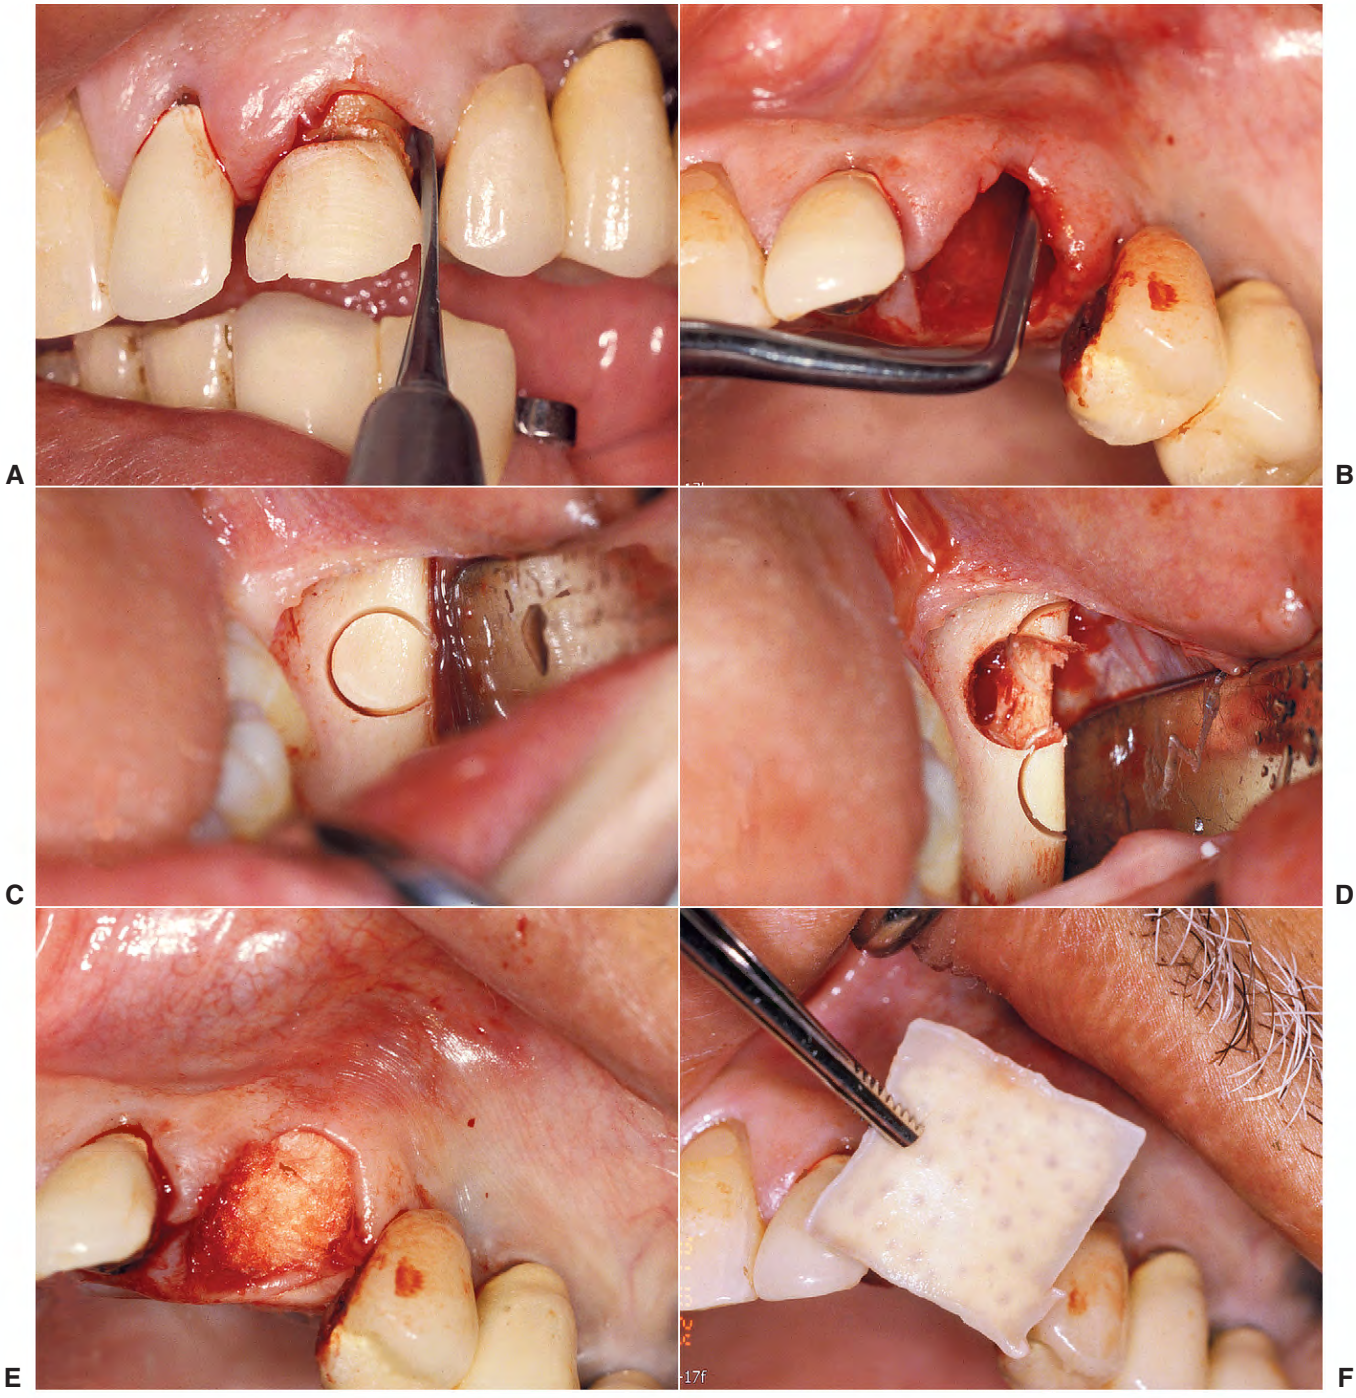

Figure 37-14 **A,** A canine tooth is atraumatically extracted. **B,** The extraction site has the facial wall missing, and the palatal and apical region has more bone loss than a typical extraction site. **C,** An ascending ramus is exposed, and a trephine bur is used along the lateral border. **D,** Overlapping trephine bur osteotomies are made so each bone segment is approximately 3 × 5 mm. **E,** The socket is filled with particulate autograft harvested from the ramus. **F,** The region above the bone is filled with demineralized freeze-dried bone cortical fibers. A barrier membrane (AlloDerm) is inserted along the facial aspect of the ridge; it extends above the crest and is tucked under the palatal tissue to cover the palatal plate. *Continued*

implant surgery may be flapless (when indicated) or the incision reflection of the tissue may be related solely to the indications for the implant not to remove the barrier membrane.[55-57] Absorbable membranes have fewer incision line opening complications, and when they do occur, they do not harbor bacteria, are treated more predictably, and regenerate more bone.[49-52] A second advantage is fewer incision line opening complications; if they do occur, management is more predictable and the amount of bone regenerated is greater than similar complications with nonresorbable materials.[40]

There are three primary categories of absorbable BM for GBR: collagen membranes, polylactic/polyglycolic acid membranes, and acellular dermal matrix. Collagen

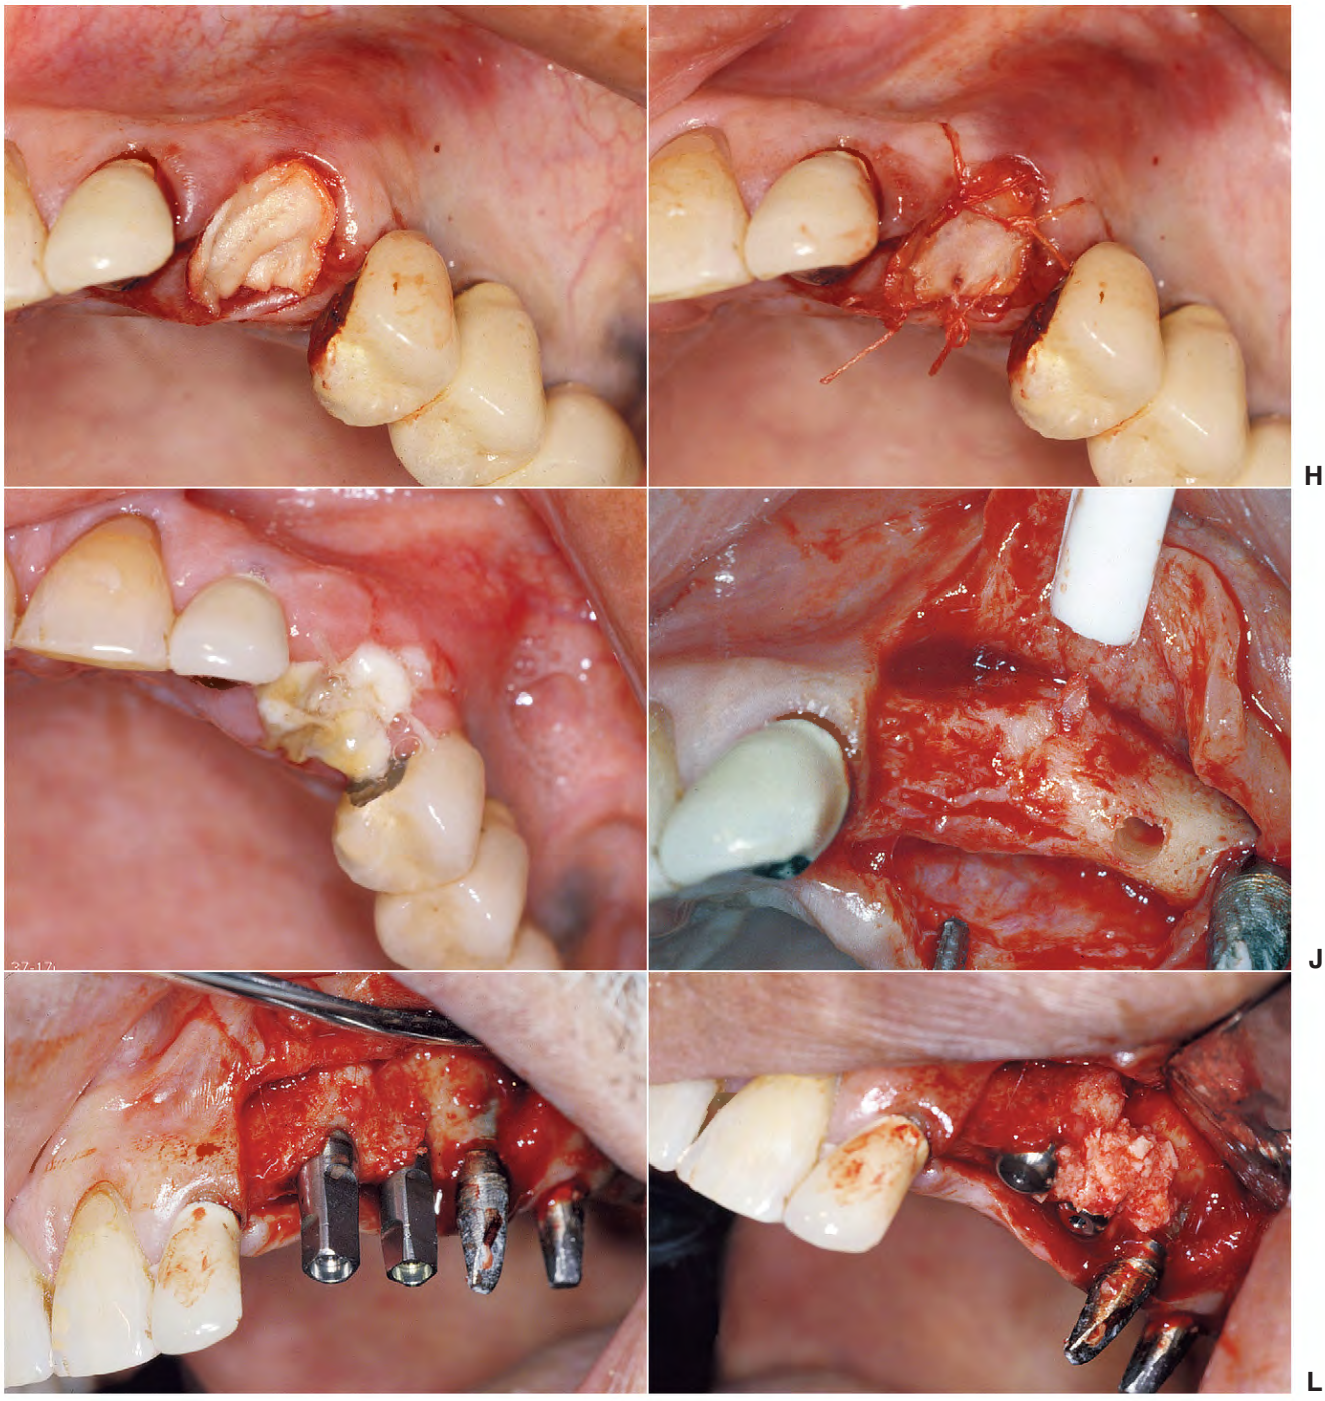

Figure 37-14, cont'd **G,** A barrier membrane of AlloDerm (acellular dermal matrix) is selected to cover the facial and palatal bony plate missing. **H,** The exposed membrane is sutured over the extraction site. **I,** Two weeks later the sutures are removed. The AlloDerm expands and, when exposed, appears soft and often has a taste or odor. One week later the site is improved. **J,** A reentry into the defect site demonstrates adequate bone volume in the canine site. The first premolar site (nongrafted) is deficient in width (Division). **K,** Endosteal implants are inserted into the canine and first premolar sites. Implants were previously positioned in the second premolar and molar sites, supporting a cantilevered restoration. **L,** Cover screws are inserted into the two implants placed at this time, and an autograft is placed over the first premolar implant site, as the facial bone is less than 1.5 mm thick.

membranes have several properties advantageous to GBR, including relative ease of use, hemostasis, and soft tissue compatibility, including the ability to act as a scaffold for migrating cells.[58-62] The most common sources are bovine type I collagen from the deep flexor tendon or dermal sites. After processing, it has minimal antigenicity with human tissue, as processing removes the antigenic portions of the polypeptide chain.

Not all absorbable collagen dressings may be considered a BM. In order for the material to act as a BM for GBR, the membrane should prevent unfavorable tissue cells from entering the bone augmentation site

WWW.HIGHDENT.IR

همیار دندانسازان

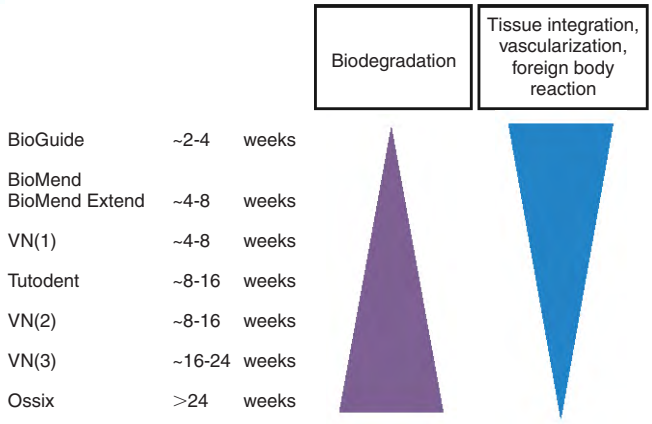

Figure 37-15 Different barrier membranes have different biodegradation times, which are inversely proportional to the tissue integration and vascularization schedule. For example, Biomend has an absorption rate of 4 to 8 weeks, whereas Ossix is more than 6 months. *(From Rothamel D, Schwarz F, Sager M et al: Biodegradation of differently cross-linked collagen membranes: an experimental study in the rat,* Clin Oral Implants Res *16:369-378, 2005.)*

for at least 6 to 8 weeks.[45,63] The greater the porosity of the collagen dressing (e.g., CollaTape, Zimmer Dental, Carlsbad, Calif.), the faster the absorption[64] (Figure 37-15). These materials provide a benefit for hemostasis, soft tissue healing, carry growth factors (e.g., PRP) to the graft site, and maintain the particulate material to a graft site (e.g., the maxillary sinus floor). However, it fully resorbs in 10 to 14 days. These features may help spark the regeneration process of both hard and soft tissue within this time frame, but it is not a BM for GBR. Likewise, PRP has been called a *quasi-membrane* when placed over a bone graft site. Because this material degranulates in 3 to 5 days, it is not a BM for GBR.

More dense and less porous collagen membranes may be fabricated in laminated sheets (e.g., Biomend, Zimmer Dental, Carlsbad, Calif.) and absorb over 4 to 8 weeks. BioGuide (Geistlich Biomaterials, Wohlhusen, Switzerland) is a bilayer collagen membrane from types I and III porcine collagen and absorbs over a 2- to 4-week period. Ossix (Colbar Life Science, Herzliya, Israel) is a porcine barrier membrane that may take more than 6 months to absorb. Clinical studies of GBR with different resorption rates, from 6 weeks to 6 months, often demonstrate similar bone augmentation results. It appears once the blood vessels from host bone invade the bone graft space, the other key factors are more relevant (e.g., graft immobilization).

Acellular dermal allograft (AlloDerm, LifeCell, Branchburg, N.Y.) is a processed human donor skin tissue that causes deepithelialization of the soft tissue and decellularization. Because there are no cells after the processing of the allograft tissue, rejection is eliminated. The acellular dermal matrix is undamaged and the collagen, elastin, and proteoglycans are still present, which augment the overlying soft tissue. As a result, an inert avascular connection tissue is obtained.[64] This tissue has been used in the medical community for treatment of third-degree burns, hernia repair, and tissue augmentation (including breasts).[65] In dentistry, it is often used to create zones of immobile tissue around teeth (or implants), root coverage,[66-70] soft tissue grafting, and augmentation.[71-77] This material also offers unique properties when used for GBR.[78,79]

Because the acellular allograft tissue material may become completely and permanently incorporated into the soft tissue after 6 weeks rather than resorbing as a collagen BM, it may increase tissue thickness over the graft site. This is beneficial in esthetic zones when the soft tissue drape needs to be developed. Because it binds to the overlying soft tissue, it may create a zone of immobile tissue. This is a benefit for particulate graft immobilization and for implant soft tissue maintenance after the prosthesis delivery.

In addition, a few clinical reports expose the acellular dermal matrix to the oral cavity during healing and allow it to act as a scaffold for the soft tissue to migrate over the material. This clinical factor may also be a benefit if incision line opening occurs during initial bone graft healing.[75,79-82]

The disadvantages of acellular dermal matrix include at least 10- to 20-minute preparation time. The material is placed into sterile saline for at least 10 minutes to rehydrate the freeze-dried tissue. After this initial period, another bowl of saline and an additional 10-minute period are suggested, to "wash" from the material the antibiotics that were used as part of the processing. In addition, the dermal matrix tissue swells in thickness and size during initial healing. This may cause incision lines to expose the material to the oral cavity.

SOFT TISSUE HEALING

One of the keys to bone grafting is initial soft tissue coverage and tissue healing. The understanding of the cytokine-mediated processes of connective tissue formation is the basis for the development of new innovative therapeutic strategies.[83] These may include the modulation of chemotaxis, differentiation, proliferation of fibroblasts, synthesis of extracellular matrix proteins, and, as a result, control of soft tissue formation.[83]

Both lack and overexpression of transforming growth factor-β (TGF-β) may be responsible for an impaired healing process.[83] TGF-β attracts fibroblasts, monocytes, and macrophages to the site of inflammation. Furthermore, it provokes a reduced phagocytosis capability of granulocytes and macrophages.[84] During new tissue formation, it induces the expression of integrins, which control the migration of keratinocytes to the wound surface.[85] Additionally, TGF-β stimulates the synthesis of collagen during the wound healing process.[86] In the course of remodeling, the cytokine is

WWW.HIGHDENT.IR

believed to influence composition and cross-linking of permanent collagen structures by regulating the pattern of integrin expression in fibroblasts.

Interleukin 1 (IL-1) fulfills a key role within the inflammatory signal transduction processes.[87] IL-1 is produced by monocytes and macrophages and serves as the main stimulus of extracellular matrix catabolism, production of collagenase and proteinase (matrix metal proteinase), and degranulation of neutrophil granulocytes.[88,89] As reported by Panagakos et al.,[90] increased levels of IL-1 are found during the loss of attachment within the scope of peri-implantitis. Implant-surrounding soft tissue altered by inflammatory processes expresses noticeably higher levels of IL-1β in comparison to the physiologic mucosa.[91] It can be used as a marker for a proinflammatory cellular response in the peri-implant soft tissue.[92]

Vascular endothelial growth factor (VEGF) is a glycoprotein that induces the microvascular permeability and angiogenesis during the stage of proliferation.[93] The cytokine is activated by hypoxic conditions and furthermore by IL-1β and TGF-β.[94,95] The VEGF gene is organized in eight exon subunits separated by seven intron sequences.[96] $VEGF_{165}$ is the prevalent molecular type synthesized and secreted by fibroblasts and keratinocytes.[83] Native $VEGF_{165}$ is a basic, heparin-binding, homodimeric glycoprotein.[97] Johnson et al. found significantly higher concentrations of VEGF in inflammatory gingival tissue compared with unaffected oral mucosa.[98] Suthin et al.[99] described bacterial liposaccharides to be responsible for the stimulation of VEGF secretion. Independent from this involvement in inflammatory processes, VEGF is excreted during every wound healing by keratinocytes.[100]

Whether the surgical implantation itself may cause a potential increase in the expression of inflammatory cytokines such as TGF-β_1, IL-1β, and VEGF in peri-implant soft tissue has not yet been investigated in a clinical follow-up.[83]

Peri-implant tissues become hemorrhagic and edematous in the course of healing disturbance or peri-implantitis.[83] There is little information concerning the biological mechanisms that may produce these alterations.[83] Existing clinical trials have investigated the expression of cytokines in the peri-implant region in inflammatory impaired soft tissues and have reported increased levels of IL-1β, TGF-β_1, and VEGF in the course of inflammation.[90,101-103] In vitro data show increased values of IL-1β, IL-6, and tumor necrosis factor alpha if tissue is incubated with dental implants.[104,105]

In an experimental setting, Shull et al.[106] described severe and uncontrollable inflammatory reactions in TGF-β–negative mice. The phagocytosis activity of neutrophil granulocytes and macrophages may be reduced.[83] High levels of TGF-β_1 can further result in impaired cross-linking of collagen structures and fibrotic transformation of tissue.[107] In experimental models the use of TGF-β–neutralizing antibodies results in a reduction of fibrotic processes during wound healing.[108] In contrast, higher levels of TGF-β_1 itself seem to have a positive influence on successful implant integration: the synthesis of extracellular matrix and the proliferation of fibroblasts is stimulated while the expression of adhesion molecules in mucosal fibroblasts is enhanced.[109] In vitro studies also used topical application of TGF-β for enhancement of healing and strength of granulation skin wounds.[110]

Lipopolysaccharide adsorption processes on the titanium surface of implants may contribute to this cytokine activation, especially because the use of different implant types results in variable expression levels, as reported by Perala et al.[104] Because elevated levels of IL-1 cause tissue destruction, the application of IL-1 antagonists (IL-1 receptor antagonists or monoclonal antibodies) results in a reduction of tissue damage and limited inflammatory processes during experimentally induced periodontitis.[111,112] It has further been shown that IL-1 antagonism results in a reduced progression of inflammatory processes and a reduction in loss of attachment and bone destruction.[113]

VEGF is a powerful mitogen for endothelial cells and fulfills an important role in angiogenesis.[114] The differences in terms of stromal cell positivity for VEGF between healthy and peri-implantitis sites have been studied, and higher values were found in peri-implantitis.[115] Other studies proved VEGF to be an important factor in the initiation and progression of gingivitis to periodontitis, promoting expansion of the vascular network that coincides with progression of the inflammation.[98,116] The demonstration of high expression levels may point to the induction of neoangiogenesis during the periimplant healing processes.[98,115] This capability is also underlined by a study in which intramuscular application of recombinant VEGF improved perfusion and formation of vascular structures.[117]

TGF-β is composed of a family of multifunctional polypeptide growth factors involved in embryogenesis, inflammation, regulation of immune response, angiogenesis, wound healing, and extracellular matrix formation. TGF-β_1 is the most common isoform found in human tissues. A role for TGF-β in the pathogenesis of periodontal disease has been suggested.[101]

TGF-β_1 may be one of the most important factors in the regulation of the infiltrate and in the production of tissue repair with a stimulation of fibroblasts and endothelial cells.[101]

The long-term clinical and esthetic success of implant-supported restorations is determined by osseointegration and optimal remodeling of peri-implant soft tissues. Complications of soft tissue management are often caused by fibrotic regeneration of oral mucosa after multiple surgical procedures.[82] Knowledge of the proliferative processes in wound healing is necessary to attain adequate soft tissue conditions. Successful reconstruction of peri-implant soft tissues is feasible, even in fibrotic conditions when appropriate surgical techniques are selected. The pleiotropic proliferative

WWW.HIGHDENT.IR

همیار دندانسازان

cytokine TGF-β is involved in the regulation of all phases of wound healing and tissue remodeling.[83]

The isoform TGF-β_1 is a cytokine associated with the development of fibrotic tissue. Overexpression of TGF-β_1 causes scarring and fibrosis and results in limited clinical success of intraoral soft tissue management.[118] Experimental therapeutic approaches with neutralizing antibodies to block TGF-β_1 resulted in less scarring and a reduction of fibrosis.[118] Further molecular biological research of cell-matrix-cytokine interactions in wound healing will provide highly specific antifibrotic therapeutic approaches in the future.[118]

The extended elevation in the cytokine expression may be linked to the surgical process or to the existence of an implant-mucosa interface.[83] Clinical implications of these prolonged tissue remodeling processes may be the development of protocols with extended interim solutions to await the completion of soft tissue remodeling before permanent loading.[83]

Inflammatory infiltrate may be important in the evolution of inflammatory processes involving peri-implant tissues. Angiogenesis is an important feature of inflammation and healing, but its role in the development and progression or in the healing of periodontal lesions has not been elucidated. VEGF is a potent inducer of endothelial cell proliferation.[113]

Because of its extensive presence, VEGF is probably a factor in both the maintenance of periodontal physiology and in the progression of peri-implant inflammatory disease.[113]

Recombinant human platelet-derived growth factor (rhPDGF-BB) is a bioactive protein that has been combined with bone graft materials in an effort to regenerate the periodontium to its prediseased state more predictably. The combination of a biocompatible scaffold with this highly purified, recombinant human growth factor capitalizes on the stimulatory effects of PDGF on cellular migration and proliferation, with subsequent matrix formation, to drive the healing process toward regeneration.[119]

When using a growth factor such as rhPDGF-BB with broad wound healing activity, an added clinical benefit is the more rapid soft tissue wound healing pattern observed at the surgical site. This also may be seen as a patient-centered benefit because it allows dentists to provide for a patient's prosthetic care on a timely basis, leading to a faster return to normal function. Also, the patient may resume plaque control efforts earlier, which further facilitates the wound healing process.[119]

Barrier Membrane and Guided Bone Regeneration: The Layered Approach

Defect Size and Topography

The most predictable topography for a barrier membrane bone graft is for (1) an edentulous site that is 0.5 to 3.5 mm inadequate in width, or a Division B bone volume; (2) an extraction socket missing one wall of bone; (3) an implant insertion missing one wall of bone, or an implant repair at stage II uncovery missing one wall of bone. The size of bone defect is most predictable when a four or fewer tooth span is present. Edentulous spans of more than a quadrant become less predictable for BM augmentation. Therefore the more walls of bone missing, or the more width or length of bone desired, the less predictable the BM bone graft.

The clinical procedure for BM GBR should attempt to provide as many keys for bone augmentation as practical. The keys include: (1) absence of infection; (2) soft tissue closure; (3) space maintenance; (4) graft immobilization; (5) RAP; (6) host bone vascularization; (7) growth factors; (8) BMPs; (9) healing time; (10) defect size and topography; and (11) transitional prosthesis. The general principles for these keys are addressed in Chapter 36. The specifics of these factors for BM and GBR will be addressed in this section.

The layered approach to GBR was developed by Misch in the early 1990s.[12,120] This concept provides as many keys of bone grafting as possible to the GBR process. The "layers" in the GBR process include the following:

1. *The host bone.* The host bone provides a wall(s) of surrounding bone. Because it is also decorticated by holes through the cortical plate, the RAP of regeneration is increased and provides host bone blood vessels to the bone graft site. This action carries bone induction growth factors to the graft.
2. *An autograft.* An autograft placed directly on bone allows blood vessels to reach the bone graft to maintain viability for osteogenesis. The autograft also provides FGF to accelerate blood vessel growth from the host bone into the graft. It also has BMPs and other cell enhancement factors to grow bone by osteoinduction. The autograft acts as the spark to grow the bone more predictability and faster.
3. *A mixture of DFDB (30%), FDB (70%), and PRP.* The next layer for GBR provides growth factors (not as much as RAP and autograft) and space maintenance in the graft site. Bone is formed by osteoinduction from the DFDB and PRP and osteoconduction from the FDB (or mineralized bovine source) in this area.
4. *A BM and tent screw.* A BM prevents fibroblasts and connective tissue from invading the graft site for at least 6 weeks. By that time, the graft site is programmed to form bone. A tent screw decreases mobility of the particulate particles and helps ensure space maintenance for bone to form.
5. *Primary closure without tension.* Primary closure prevents contamination and loss of graft material.

Procedure

Host Site Preparation

The recipient site is first prepared for the BM GBR procedure. In the maxilla, the crestal incision is made

WWW.HIGHDENT.IR

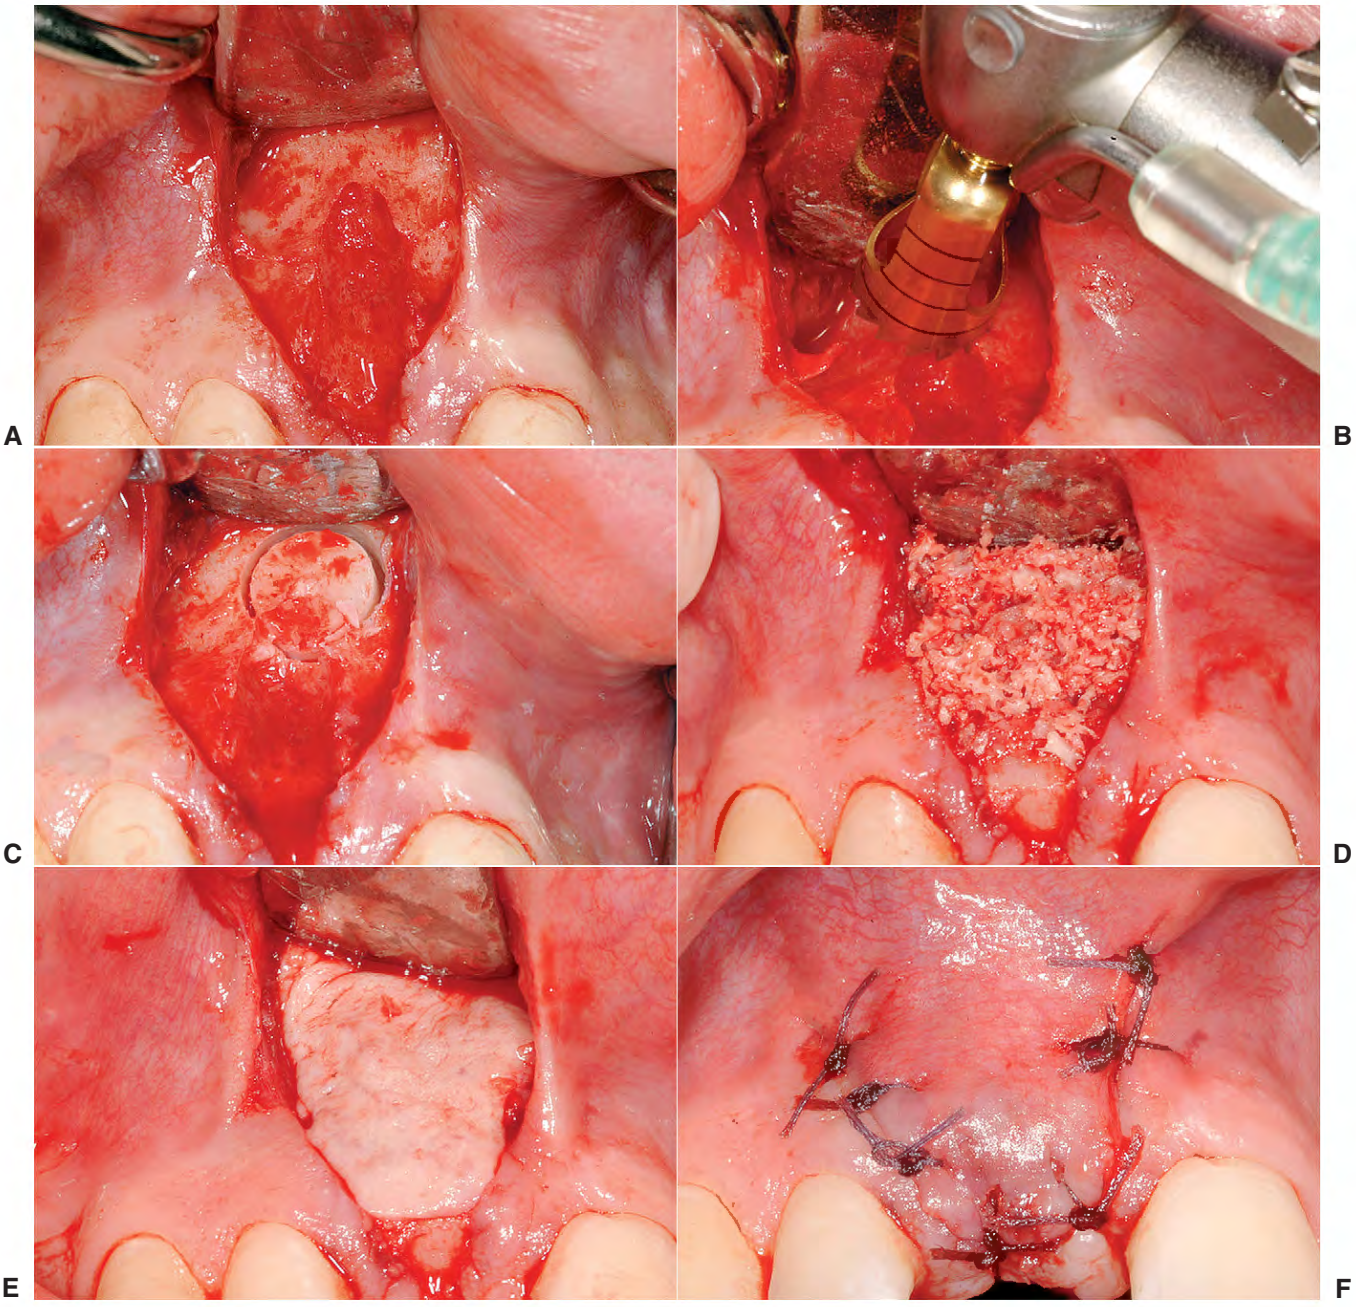

Figure 37-16 **A,** Papilla "saving" incisions are made to augment a central incisor region. **B,** A trephine bur is used to prepare a harvest site from above the apices of anterior teeth. **C,** The osteotomy of the donor site is observed. This bone core is removed and placed directly on the host bone. **D,** A mixture of 30% demineralized freeze-dried bone and 70% mineralized graft (MinerOss) is placed over the autograft. **E,** A barrier membrane (AlloDerm) is placed over the resorbable graft materials. The membrane is soaked in platelet-poor plasma. **F,** The soft tissue is approximated for primary closure.

slightly toward the palate or lingual, to place more keratinized tissue on the facial. Vertical release incisions are dependent upon the interdental papilla height next to the edentulous site. When the interdental papilla are ideal, a papilla-saving incision is made and the interdental papilla is not reflected (Figure 37-16). When the papilla is depressed in the height and contour, the usual vertical release incisions are one tooth distal to the graft site. When the interdental papilla has a probing depth of 6 mm or more, there is a risk the papilla will shrink after reflection and be more difficult to return to an ideal height. If the distal papilla has a probing depth less than 6 mm, the incision is distal to this structure and the papilla is reflected. If the probing depth of the distal papilla is greater than 6 mm and the papilla is in ideal position, it is not reflected and the vertical release incision is made mesial to the papilla. The vertical release incisions are made to the mucogingival junction (MGJ) (Figure 37-17).

A split-thickness reflection is made distal to the graft site and a full-thickness incision is made over the graft

amounts of saline to prepare multiple holes in the facial cortical plate, 3 to 5 mm apart for the entire site of the graft. The holes should penetrate the lingual plate when bone augmentation is desired on both the facial and lingual aspects of the ridge. Ridge resorption primarily affects the facial plate dimension, but 20% to 30% of the ridge resorption is at the expense of the lingual plate dimension. Remember, for every 0.5 mm of bone grown on the lingual, 0.5 mm less bone needs to be grown in the facial for adequate bone width for an implant. Regardless, at least one to three holes are drilled through the lingual plate, as these sites will be used for tent screws.

A large pear-shaped drill is then used to contour the facial plate and ensure any fibrous tissue attached to the bone in the graft site is removed, including any

WWW.HIGHDENT.IR

همیار دندانسازان

remaining periosteum. The margins of the graft site are especially prepared, to ensure blood vessels from the host trabecular bone can enter the graft site. This prepared host bone surface is the bottom layer of the graft site.

The facial flap is held with a tissue pick-up at the height of the MGJ. The flap is elevated 3 to 5 mm above the height of the MGJ (on the tissue side), and the periosteum is incised with a scalpel 1 to 2 mm deep. The incision is parallel to the crestal incision and extends above and beyond the vertical release incisions.

A soft tissue scissors (e.g., Metzenbaum) with the blades closed is pushed through the periosteal incision and parallel to the surface mucosa for approximately 10 to 15 mm. The blades of the scissors are then opened to form a split-thickness submucosa space to be developed. This procedure allows the facial flap to be advanced over the bone graft for primary closure without tension.

One to three fixation screws are then inserted into the host site and extend above the bone for the desired dimension of the graft after healing. If the desire is to gain 3 mm in width, the screw is elevated 3 mm above the host bone. The tent screw has three primary functions. First it gives a visual indication of how much autograft should be harvested. Second, it helps maintain the space under the barrier membrane during bone formation. Third, it decreases movement of the particulate graft under the transitional prosthesis.

Autologous Donor Site Preparation

The autograft donor site is then addressed. This graft harvest is usually with a trephine bur and, when possible, is near the recipient site. The donor site may be above the graft site in the maxilla or below the site in the mandible. Other sites include the maxillary tuberosity, the ascending ramus, exostoses or tori, debris from the implant osteotomies, the tibia, the mandibular symphysis, palate, and zygomatic process. (In other words, anywhere the surgeon and patient feel comfortable.) Ideally, the pieces of bone harvested are 3 × 5 × 5 mm in size and the amount of bone is enough to cover the bone graft host site to the height of the tent screw.

LAYER GRAFT POSITIONS

The pieces of donor bone are placed directly on top of the host bone site, fill the desired shape and height/width of the desired augmentation graft site and represent the bottom layer of the bone graft. This autograft position is best suited for osteogenesis, osteoinduction, and growth factor for bone and blood vessels to bone.

A mixture of 30% DFDB fibers (Grafton) and 70% FDB (MinerOss) or mineralized HA source (e.g., BioOss, Osteograf N-300) is mixed with PRP harvested from 10 to 20 mL of blood that is collected at the start of the procedure. These materials are all mixed together, inserted into an open bone 3-mL syringe, and transferred to the mouth. The material is placed over the autograft and serves as the third layer of the bone graft.

A BM (collagen [Biomend, Ossix] or acellular dermal matrix [AlloDerm]) is soaked in PRP (when enough is present) or platelet-poor plasma (PPP) and covers the previous layer of the graft site. This is the next layer of the bone graft. The barrier membrane may be sutured under the palatal/lingual flap before placing the autograft and the graft mixture. Once the BM is rotated over the graft material, it may be fixed above the graft site to the facial plate by fixation tacks. The membrane is compressed with a moist surgical sponge to ensure close adaptation of the graft to the host bone. The membrane should not be placed under the vertical release incisions. Instead, the reflected soft tissues should be over the split-thickness tissue and bone. The membrane should also be 2 to 3 mm from the sulcus of a tooth.

The tissues are approximated over the BM for primary closure without tension. If tension on the incision line is observed, a deeper submucosal space is created with blunt dissection using the tissue scissors. The vertical release incisions are first approximated to ensure correct position of the soft tissue around the teeth. A horizontal mattress suture is often placed in the middle of the graft site to overt the margins of the incision and ensure closure without tension. A continuous nonlocking suture usually finalizes the primary closure on the crest. The donor site is then filled with resorbable collagen (CollaTape) and the tissue approximated (Figure 37-18).

Gentle pressure is applied to the graft site for 3 to 5 minutes; any blood below the tissue is milked through the incision line and the incision inspected to ensure no particulate graft or BM material is present.

Reentry into a BM GBR is most often after 6 to 9 months, dependent upon the size of the defect and the amount of autograft (Figures 37-19, 37-20). When incision line opening has occurred during the first month, a longer healing time is required to compensate for the compromised conditions on the crestal portion of the graft site.

Implant Insertion and Guided Bone Regeneration

Guided bone regeneration has been successfully reported at the time of implant insertion in both animal and human trials.[29,121-124] In most of these reports, the threads of the implant were exposed on only one side.[29,121] The procedure is less at risk when the GBR is for width only, not for both width and height. The technique is very similar to that already presented. The osteotomy of the implant site is prepared to the opposing landmark (when

Continued

possible), and the bone debris is harvested from the drills. The implant length does not need to be as deep as the osteotomy, but the extra depth allows more bone to be harvested.

Holes in the cortical bone distal to the implant (not directly over the intact lateral bone), tent screws, autograft, the second layer of DFDB (30%), FDB (70%), PRP, and the top of the graft are covered with a BM with primary closure of the soft tissue.

The most difficult part of GBR at the time of implant insertion is to ensure that the implant is positioned for the prosthesis without compromise, rather than positioned

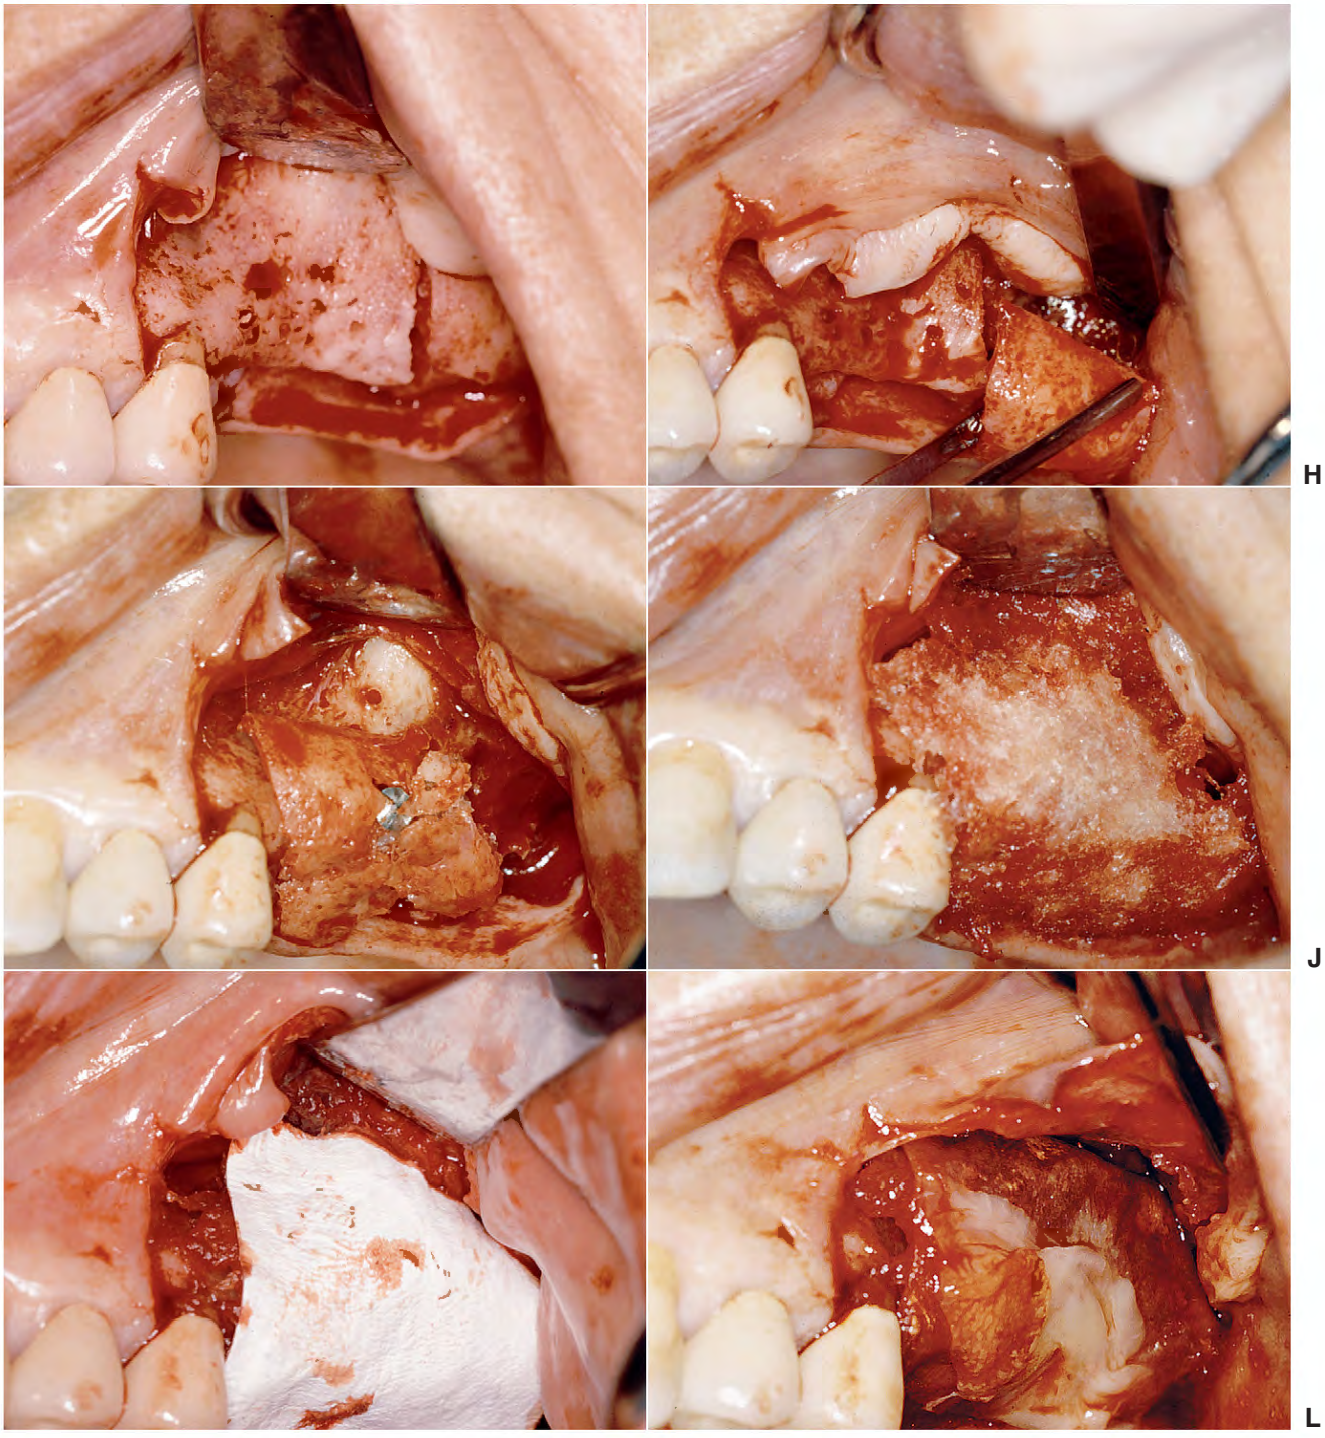

Figure 37-18, cont'd **G,** A large pear-shaped drill contours the facial bone to increase the regional acceleratory phenomenon and eliminate any remaining soft tissue on the surface. **H,** The tuberosity is harvested with chisels and a mallet. **I,** A tent screw is inserted into the facial plate and extends out from the bone the desired distance of augmentation. Autograft from the tuberosity is placed directly on host bone to the level of the tent screw. **J,** A 30% demineralized freeze-dried bone and 70% mineralized bone mixed with platelet-rich plasma (PRP) is placed over the autograft. **K,** A collagen barrier membrane (BM) (Biomend, Zimmer) is placed over the layered graft material. **L,** PRP is placed on the BM. *Continued*

more palatal (lingual) or angled to engage more host bone. The position of the implant should not be compromised so as to improve the success of the bone graft or to improve the osteointegration rate. The implants are useful for the prosthesis, not the bone graft. When the implant cannot be inserted in the correct position (in all three planes) because of the inadequate host bone, only the bone graft should be performed. Only after graft maturity can the implant be inserted.

It should be noted in the anterior regions of the mouth, the GBR procedure (with acellular dermal matrix) is used over the labial plate whenever it is less than 1.5 mm thick. This reduces the risk of marginal bone loss on the facial, which would result in shrinkage

The tissues are sutured around the healing abutment for primary closure. **Q,** After 5 months, abutments are inserted into the implant and a periapical radiograph confirms proper seating and the maintenance of bone levels. **R,** The abutments are prepared to restore the maxillary first and second molars.

or recessing of the soft tissue at the cervical of the implant crown (Figure 37-21).

Tooth Extraction and Immediate Implant Insertion

The GBR procedure may be used when an implant is immediately placed after a tooth extraction when conditions permit the implant to be positioned without compromise to the prosthesis.[125-127] The osteotomy for the implant is made to the opposing landmark. The autograft is positioned over the implant and completely fills the extraction defect. The second layer of graft material is placed over the facial thin or missing bone. The barrier membrane is placed over the missing (or thin) bony wall, usually the facial. When a facial

plate of the bone is missing, primary closure of the soft tissue is preferred (Figure 37-22).

Transitional Prosthesis

The transitional prosthesis over a particulate graft should not rest on the soft tissue over the graft site. The tent screws provide some protection to the graft site; in addition, an FTP is more predictable for the process. Particulate grafts are more prone to movement during healing, which prevents blood vessels from entering and forming bone in the site.

Healing Time

The healing time of a layered particular BM GBR process is variable and may be from as little as 3 to 4 months to as long as 10 months, depending upon the size of

WWW.HIGHDENT.IR

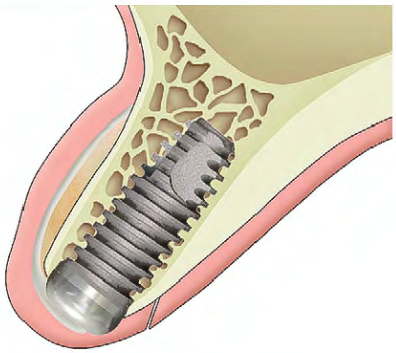

Figure 37-21 An implant may be inserted in the correct position, but the labial plate is less than 1.5 mm thick. A graft and a barrier membrane on the facial of an implant are indicated when the facial plate is thin and bone loss increases the risk of an esthetic compromise.

the augmentation, the number of walls of host bone, and the amount of autograft used in the graft site. As a general rule, it is better to wait 2 months too long than 2 days too little. Many graft sites that are entered too soon give the appearance the technique did not succeed. In reality, the immature bone and cartilage that initially form may be mixed with the bone graft materials, and the creeping substitution process of osteoconduction may be incomplete. Therefore waiting more than 6 months and less than 10 months is the general rule.

The period for graft maturity begins after the soft tissues have healed over the graft site. If incision bone opening occurred during the few weeks of initial healing,

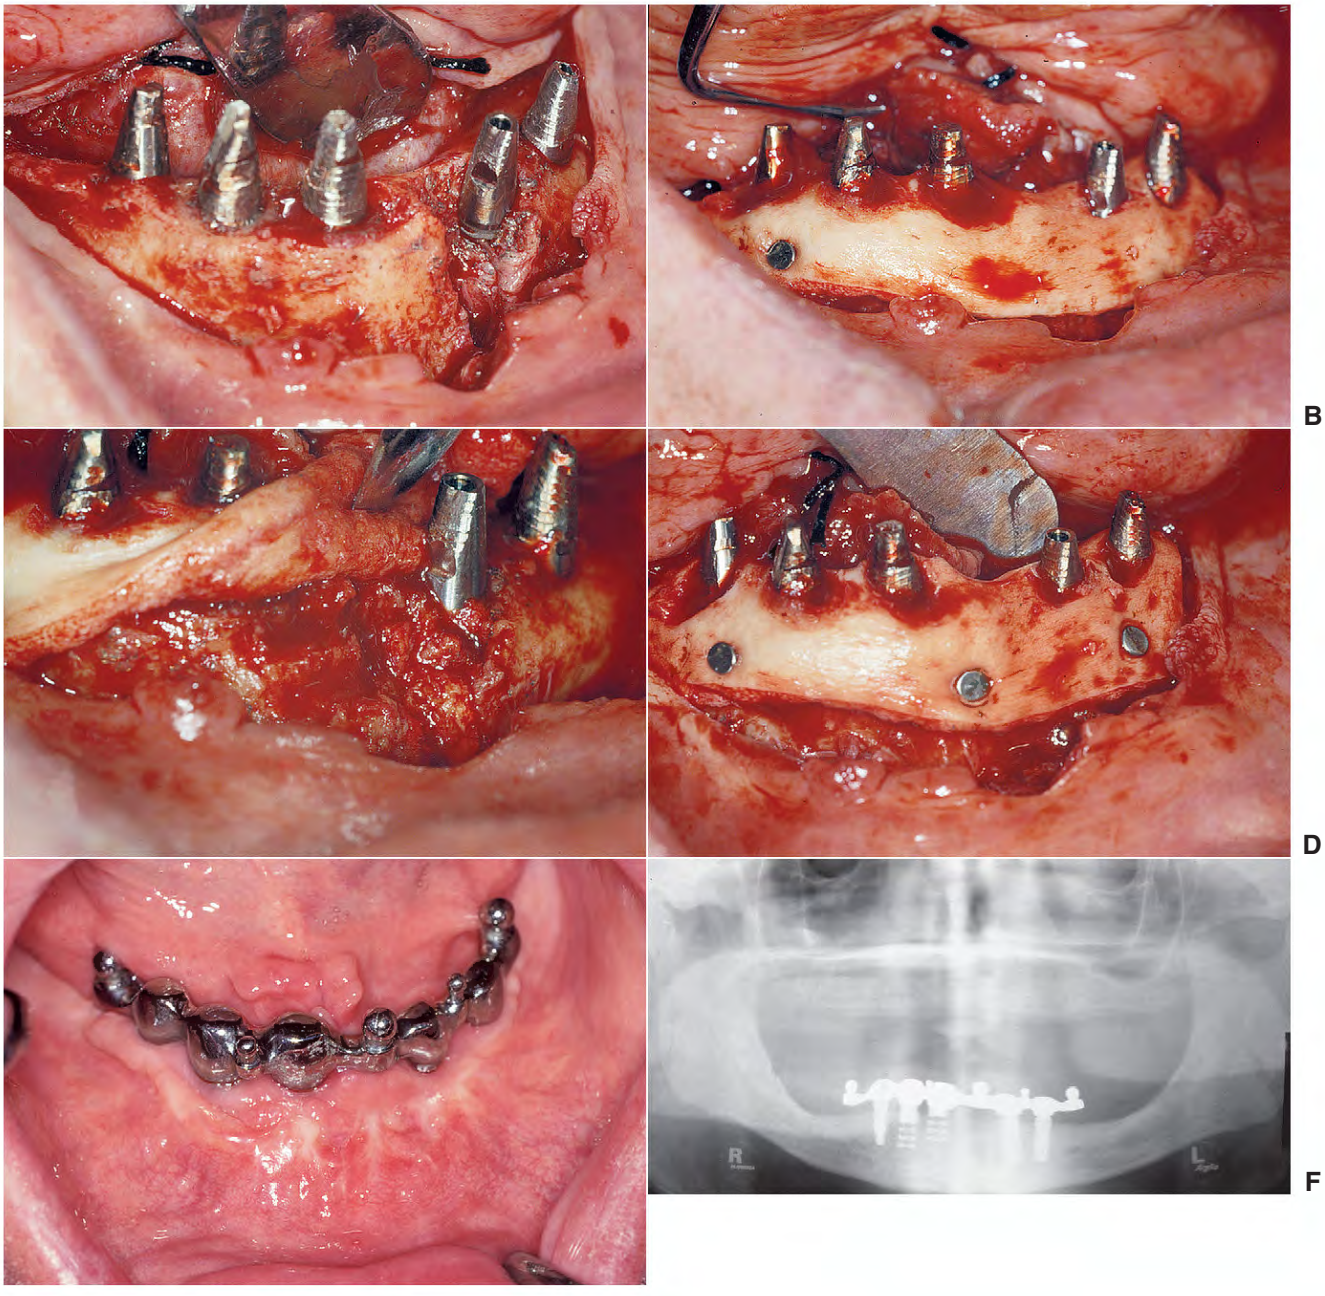

Figure 37-22 **A,** Five implants A, B, C, D, and E are inserted into an anterior mandible, and a large defect is present on the mesial of the D implant. **B,** An acellular dermal matrix barrier membrane (AlloDerm) is placed around the implants. **C,** Autograft is placed into the defect. **D,** The AlloDerm covers the autograft. **E,** Soft tissue healing is uneventful. **F,** A panoramic radiograph of the integrated implants and overdenture bar.

WWW.HIGHDENT.IR

the period of the graft should not begin until the soft tissues are healed over the graft site.

SUMMARY

The use of BMs in implant dentistry is common in conjunction with bone augmentation, implant insertion after extraction, and extraction sites with ridge preservation. A layered approach to BM and GBR improves the success rates and decreases the healing time. Trephine bur particulate bone harvesting from the tuberosity and ramus is often used for this technique. The learning curve of these procedure are easier than block bone grafting and the complications are fewer. As a result, nearly all implant surgeons should be able to use BM as a regular part of a surgical implant treatment protocol.

Chapter 38

Maxillary Sinus Anatomy, Pathology, and Graft Surgery

Carl E. Misch, Randolph R. Resnik, Francine Misch-Dietsh

Maxillary posterior partial or complete edentulism is one of the most common conditions in dentistry.[1] Thirty million people in the United States, or 17.5% of the adult population, are missing all of their maxillary teeth. In addition, 20% to 30% of the adult partially edentulous population older than 45 years is missing maxillary posterior teeth in one quadrant, and 15% of this age group is missing the maxillary dentition in both posterior regions. In other words, approximately 40% of adult patients are missing at least some maxillary posterior teeth. This chapter addresses the treatment concepts specific to the maxillary posterior partial or complete edentulous regions.

The maxillary posterior edentulous region presents many unique and challenging conditions in implant dentistry. Most noteworthy surgical methods include sinus grafts to increase available bone height, onlay grafts to increase bone width, and modified surgical approaches to insert implants in areas with poorer bone density.[2] Grafting of the maxillary sinus to overcome the problem of reduced vertical available bone has become a very popular and predictable procedure over the last decades. After the initial introduction by Tatum in the mid 1970s and the initial publication of Boyne and James in 1980, many studies have been published about sinus grafting with positive results.[3-38] In 1983, Misch[2] observed the most predictable intraoral region to grow bone height is on the maxillary sinus floor, once the sinus mucosa has been elevated. This statement still holds true today.

ANATOMICAL CONSIDERATIONS OF THE POSTERIOR MAXILLA

The maxilla has a thinner cortical plate on the facial compared with any region of the mandible. In addition, the trabecular bone in the posterior maxilla is finer than other dentate regions. The loss of maxillary posterior teeth results in an initial decrease in bone width at the expense of the labial bony plate. The width of the posterior maxilla decreases at a more rapid rate than in any other region of the jaws.[39] The resorption phenomenon is accelerated by the loss of vascularization of the alveolar bone and the existing fine trabecular bone type. However, because the initial residual ridge is so wide in the posterior maxilla, even with a 60% decrease in the width of the ridge, adequate-diameter root form implants usually can be placed. However, the ridge progressively shifts toward the palate until the ridge is resorbed into a medially positioned narrower bone volume.[40] The posterior maxilla continues to progressively remodel toward the midline as the bone resorption process continues. This results in the buccal cusp of the final restoration often being cantilevered facially to satisfy esthetic requirements at the expense of biomechanics in the moderate to severe atrophic ridges.[41]

DENTAL CONTRAINDICATIONS FOR IMPLANT TREATMENT OF THE POSTERIOR MAXILLA

A rule in traditional prosthodontics is that a fixed prosthesis is contraindicated when the canine and two adjacent teeth are missing. Therefore, when the canine and both premolars are missing, a fixed restoration is contraindicated. A removable prosthesis that has no movement under function is considered a fixed prosthesis and therefore should follow the rules of treatment planning for a fixed prosthesis in relation to implant number and position. A minimum of a healthy natural canine tooth or an implant abutment in the canine region is required before posterior implants are considered in the quadrant.

WWW.HIGHDENT.IR

همیار دندانسازان

Abnormal intraoral conditions may compromise the final outcome of sinus-grafting procedures and/or the survival rates of dental implants placed in the grafted sinuses. These contraindications are similar to those reported for standard implant treatment of edentulous patients and may be summarized as follows:

- Inadequate oral hygiene
- Untreated periodontal disease of the residual dentition
- Severe malocclusion
- Severe bruxism with loss of incisal guidance
- Active infection

Decreased Crown Height Space

The crown height space (CHS) should be evaluated before implant placement. Once the occlusal plane is properly restored or modified, the CHS should be greater than 8 mm (Figure 38-1). If less space is available for prosthodontic reconstruction, then a gingivectomy is first considered because it is not uncommon for excess tissue thickness to be present in this region. However, if tissue reduction cannot correct the CHS problem, then osteoplasty and/or vertical osteotomy of the maxillary posterior alveolar process are indicated to improve the vertical ridge orientation before implant surgery.

Poor Bone Density

In general, the bone quality is poorest in the posterior maxilla compared with any other intraoral region.[42] A literature review of clinical studies from 1981 to 2001 reveals the poorest bone density may decrease implant loading survival by an average of 16%, and it has been reported as low as 40%.[43] The cause of these failures is related to several factors. Bone strength is directly related to its density, and the poor-density bone of this region is often five to 10 times weaker compared with bone found in the anterior mandible.[44] Bone densities directly influence the bone-implant contact percent (BIC), which accounts for the force transmission to the bone. The BIC is least in D4 bone, and the stress patterns in this bone migrate farther toward the apex of the implant (Figure 38-2). As a result, bone loss is more pronounced and occurs also along the implant body, rather than only crestally as in other denser bone conditions. D4 bone also exhibits the greatest biomechanical elastic modulus difference when compared with titanium under load.[44] As such, strategic choices to increase BIC are suggested.

In the posterior maxilla, the deficient osseous structures and an absence of cortical plate on the crest of the ridge is often observed, which further compromises the initial implant stability at the time of insertion. The labial cortical plate is thin, and the ridge is often wide. As a result, the lateral cortical BIC to stabilize the implant is often insignificant. Implant surgery more often uses bone compression rather than bone extraction to create the implant osteotomy to compensate for these deficiencies. As a consequence, initial healing of an implant in D4 bone is often compromised.

Figure 38-1 The crown height space (CHS) in the posterior maxilla should be at least 8 mm for prosthetic reconstruction. Reduced CHS requires osteoplasty before implant insertion, which reduces the existing available bone height.

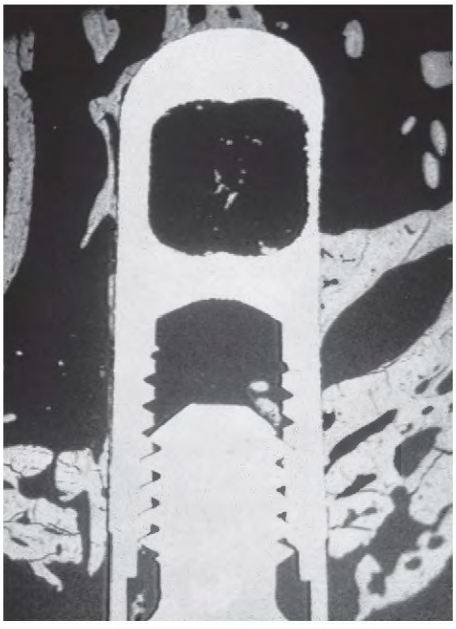

Figure 38-2 The bone-implant contact percent is often reduced in the posterior maxilla, because the quality of bone is poorer than other regions of the mouth.

Implant Size

The ideal length of the implant is directly related to the implant width, the design, the amount of the forces, and the bone density. Because implant success after loading is reduced in implants shorter than 10 mm, it is logical

WWW.HIGHDENT.IR

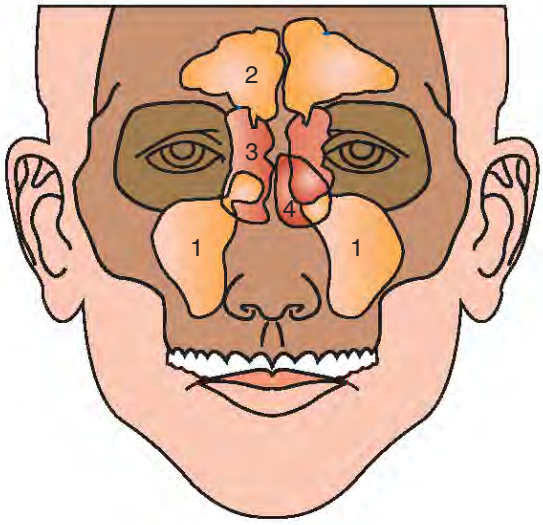

Figure 38-3 The maxillary sinuses *(1)* are the largest of the paranasal sinuses, followed by the frontal *(2)*, ethmoid *(3)*, and sphenoid sinuses *(4)*.

to treatment plan longer implants in the region. In general, 4-mm threaded root form implants should be at least 12 mm in length when the bone density is poor. This usually provides adequate BIC to dissipate the loads applied to the prosthesis. Implants longer than 16 mm are not necessary, even in the softest bone type, because the stress transfer is not dissipated beyond this length. Therefore the implant most often should be 12 to 16 mm long in this region of the mouth. Sinus grafting is usually required before or in conjunction with implant placement to gain adequate bone height for implants of adequate length in this region. The poor bone density requires implants of a larger size, including length. The implant length requirement is greater because the transmission of stress is expressed farther down the implant length.

MAXILLARY SINUS

The anatomy of the maxillary sinuses was first illustrated and described by Leonardo da Vinci in 1489 and later documented by the English anatomist Nathaniel Highmore in 1651.[45] The maxillary sinus (or antrum of Highmore) lies within the body of the maxillary bone and is the largest of the paranasal sinuses, as well as the first to develop (Figure 38-3).

Maxillary Sinus Development

A primary pneumatization of the maxillary sinus occurs at about 3 months of fetal development by an out-pouching of the nasal mucosa within the ethmoid infundibulum. At this time the maxillary sinus is a bud situated at the infralateral surface of the ethmoid infundibulum between the upper and middle meatus.[46] Prenatally, a secondary pneumatization occurs. At birth, the sinuses are filled with fluid and the maxillary sinus is still an oblong groove on the mesial side of the maxilla, just above the germ of the first deciduous molar.[47]

Postnatally and until the child is 3 months of age, the growth of the maxillary sinus is closely related to the pressure exerted by the eye on the orbit floor, the tension of the superficial musculature on the maxilla, and the forming dentition. As the skull matures, these three elements influence its three-dimensional (3D) development. At 5 months, the sinus appears as a triangular area medial to the infraorbital foramen.[48]

During the child's first year, the maxillary sinus expands laterally underneath the infraorbital canal, which is protected by a thin bony ridge. The antrum grows apically and progressively replaces the space formerly occupied by the developing dentition. The growth in height is best reflected by the relative position of the sinus floor. At 12 years of age, pneumatization extends to the plane of the lateral orbital wall, and the sinus floor is level with the floor of the nose. The main development of the antrum occurs as the permanent dentition erupts and pneumatization extends throughout the body of the maxilla and the maxillary process of the zygomatic bone. Extension into the alveolar process lowers the floor of the sinus about 5 mm (Figure 38-4). Anteroposteriorly, the sinus expansion corresponds to the growth of the midface and is completed only with the eruption of the third permanent molars when the young person is about 16 to 18 years of age.[46-48]

In the adult, the sinus appears as a pyramid of five thin, bony walls. The base of this pyramid faces the lateral nasal wall and often measures 33 × 33 mm; its apex extends approximately 23 mm toward the zygomatic bone.[49,50] The dentate adult maxillary sinus has an average volume of 15 mL, although the range is 9.5 to 20 mL.[51] The floor of the maxillary sinus cavity is reinforced by bony or membranous septa joining obliquely or transversely from the medial and/or lateral walls with buttresslike webs. They may be genetic or develop as a result of stress transfer within the bone over the roots of teeth. These have the appearance of reinforcement webs in a wooden boat and rarely divide the antrum into separate compartments. These elements are present from the canine to the molar region, and Misch[41] has observed they tend to disappear in the maxilla of the long-term edentulous patient when stresses to the bone are reduced. Karmody et al.[52] found that the most common oblique septum is located in the superior anterior corner of the sinus or infraorbital recess (which may expand anteriorly to the nasolacrimal duct). The medial wall is juxtaposed with the middle and inferior meatus of the nose.

Although the adult maxillary sinus maintains its overall size while the teeth are present, a rather rapid expansion phenomenon of the maxillary sinus occurs

WWW.HIGHDENT.IR

همیار دندانسازان

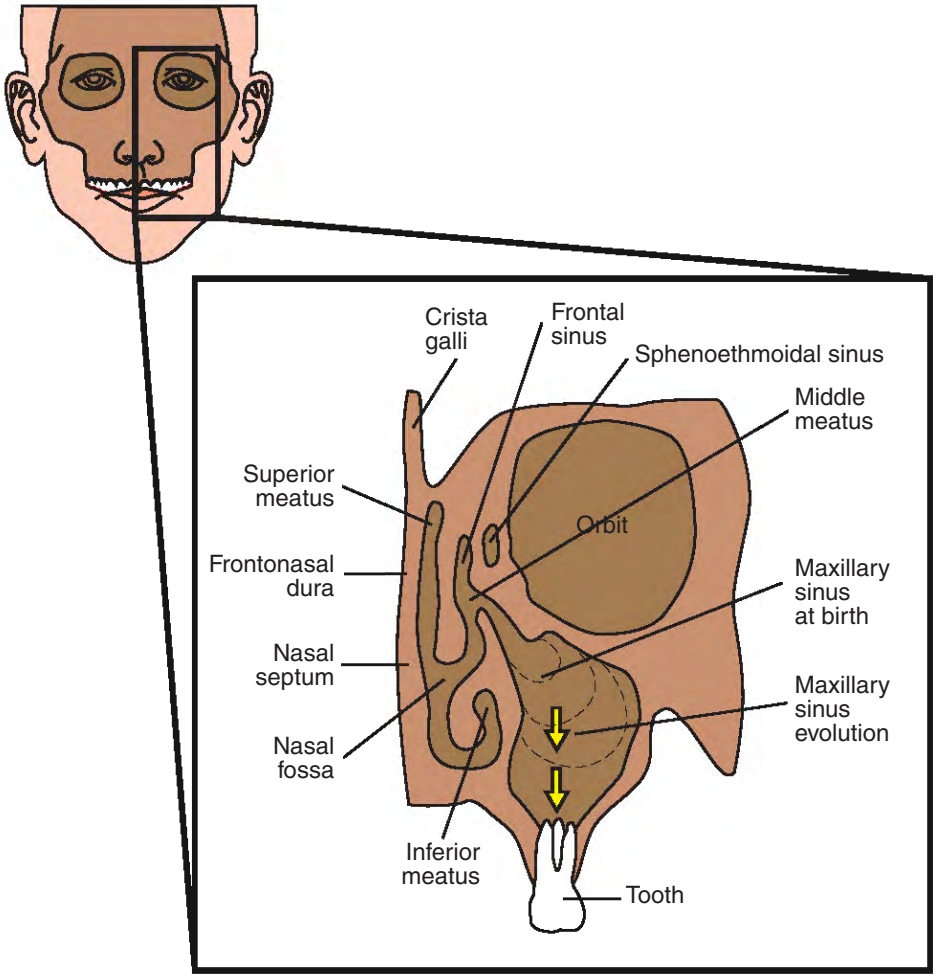

Figure 38-4 The maxillary sinus development increases in size during the growth of the midface of the maxilla and is also related to the eruption of the deciduous teeth, followed by the permanent dentition.

with the loss of posterior teeth. In fact, even with the loss of a single molar, the sinus expands between the adjacent tooth roots. In the edentulous maxilla, the antrum expands in both inferior and lateral dimensions and may even invade the canine eminence region and proceed to the lateral piriform rim of the nose. This results in a lack of available bone in the posterior maxilla and a greatly decreased height from both the sinus expansion and the crestal resorption. Frequently, less than 10 mm remains between the alveolar ridge crest and the floor of the maxillary sinus in the edentulous posterior maxilla. This limited dimension is compounded by the problem of bone of reduced quality and the resultant medial posterior position of the ridge after resorption of bone width. As a result, compromises in the long-term prognosis of many endosteal implant systems are reported.[43]

Maxillary Sinus Anatomy

Maxillary sinus grafts have become a predictable procedure before or in conjunction with implant insertion. However, infections of the maxillary sinus are common and may not only cause implant failure but also may be life-threatening to the patient. As a result, the dentist should be knowledgeable of both the macroscopic and microscopic anatomy, as well as the pathologic conditions that may occur before or postoperative to the sinus graft procedure.

Six bony walls that contain many structures of concern during sinus graft surgery surround the maxillary sinus.[45,53] Knowledge of these structures is crucial for both preoperative assessment and postsurgical complications.

Anterior Wall

The anterior wall of the maxillary sinus consists of thin, compact bone extending from the orbital rim to just above the apex of the cuspid. With the loss of the canine, the anterior wall of the atrum may approximate the crest of the residual ridge. Within the anterior wall and approximately 6 to 7 mm below the orbital rim, with anatomic variants as far as 14 mm from the orbital rim, is the infraorbital foramen (Figure 38-5).

WWW.HIGHDENT.IR

Figure 38-5 The infraorbital foramen is located approximately 10 mm below the orbital rim. The anterior wall of the maxillary sinus in this skull has a horizontal cut just below the infraorbital foramen. The thin anterior wall is often used for surgical access to the maxillary sinus for Caldwell-Luc procedures.

Figure 38-6 A frontal section of a head demonstrates the frontal sinus above and between the orbits and the maxillary sinuses directly below the orbits. A thin bony wall acts as the floor of the orbit and superior wall of the maxillary sinus. On the left, the infraorbital canal is in the outer third of the superior wall. On the right, the infraorbital canal is located at the junction of the apex of the superior and lateral-wall connection. The lateral wall of the sinus in this edentulous adult is the thickest wall but is only 1 mm thick. The medial wall of the maxillary sinus is thin, separates the maxillary sinus from the nares, and houses the inferior meatus in the bottom half of the sinus. Located in the superior-most aspect of this wall is the primary ostium that connects the maxillary sinus to the nares. The inferior wall represents the base of the existing posterior available bone and is the floor of the maxillary sinus.

The infraorbial nerve runs along the roof of the sinus and exits through the foramen. The infraorbital blood vessels and nerves lie directly on the superior wall of the interior and within the sinus mucosa. Tenderness to pressure over the infraorbital foramen or redness of the overlying skin may indicate inflammation of the sinus membrane from infection or trauma. The anterior wall of the maxillary sinus may serve as surgical access during Caldwell-Luc procedures to treat a preexisting or post–sinus graft, pathologic condition.

Superior Wall

The superior wall of the maxillary sinus is shared with the thin orbital floor (Figure 38-6). The orbital floor slants inferiorly in a mediolateral direction and is convex into the sinus cavity. A bony ridge is usually present in this wall that houses the infraorbital canal containing the infraorbital nerve and associated blood vessels. Dehiscence of the bony chamber may be present, resulting in direct contact between the infraorbital structures and the sinus mucosa. Ocular symptoms may result from infections or tumors in the superior aspects of the sinus region and may include proptosis (bulging of the eye) and diplopia (double vision). When these problems occur, the patient is closely supervised and a medical consult is advised to decrease the risk of severe complications that may result from the spread of infection in a superior direction. Superior spreading infections may lead to a brain abscess and death. As a result, when these symptoms appear, aggressive therapy to decrease the spread of infection is indicated. Overpacking the maxillary sinus with bone graft material during a sinus graft may result in pressure against the superior wall if a sinus infection develops.

Posterior Wall

The posterior wall of the maxillary sinus corresponds to the pterygomaxillary region, which separates the antrum from the infratemporal fossa. The posterior wall usually has several vital structures in the region of the pterygomaxillary fossa, including the internal maxillary artery, pterygoid plexus, sphenopalatine ganglion, and greater palatine nerve. The posterior wall should always be identified on the radiograph. When lack of a posterior wall is present, a pathologic condition (including neoplasms) is to be suspected.

It should be noted that pterygoid implants placed through the posterior sinus wall and into this region might approach vital structures, including the maxillary artery. Therefore a blind surgical technique to place a pterygoid implant through the posterior wall may have increased surgical risk. Because pterygoid implants are often positioned in the third or fourth molar region, they are of benefit primarily when third or fourth molars are needed for prosthetic reconstruction or sinus grafts are contraindicated and available bone posterior to the antrum is present.

WWW.HIGHDENT.IR

همیار دندانسازان

Medial Wall

The medial wall of the antrum coincides with the lateral wall of the nasal cavity and is the most complex of the various walls of the sinus (see Figure 38-6). On the nasal aspect, the lower section of the medial wall corresponds to the lower meatus and floor of the nasal fossa; the upper aspect corresponds to the middle meatus. The medial wall is vertical and smooth on the antral side. Located in the superior aspect of the medial wall is the maxillary or primary ostium. This structure is the main opening through which the maxillary sinus drains its secretions via the ethmoid infundibulum through the hiatus semilunaris into the middle meatus of the nasal cavity. The infundibulum is approximately 5 to 10 mm long and drains via ciliary action in a superior and medial direction. This opening corresponds to the initial site of embryonic evagination from the nasal chamber. The ostium diameter averages 2.4 mm in health; however, pathologic conditions may alter the size to vary from 1 to 17 mm. Smaller, accessory or secondary ostia may be present that are usually located in the middle meatus posterior to the main ostium. These additional ostia are usually the result of chronic sinus inflammation and mucous membrane breakdown. They are present in approximately 30% of skulls, range from a fraction of a millimeter to 0.5 cm, and are commonly found within the membranous fontanelles of the lateral nasal wall.[54] Fontanelles are usually classified either as anterior fontanelles (AFs) or posterior fontanelles (PFs) and termed by their relation to the uncinate process. These weak areas in the sinus wall are sometimes used to create additional openings into the sinus for treatment of chronic sinus infections. Primary and secondary ostia may, on occasion, combine and form a large ostium within the infundibulum.

Lateral Wall

The lateral wall of the maxillary sinus forms the posterior maxilla and the zygomatic process (see Figure 38-6). This wall varies greatly in thickness from several millimeters in a dentate patient to less than 1 mm in an edentulous patient. The lateral wall houses an endosseous anastamosis of the infraorbital and posterior superior alveolar artery. The Tatum lateral-wall approach sinus graft procedure uses this area for entrance into the maxillary sinus (Figure 38-7).

Inferior Wall

The inferior wall or floor of the maxillary sinus is in close relationship with the apices of the maxillary molars and premolars (see Figure 38-6). The teeth usually are separated by the sinus mucosa by a thin layer of bone; however, on occasion, teeth may perforate the floor of the sinus and be in direct contact with the sinus lining. Studies have shown that the first molar has the most common dehiscent tooth root, occurring approximately 2.2% of the time. In dentate patients, the floor is approximately at the level of the nasal floor. In edentulous posterior maxillae, the sinus floor is often 1 cm below the level of the nasal floor. Complete or incomplete bony septa may exist on the floor in a vertical or horizontal plane. Almost 30% of the dentate maxillae have septa, with three fourths appearing in the premolar region.[55,56] Complete septa separating the sinus into compartments are very rare, occurring in only 1.0% to 2.5% of maxillary sinuses.

Maxillary Sinus: Vascular Supply and Innervation

The blood supply to the maxillary sinus comes directly from the maxillary artery, which emanates from the external carotid artery. The maxillary artery supplies the bone surrounding the sinus cavity and also the sinus membrane. Branches of the maxillary artery, which most often include the posterior superior alveolar artery and infraorbital artery, form endosseous and extraosseous anastomoses that encompass the maxillary sinus. The endosseous anastomosis is found within the lateral wall of the sinus and supplies this structure and the lateral aspect of the sinus membrane. A posterior lateral nasal artery (a branch of the sphenopalatine artery that also rises from the maxillary artery) also supplies this region from the medial aspect of the sinus.

The formation of the endosseous and extraosseous anastomoses in the maxillary sinus is termed the *double arterial arcade*. The extraosseous anastomosis is less common (present in 44% of the population) and is found near the periosteum of the lateral wall. The extraosseous anastomosis is superior to the endosseous unit, which is approximately 15 to 20 mm from the dentate alveolar crest. In addition to the double arterial arcade, a blood supply from the sphenopalatine artery supplies the central and medial parts of the sinus

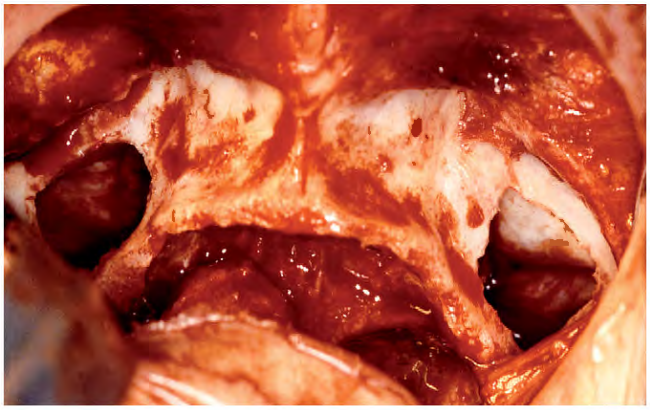

Figure 38-7 The lateral wall of the maxillary sinus most often extends from the second premolar region to the posterior wall of the maxilla. This wall serves as the surgical access to the sinus floor and medial wall for the sinus graft procedure. In this intraoral view, the lateral sinus wall has been infractured and now serves as part of the ceiling of the sinus graft or as the floor of the smaller maxillary sinus.

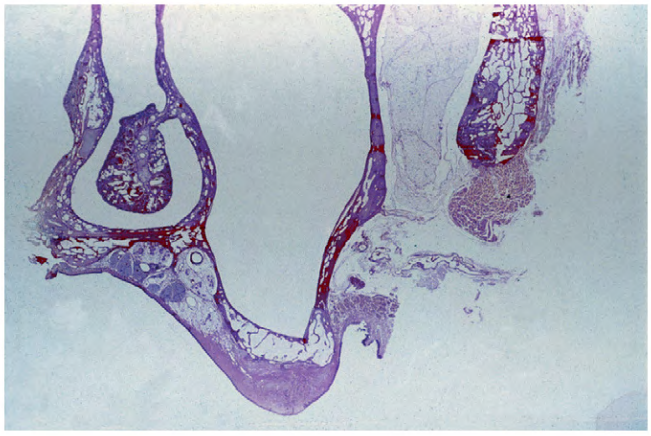

Figure 38-8 A maxillary ridge with advanced resorption results in a thinner lateral wall with no endosseous anastomosis. In this histologic cross section of a posterior edentulous maxilla, the available bone below the antrum is 2 mm in height and the lateral wall is 0.5 mm thick; a lack of endosseous anastomosis is evident.

membrane. This artery is also a branch of the maxillary artery and enters the maxillary sinus on the medial aspect via the maxillary ostium[57] (Box 38-1).

In an edentulous maxilla with posterior vertical bone loss, the endosseous anastamosis may be 5 to 10 mm from the edentulous ridge. The endosseous artery was able to be observed on computed tomography (CT) scans in approximately one half of the patients requiring a sinus graft.[58] In a long-term edentulous patient with a thin lateral wall, the artery may be atrophied and almost nonexistent. On rare occasions, this anatomical structure may be a concern for arterial bleeding complications during lateral-approach sinus elevation surgery.

Most often, implants of 12 to 16 mm in length should be used to support prostheses in the posterior maxilla, because the bone quality is poor and the occlusal force factors are high. Because the endosseous anastomosis is often present and ranges from 5 to 20 mm from the residual crest of the ridge, the lateral-access window for the sinus graft procedure often violates this arterial supply. However, this is usually of little concern during the surgical procedure and may even be of benefit postsurgery to provide a blood supply to the graft.

The size of the lateral-wall arterial anastomoses usually approximates 1.5 mm in a dentate patient and has little arterial pressure. Although the artery is often in the pathway of surgery for the Tatum lateral-wall approach to sinus grafting, endosseous bleeding is rarely observed as a pulsating rhythm and may be easily arrested by the following: (1) cutting the bone and vessel with a high-speed diamond and no irrigation (which cauterizes the vessel), (2) using electrosurgery on the vessel, and/or (3) elevating the head and using a surgical sponge (gauze) and slight pressure over the region for a few minutes. A hemostat may also be used to clamp the vessel, because it is readily observed; however, fracture of the lateral wall may occur.

The medial and posterior aspects of the maxillary sinus mucosa receive their blood supply from the posterior lateral nasal artery. The sphenopalatine artery is the third or fourth branch of the maxillary artery and enters the nasal cavity through the sphenopalatine foramen, which is near the posterior portion of the superior meatus of the nose. Once through the foramen, the sphenopalatine artery branches into the posterior lateral nasal artery and the posterior septal artery. The posterior lateral nasal artery supplies the medial and posterior walls of the antrum (nasal cavity).

The entire circulatory system in the maxillary sinus is a vital part of the healing and regeneration of bone after a sinus graft. Different factors can alter the vascularization in this area. With increasing age, the number and size of blood vessels in the maxilla decrease. As bone resorption increases, the cortical bone becomes thin, resulting in less vascularization. As the lateral wall becomes thinner, the blood supply to the lateral wall and lateral aspect of the bone graft comes primarily from the periosteum, resulting in a compromised vascularization to the region (Figure 38-8). After surgery the arterial supply in the lateral outer wall (in spite of being severed during the procedure) may help vascularize the sinus graft, because the anastomoses may vascularize the graft from both the posterior region and anterior region.

The venous drainage of the maxillary sinus originates from a vascular plexus near the maxillary ostium that drains anteriorly into the facial vein and posteriorly into the maxillary and jugular veins.

The nerve supply to the maxillary sinus is via numerous branches of the second division of the trigeminal nerve, including the posterior alveolar nerves, anterior palatine, and infraorbital nerves. The infraorbital nerve is of concern in sinus elevation surgery because of its anatomical position. This nerve enters the orbit via the inferior orbital fissure and continues anteriorly; the

WWW.HIGHDENT.IR

همیار دندانسازان

nerve lies in a groove in the orbital floor (which is also the maxillary sinus superior wall) before exiting the infraorbital foramen. Anatomical variants have been reported to include a dehiscence and malpositioned infraorbital foramen, along with the nerve transversing the lumen of the maxillary sinus rather than coursing through the bone within the sinus ceiling (orbital floor).

Maxillary Sinus Mucosa: Microscopic Anatomy

The microscopic primary epithelial cells of the maxillary sinus are a continuation of the nasal mucosa and classified as a pseudostratified, ciliated columnar epithelium. However, the epithelial lining of the maxillary sinus is much thinner and contains fewer blood vessels compared with the nasal epithelium. This accounts for the membrane's paler color and bluish hue. Five primary cell types exist in this tissue: (1) ciliated columnar epithelial cells, (2) nonciliated columnar cells, (3) basal cells, (4) goblet cells, and (5) seromucinous cells. The ciliated cells contain approximately 50 to 200 cilia per cell. In a healthy patient, they help to clear mucus from the sinus and into the nose. The nonciliated cells comprise the apical aspect of the membrane, contain microvilli, and serve to increase surface area. These cells have been theorized to facilitate humidification and warming of inspired air. The basal cell's function serves most likely as a stem cell that can differentiate as needed. The goblet cells produce glycoproteins that are responsible for the viscosity and elasticity of the mucus produced. The maxillary sinus has the highest concentration of goblet cells in comparison with the other paranasal sinuses.

Although the sinus mucosa has been called a *mucoperiosteum*, Sharawy and Misch[59] suggested that the periosteal portion of this membrane is not similar to the periosteum covering the cortical plates of the maxillary or mandibular residual ridges of the jaws and should not be considered a mucoperiosteum (Figure 38-9). The very minimal and usual absence of osteoblasts in this tissue and, instead, the presence of osteoclasts, may account for the enlargement of the antrum after tooth loss. The maxillary sinus membrane also exhibits few elastic fibers attached to the bone,[59] which simplifies elevation of this tissue from the bone. The thickness of the sinus mucosa varies, but is generally 0.3 to 0.8 mm.[60] In smokers, it varies from very thin and almost nonexistent to very thick, with a squamous type of epithelium.

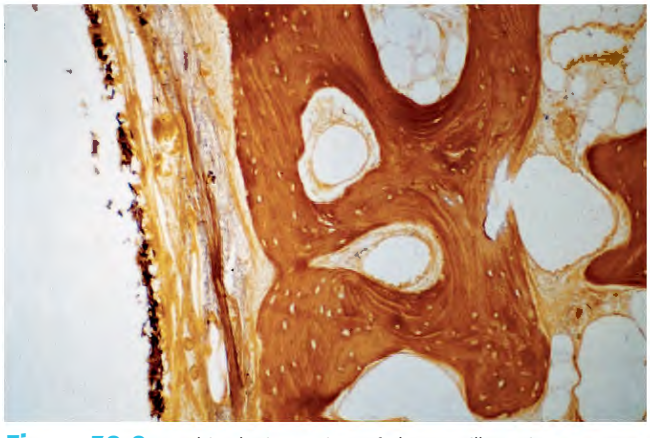

Figure 38-9 A histologic section of the maxillary sinus mucosa demonstrates cilia to the left. An absence of blood vessels and elastic fibers exists in the tissue adjacent to the surrounding bone. No osteoblasts are evident between the sinus mucosa and the surrounding walls of bone.

Maxillary Sinus Mucous Clearance

The mucus of the maxillary sinuses is produced from serous and goblet cells, which produce 1 L of mucus each day in healthy conditions. The cilia in the maxillary sinus beat toward the ostium. A blanket of mucus is propelled toward the ostium by the beating motion of the ciliated lining cells. The mucous material of the sinus in health has two layers: (1) a top mucoid layer and (2) a bottom serous layer (Figure 38-10). The top layer is sticky and collects bacteria and other debris, whereas the serous layer is thin and acts as a lubricant. The cilia of the columnar epithelium beat toward the ostium at 15 cycles per minute, with a stiff stroke through the serous layer, reaching into the mucoid layer. The cilia recover with a limp reverse stroke within

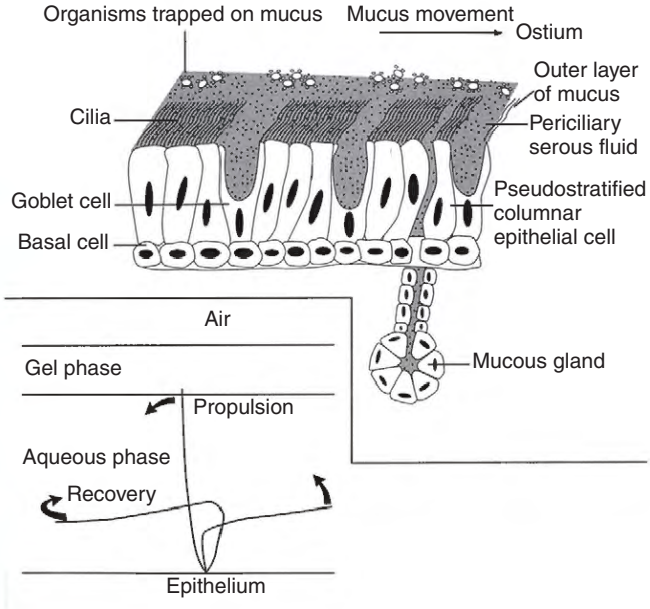

Figure 38-10 The pseudostratified columnar epithelium cells have 50 to 200 cilia per cell that beat toward the ostium to help clear 1 L of mucus from goblet and mucous glands each day from the sinus. In health, the mucous has two layers: a bottom serous layer and top mucoid layer. The cilia beat with a stiff stroke in the mucoid layer toward the ostium and a relaxed recovery stroke within the serous layer.

WWW.HIGHDENT.IR

the serous layer. This mechanism slowly propels the mucoid layer toward the ostium at a rate of 9 mm per minute and into the middle meatus of the nose.[60]

Various elements may decrease the number of cilia and slow their beating efficiency. Viral infections, pollution, allergic reactions, and certain medications may affect the cilia in this way.[61-63] Genetic disorders (e.g., dyskinetic cilia syndrome) and factors such as long-standing dehydration, anticholinergic medications and antihistamines, cigarette smoke, and chemical toxins also can affect ciliary action. Certain pathogens *(Haemophilus influenzae, Streptococcus pneumoniae, Pseudomonas aeruginosa)* associated with sinusitis have been shown to release a compound that slows and disorganizes ciliary beating along with affecting mucous transport. Various medications have also been shown to affect ciliary action. Decongestant medications may alter the various layers of the sinus membranes, thus interrupting normal ciliary activity. On the other hand, long-term antibiotic medications have been shown to have a significant increase in ciliary beat frequency.[61]

In a healthy sinus, an adequate system of mucus production, clearance, and drainage is maintained. The key to normal sinus physiologic condition is the proper function of the cilia, which are the main component of the mucociliary transport system. These cilia work to move contaminants toward the natural ostium and then to the nasopharynx. The flow of mucus is toward the ostium, which leads to the infundibulum, through the hiatus semilunaris, into the middle meatus of the nose, and ultimately into the nasopharynx (Figure 38-11). An alteration in the sinus ostium patency or the quality of secretions can lead to disruption in ciliary action resulting in sinusitis. For clearance to be maintained, adequate ventilation is necessary. Ventilation and drainage is dependent on the osteomeatal unit, which is the main sinus opening. Ciliary movements of ciliated epithelial cells dictate clearance of the maxillary sinus.

The maxillary ostium and infundibulum are part of the anterior ethmoid middle meatal complex, the region through which the frontal and maxillary sinuses drain, which is primarily responsible for mucociliary clearance of the sinuses to the nasopharynx.[64] As a result, pathogenesis of sinusitis is usually the development of obstruction in one or more areas of this complex.[65] Symptomatic sinusitis corresponds to the blockage of the osteomeatal complex that drains the paranasal sinuses. Symptoms of sinusitis may be minimal, even in the presence of extensive radiographic findings, as long as the patency of the ostium is maintained.[66]

Mucoid fluid is transported toward the ostium of the maxillary sinus and drained into the nasal cavity, eliminating inhaled small particles and microorganisms. This mucociliary transport system is an active transport system that relies heavily on oxygen. The amount of oxygen absorbed from the blood is not adequate to maintain this drainage system. Additional oxygen has to be absorbed from the air in the sinus; this is why the patency of the ostium is pivotal in maintaining this transport system. Mucociliary transport may be compromised by abnormalities in the cilia, which include a decrease in the number and poor coordination of movement. After sinus infections, the quantitative loss of cilia is reversed except when severe empyema with scarring occurs, which results in the ciliated epithelium being replaced by squamous epithelium.

Maxillary Sinus Bacterial Flora

Much debate concerns the bacterial flora of the maxillary sinus. Maxillary sinuses have been considered to be sterile in health; however, bacteria can colonize within them without producing symptoms. In theory, the mechanism by which a sterile environment is maintained includes the mucociliary clearance system, immune system, and the production of nitrous oxide within the sinus cavity. In a study of patients who underwent surgical repositioning of the maxilla, Cook and Haber[67] reported that 80% of the patients showed no bacterial growth. The remaining 20% had some bacterial growth but in negligible numbers. All specimens showed some degree of inflammatory cell infiltrate, more acute in the presence of microorganisms. They concluded that the asymptomatic adult maxillary sinus is usually sterile, but a few transient bacteria may exist in a clinically asymptomatic antrum.

However, recent endoscopically normal sinuses were shown to be nonsterile, with 62.3% exhibiting bacterial colonization. The most common bacteria cultured were *Streptococcus viridans*, *Staphylococcus epidermidis*, and *Streptococcus pneumoniae*.[68] The culture findings for secretions in acute maxillary sinusitis yielded high numbers of leukocytes, *S. pneumoniae,* or *Streptococcus pyogenes*, and *Haemophilus influenzae* was recovered from the purulent exudates with lower numbers of staphylococci. In fact, the macroscopic appearance of the secretion should not be used to screen samples, because several cases with *H. influenzae* grew also from nonpurulent samples. Other reports have indicated the bacterial flora of the maxillary sinus consists of nonhemolytic and α-hemolytic streptococci, as well as *Neisseria* spp. Additional microorganisms identifiable in various quantities belong to the staphylococci, *Haemophilus* spp., pneumococci, *Mycoplasma* spp., and *Bacteroides* spp. This is important to note because the sinus graft procedure often violates the sinus mucosa, and bacteria may contaminate the graft site.

Maxillary Sinus: Clinical Assessment

To establish an adequate osseous morphologic condition for the placement of endosteal implants in the resorbed maxillary posterior region, various grafting techniques have been developed to increase bone volume. In

WWW.HIGHDENT.IR

همیار دندانسازان

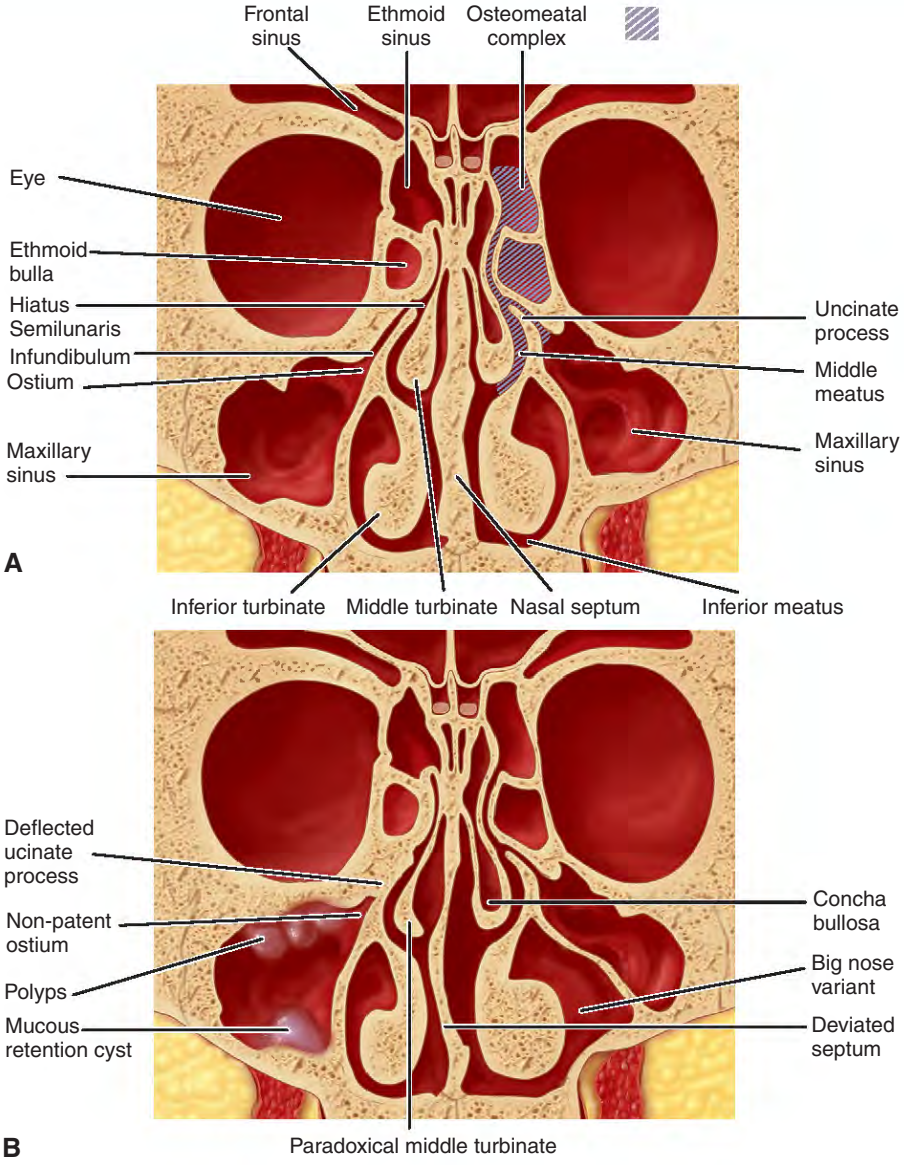

Figure 38-11 **A,** Normal paranasal anatomy. **B,** Paranasal pathology and anatomical variants.

1987, Misch[69] developed four different categories for the treatment of the posterior maxilla (termed *subantral* [SA]), as SA-1 through SA-4 (Figure 38-12). The SA-1 posterior maxilla allows implant placement inferior to the sinus cavity without sinus manipulation, thus not altering the sinus floor or membrane. As such, if the patient has a preexisting maxillary sinus condition or develops a sinus infection after implant placement, then implants are not at risk of becoming contaminated. However, the SA-2 to SA-4 surgical procedures do alter the sinus membrane and sinus floor. With these treatment options, a thorough preoperative evaluation is completed to rule out existing pathologic condition in the maxillary sinus. In this way, the risk of mucus and bacteria contaminating the graft and creating a bacterial smear layer on the implant, which results in impaired bone formation during healing, is reduced. In addition, because of the proximity of the maxillary sinus to numerous vital structures, postoperative complications can be very severe and even life threatening.

Pathologic conditions associated with the paranasal sinuses are common ailments and afflict more than 31 million people each year. Approximately 16 million people will seek medical assistance related to sinusitis; yet sinusitis is one of the most commonly overlooked diseases in clinical practice.[70] Potential infection in the region of the sinuses may result in severe complications. Infections in this area have been reported to result in sinusitis, orbital cellulitis, meningitis, osteomyelitis, and cavernous sinus thrombosis. In fact, paranasal sinus infection accounts for approximately 5% to 10% of all brain abscesses reported each year.[70]

WWW.HIGHDENT.IR

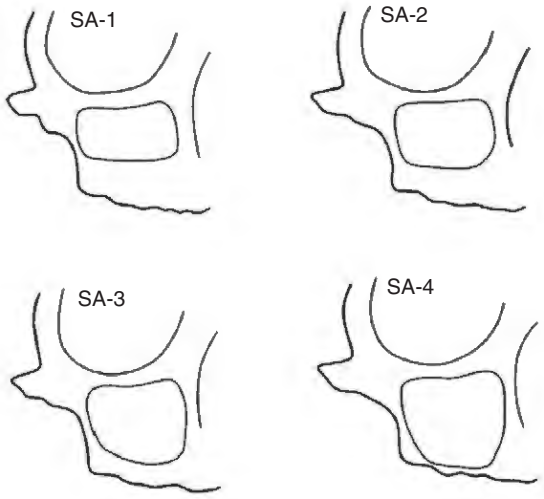

Figure 38-12 Misch classified the subantral (SA) region of the posterior maxilla in four categories: SA-1 has adequate vertical bone for endosteal implants (>12 mm), SA-2 has 0 to 2 mm less than ideal height of bone (10 to 12 mm), SA-3 has 5 to 10 mm of bone below the antrum, and SA-4 has less than 5 mm of vertical bone below the maxillary sinus.

Table 38-1 Preoperative and Postoperative Physical Examination

SITE	SIGNS OF INFECTION
Inferior wall	Bulge in hard palate, ill-fitting denture, loose teeth, hypesthesia or nonvital teeth, bleeding, palatal erosion, oroantral fistula
Medial wall	Nasal obstruction, nasal discharge, epistaxis, cacosmia, visible mass in nostril
Anterior wall	Swelling, pain, skin changes
Lateral wall	Trismus, bulging mass, exudate from incision line
Posterior wall	Midface pain, hypesthesia of one half of face, loss of function of lower cranial nerves
Superior wall	Diplopia (double vision), proptosis (eye bulging out), chemosis, pain or hypesthesia, decreased visual acuity

A physical examination of the maxillary sinus evaluates the middle third of the face for the presence of asymmetry, deformity, swelling, erythema, ecchymosis, hematoma, or facial tenderness (Table 38-1). Nasal congestion or obstruction, prevalent nasal discharge, epistaxis (bleeding from the nose), anosmia (the loss of the sense of smell), and/or halitosis (bad breath) are noted.

The clinical examination for maxillary sinusitis concerns the regions surrounding the maxillary antrum. The examination is conducted to assess each wall surrounding the maxillary sinus separately. The infraorbital foramen on the facial wall of the antrum is palpated through the soft tissue of the cheeks or intraorally to determine whether tenderness or discomfort is present. The intraoral examination assesses the floor of the antrum by alveolar ulceration, expansion, tenderness, paresthesia, and oroantral fistulae. The eyes are examined to evaluate the superior wall of the sinus for proptosis, pupillary level, lack of eye movement, and diplopia. The nasal fluids may be used to evaluate the medial wall of the sinus by asking the patient to blow the nose in a waxed paper. The mucus should be clear and thin in nature. A yellow or greenish tint or thickened discharge indicates infection. Infected maxillary sinuses typically are symptomatic, which can exhibit exudate in the middle meatus and may be inspected with a nasal speculum and headlight (rhinoscopy) through the nares.

Other methods of examination of the infected maxillary sinus may include transillumination, nasoendoscopy, bacteriology, cytology, fiber optic antroscopy, and radiography (conventional, CT, or magnetic resonance imaging [MRI]).

Maxillary Sinus Radiographic Evaluation

The maxillary sinus is often pneumatized in partial or completely edentulous patients and requires grafting. Therefore visualization of the maxillary sinus and surrounding structures are crucial for the proper diagnosis and treatment planning of the partial or complete edentulous posterior maxilla. Numerous preoperative radiographic modalities are available to evaluate the posterior maxilla and maxillary sinuses.

Waters' Projection Radiographs

The most common medical plain-film radiograph used for the evaluation of the maxillary sinus is the occipitomental projection, also termed the *Waters' projection*. This film is taken with the patient's head tilted upwards approximately 40 degrees, allowing a clear evaluation of the superior, lateral, and medial aspects of the maxillary sinus. Before the advent of CT technology, this projection was used routinely for the evaluation of maxillary sinus disease. The Waters' projection is often complimented with similar plain films such as the Caldwell (frontal view), lateral view, and submentovertical (base view). However, the posterior teeth and/or alveolar residual bony process frequently obscure the posteroinferior part of the sinus cavity. Because the sinus floor is a critical portion of the sinus for implant treatment, a Waters' projection radiograph has little use for diagnosis or treatment planning in implant dentistry. It has been reported that 75% of these plain films are inaccurate in evaluating the pathologic condition of the sinuses.[71]

Panoramic Radiographs

The panoramic radiograph is often used as a preliminary diagnostic radiograph in implant dentistry. This

WWW.HIGHDENT.IR

همیار دندانسازان

radiograph can provide direct visualization of the anterior, lateral, and inferior regions of the maxillary sinus. It is often sufficient to evaluate the amount of bone present below the maxillary sinus (Figure 38-13).

When a panoramic radiograph is first evaluated, attention is brought to the amount of bone height in the posterior maxilla from the crest of the ridge to the floor of the maxillary sinus. This available bone height may place the patient in a category of SA-1 (obviously enough bone below the antrum for implants) or SA-4 (obviously not enough bone for implants). The SA-2 and SA-3 categories are less obvious, because the specific bone height range of 5 or 10 mm of bone may be influenced by film magnification.

The hard palate appears as two radiopaque lines on the panoramic radiograph: one line represents the structure on that side, and a second, lighter and fuzzier line represents the ghost image from the other side. When these lines are observed several millimeters above the floor of the antrum, the posterior maxilla has good surgical access for a lateral-wall approach for an SA-3 or SA-4 sinus graft option. When the palate line is near the crest of the edentulous ridge, surgical access is more difficult and the surgical lateral-access wall may even be within the zygomatic process.

The panoramic radiograph is useful for preliminary evaluation of the posterior maxilla. However, it is not the standard radiograph used to evaluate the maxillary sinus for abnormalities or pathologic conditions. Ghost and overlapping images will often obscure or distort the anatomy of the maxillary sinus. If the patient is positioned upward with respect to the Frankfort horizontal plane, then the hard palate and the shadow of the occipital bone will obscure the sinus. Another common positioning mistake is not placing the tongue in the roof of the mouth. This will result in radiolucency over the maxilla that represents the palatoglossal air space, as well as a radiopaque region from the tongue. This radiopaque region may be misinterpreted as a pathologic condition. The posterior wall of the maxillary sinus is often misinterpreted as the panoramic innominate line. This artifact is a thin, vertical radiopaque line in the posterior one third of the maxillary sinus that corresponds to the superimposition of the zygomatic process of the maxilla and the frontal process of the zygoma. The posterior region behind this innominate line is often more radiopaque and may be misinterpreted as available bone "behind the sinus" for endosteal implants (Figure 38-14).[72]

The panoramic radiograph may be used as the only radiographic tool in an SA-1 treatment option. Because the sinus and/or floor is not manipulated during the surgery, the condition of the sinus proper is much less

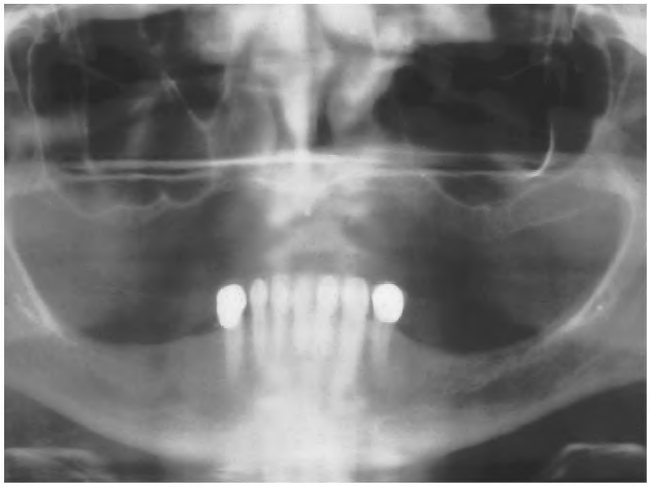

Figure 38-13 A panoramic radiograph is often the first radiograph used in the treatment of an edentulous patient. It is obvious that the patient's right side (*left side of the picture*) does not have adequate bone below the antrum for an endosteal implant. The left side of the patient is less obvious, because magnification and distortion do not permit exact measurements. The two radiopaque horizontal lines of the palate are above the sinus floor and indicate the posterior maxillary access to the lateral wall for a sinus graft is adequate for surgical access.

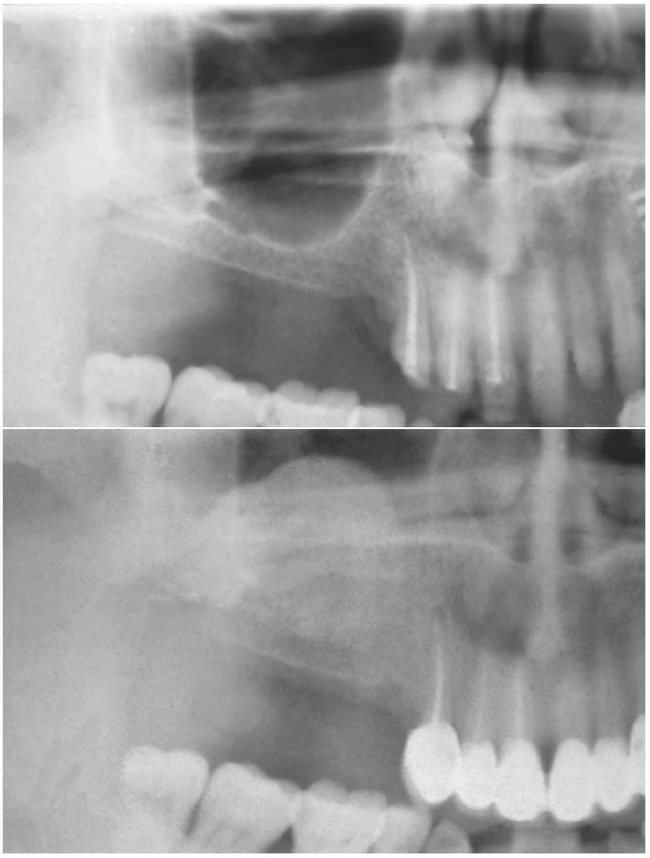

Figure 38-14 **A,** A panoramic radiograph of a posterior maxilla that demonstrates the vertical innominate line. This is not the posterior wall of the maxillary sinus. It is actually the juxtaposition of the zygomatic process and temporal bone lateral to the sinus. The radiopaque region behind this line is not bone. **B,** A sinus graft was performed on this patient. The reader should note that the sinus graft extends posterior to the innominate line on the panoramic image.

WWW.HIGHDENT.IR

relevant to implant insertion. Because the SA-3 or SA-4 sinus graft procedure augments the posterior maxilla, it transforms the region to an SA-1 condition after graft maturity. Therefore after a sinus graft has positively modified the existing bone volume, a panoramic radiograph is often the only radiographic modality used before implant surgery.

Periapical Radiographs

Periapical (PA) radiographs are of little value in the posterior maxilla, because the observed area is small and inadequate. Cysts and inflammation of the membrane can sometimes be seen in association with the apex of the tooth. In addition, certain cases of odontogenic sinusitis may be clearly seen on PA radiographs. Although the PA radiograph can indicate a pathologic condition in the sinuses, it usually does not provide enough information for reliable diagnosis. In general, plain-film PA radiographs of the sinuses are of little value in precise osseous measurements and evaluation of pathologic conditions in the maxillary sinuses.

Computerized Tomography

Currently, no radiographic modality provides more information about the paranasal sinuses than CT. This type of radiography provides much more detailed information about the anatomy and pathologic condition of the sinuses compared with plain films. CT is the best option for viewing the surrounding osseous structures and pathologic condition in the maxillary sinuses.[65,73,74] With the addition of reformatted images, axial, panoramic, cross-sectional, and 3D images provide comprehensive evaluation of the entire sinus cavity and the existing bone below the antrum. In medical evaluation of the sinus cavity, images are taken in the coronal plane. For dental reformatted images, scans are usually taken in numerous transaxial slices (Figure 38-15).

Magnetic Resonance Imaging

MRI is an imaging technique that allows for better differentiation of the soft tissues within the sinuses. MRI has advantages over CT scanning for the evaluation of neoplasms, tumor mapping, and evaluation of fungal sinusitis. However, these images have a high false-positive finding, show very poor bony imaging, and have a higher associated cost. As a consequence, CT reformatted images are superior for implant dentistry.

Ultrasound Evaluation

Mode ultrasound may be used to evaluate for fluid in the maxillary sinus and for mucosal thickening or soft tissue masses in the sinus. Therefore ultrasound can be used for diagnosing acute maxillary sinusitis. However, the diagnostic properties vary greatly and are highly operator dependent. Studies have shown ultrasound sensitivity and specificity to be equal to standard, plain-film radiographs.

Maxillary Sinus: Computed Tomography Radiographic Anatomy

Over the years, preoperative CT scan evaluation has become the standard method for evaluating the pathologic condition of the sinuses before sinus graft procedures. Therefore the practitioner should have an understanding of the CT radiographic anatomy and the pathologic conditions associated with the posterior maxilla and maxillary sinus regions.

Maxillary Sinus Membrane

A CT scan of normal, healthy paranasal sinuses reveal a completely radiolucent (dark) maxillary sinus. Any radiopaque (whitish) area within the sinus cavity is abnormal, and a pathologic condition should be suspected. The normal sinus membrane is radiographically invisible, whereas any inflammation or thickening of this structure will be radiopaque. The density of the diseased tissue or fluid accumulation will be proportional to varying degrees of gray values.

Ostiomeatal Complex

The ostiomeatal unit is composed of the maxillary ostium, ethmoid infundibulum, anterior ethmoid cells, and the frontal recess. The main drainage avenue of the maxillary sinus is through the ostium. The maxillary ostium is bounded superiorly by the ethmoid sinuses and inferiorly by the uncinate process. The uncinate process is a bony knifelike projection that is attached inferiorly to the inferior turbinate and posteriorly has a free margin. Drainage continues through the ostium into the infundibulum, which is a narrow passageway leading into the middle meatus. The middle meatus is the radiolucent space bounded by the middle and inferior turbinates.

Within the nasal cavity, three nasal turbinates or conchae (superior, middle, inferior) exist that are small downward projections of bone. Between the turbinates is a space or recess termed a *meatus*. The respiratory epithelium covers the turbinates and meatus and warms, moistens, and cleans the air that is respirated into the lungs.

The nasal septum is the bony partition that creates a barrier between the right and left sides of the nasal cavity (see Figure 38-11, *A*). Obstructions within any aspect of the nasal system predispose the area to pathologic conditions (see Figure 38-11, *B*).

Maxillary Sinus: Anatomical Variants

Numerous anatomical variants arise that can predispose a patient to postsurgical complications. When these conditions are noted, a pharmacologic discipline may be altered and/or implants may be placed after the sinus graft has matured, rather than predisposing them to an increased risk by inserting them at the same time as the sinus graft. As stated previously, patency of the ostium is paramount to maintain drainage.

WWW.HIGHDENT.IR

همیار دندانسازان

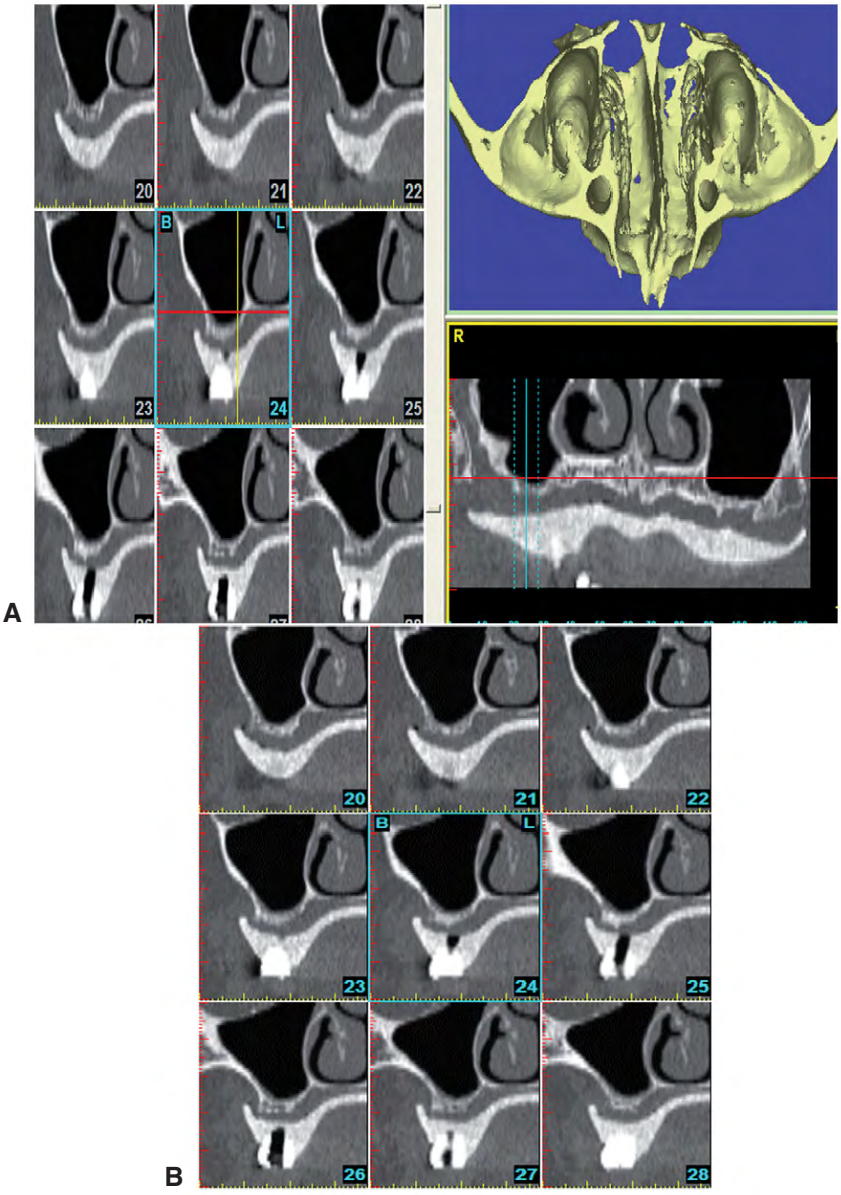

Figure 38-15 **A,** Reformatted transaxial computed tomography images of an edentulous maxilla provide comprehensive evaluation of the sinus cavity and surrounding available bone volumes. A radiopaque template is observed below the bone images and indicates the final teeth position. **B,** Cross-sectional views of a posterior maxilla with a healthy sinus and 1 to 2 mm of bone below the sinus floor. A radiopaque template indicates the soft tissue thickness on the ridge and the ideal tooth position.

Preexisting skeletal and bony abnormalities of the osteomeatal complex may compromise the unit, leading to maxillary sinusitis.

Nasal Septum Deviation

A nasal septum deviation is a very common anatomical variant, occurring in as much as 70% of the population older than 14 years. This bony variant in extremes may cause obstruction of the ostiomeatal unit, which results in inflammation from air turbulence, causing increased mucosal drying and particle deposition. If the deviation is long standing, then atrophy of the middle turbinate may occur, resulting in narrowing of the ostiomeatal complex (Figure 38-16).[75]

Timmenga et al.[76] evaluated 45 patients who received 85 sinus grafts with endoscopy postsurgery. Of the 45 patients, five were found to have sinusitis postsurgery; all five of those patients had a nasal deviation or oversized turbinate. Therefore when these conditions are observed, the implant should not be placed at the same time as the sinus graft, and the recommended preoperative and postoperative pharmacologic protocol is especially warranted.

Middle Turbinate Variants

The middle turbinate plays a significant role in proper drainage of the maxillary sinus. A *concha bullosa* is a pneumatization within the middle turbinate and may

WWW.HIGHDENT.IR

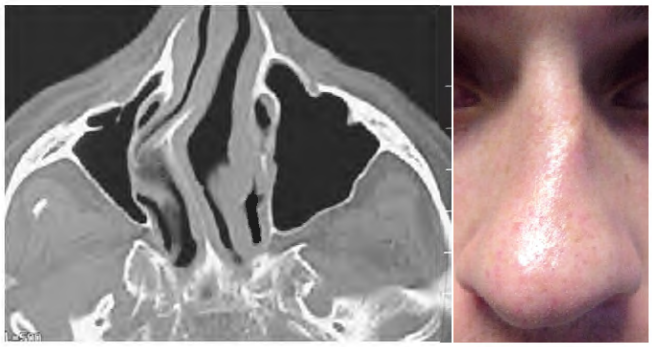

Figure 38-16 A nasal septum deviation is a common variant. Extreme cases may obstruct the ostiomeatal unit and increase the risk of sinusitis after a sinus graft.

occlude the osteomeatal complex, thus compromising adequate drainage. This variant is seen in approximately 4% to 15% of the population (see Figure 38-11).[77] Another variant in this anatomical structure is a paradoxically curved middle turbinate, which presents a concavity toward the septum, thus decreasing the size of the meatus. This also predisposes the patient to sinus disease.

Uncinate Process Variants

A deflected uncinate process (either laterally or medially) can narrow the ethmoid infundibulum, thus affecting the osteomeatal complex. Perforations may also be present within the uncinate process, leading to communication between the nasal cavity and ethmoid infundibulum. In addition, the uncinate process may be pneumatized. Although this is rare, it may compromise adequate clearance and drainage.

Supplemental Ostia

A supplemental ostium or secondary ostia may occur between the maxillary sinus and the middle meatus, which is often found in the posterior fontanelles (PFs). This may be found in approximately 18% to 30% of individuals. Because these secondary openings are usually located posterior and inferior to the natural ostium, they may predispose the patient to sinusitis by the recirculation of infected secretions from the primary meatus back into the sinus cavity. On occasion, these secondary ostia may be encountered during the elevation of the medial wall of the antrum, before placement of the sinus graft. When observed, a piece of collagen is placed over the site to prevent graft material from entering the nasal cavity.

Maxillary Hypoplasia

Hypoplasia of the maxillary sinus may be a direct result from trauma, infection, surgical intervention, or irradiation to the maxilla during the development of the maxillary bone. These conditions interrupt the maxillary growth center, thus producing a smaller-than-normal maxilla. A malformed and positioned uncinate process is associated with this disorder, leading to chronic sinus drainage problems. Most often, these patients have adequate bone height for endosteal implant placement, and a sinus graft is not required to gain vertical height.

Inferior Turbinate and Meatus Pneumatization (Big-Nose Variant)

Misch has observed, on rare occasion, the inferior third of the nasal cavity pneumatizes within the maxilla and resides over the alveolar residual ridge. An evaluation of 550 CT scans of complete or partially edentulous maxillae found this condition in 18 patients (3% incidence). When the patient has this condition, the maxillary sinus is lateral to the edentulous ridge. When inadequate bone height is present below this structure, a sinus graft does not increase available bone height for an implant. This condition is difficult to observe on a panoramic radiograph. If unaware, then the implant can be placed into the nasal cavity above the residual ridge and even penetrate the inferior turbinate. A sinus graft is contraindicated with this patient condition, because the sinus is lateral to the position of the implants. Instead, an onlay graft is required to increase bone height.

MAXILLARY SINUS PATHOLOGY

A preexisting, pathologic, maxillary sinus condition is a contraindication for many procedures that alter the sinus floor before or in conjunction with sinus grafting and/or implant insertion. The risk of postoperative infection is elevated and may compromise the health of the implant and the patient. Therefore pathologic conditions, either preoperative or postoperative, of a maxillary sinus should be evaluated, diagnosed, and treated.

Pathologic conditions of the maxillary sinus may be divided into four categories: (1) inflammation, (2) cystic conditions, (3) neoplasms, and (4) antroliths and foreign bodies. Studies have shown that 20% to 45% of the asymptomatic population has a subclinical pathologic condition in the maxillary sinus. A study completed at the Misch International Implant Institute evaluated 350 consecutive prospective candidates for maxillary sinus augmentations. The results concluded 30.7% of asymptomatic patients had maxillary sinus pathologic condition on CT scan evaluation. Because of this high incidence, it is highly recommended that a thorough radiographic evaluation be completed on all prospective sinus elevation patients.

INFLAMMATION

Inflammatory conditions can affect the maxillary sinus from odontogenic and nonodontogenic causes.

WWW.HIGHDENT.IR

همیار دندانسازان

Odontogenic Sinusitis (Periapical Mucositis)

The close proximity of the roots of the maxillary posterior teeth to the floor of the sinus means that any inflammatory changes in the periodontium or surrounding alveolar bone may cause pathologic conditions in the maxillary sinus.

Etiology

Odontogenic sinusitis is caused by a periapical abscess, cyst, granuloma, or periodontal disease that causes an expansile lesion within the floor of the sinus. Other causes include sinus perforations during extractions and foreign bodies (e.g., gutta-percha, root tips, amalgam). Odontogenic sinusitis is often polymicrobial, with anaerobic streptococci, *Bacteroides* spp., *Proteus* spp., and coliform bacilli being involved. Studies have reported that approximately 25% of chronic sinusitis cases may have some odontogenic origin when teeth are present in the posterior maxilla.[78,79]

Radiographic Appearance

Periodontitis may produce generalized sinus mucosal hyperplasia, which is seen as a radiopaque band that follows the contours of the sinus floor. A localized periapical mucositis reveals a thickening of the mucosal membrane adjacent to the offending tooth and, on occasion, that perforates the floor of the sinus. This radiographic appearance has been termed a *halo effect*. In the author's opinion, smoking may be the influencing factor, causing an increased risk of periodontitis, a decrease in immune response, and a decrease in the healthy flow of the mucus within the antrum.

Differential Diagnosis

This condition may be confused with acute sinusitis or mild mucosal thickening. However, in odontogenic sinusitis, the patient has teeth in the posterior maxilla and will usually exhibit symptoms related to the teeth (i.e., pain from a posterior tooth or a recent extraction, exudate around the existing natural posterior teeth).

Treatment

Before sinus augmentation or implant placement, the tooth or teeth involved should be treated periodontally, endodontically, or extracted. After intraoral soft tissue healing and resolution of the pathologic condition, the sinus graft procedure may be performed with little risk of postoperative complications.

Acute Rhinosinusitis

A nonodontogenic pathologic condition may also result in inflammation in the form of sinusitis. The most common type of sinusitis is acute rhinosinusitis. The signs and symptoms of acute rhinosinusitis are rather nonspecific, making it difficult to differentiate from the common cold, influenza type of symptoms, and allergic rhinitis. However, the most common symptoms include purulent nasal discharge, facial pain and tenderness, nasal congestion, and possible fever.

Acute maxillary rhinosinusitis results in 22 to 25 million patient visits to a physician in the United States each year, with a direct or indirect cost of 6 billion U.S. dollars. Although four paranasal sinuses exist in the skull, the most common involved in sinusitis are the maxillary and frontal sinuses.[70]

Etiology

An inflammatory process that extends from the nasal cavity after a viral upper respiratory infection often causes acute maxillary sinusitis. Microbiological cultures have shown the most common pathogens causing acute rhinosinusitis are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. These pathogens include approximately 20% to 27% β-lactamase–resistant bacteria. *Staphylococcus aureus* has also been cited with the microbiology of acute rhinosinusitis. However, this pathogen is usually only seen in nosocomial (hospital induced) sinusitis and is unlikely to be seen in an elective sinus graft patient.

The most important factor in the pathogenesis of acute rhinosinusitis is the patency of the ostium.[80,82] Local predisposing causes of sinusitis include inflammation and edema associated with a viral upper respiratory tract infection or allergic rhinitis. As a consequence, mucous production within the sinus may be abnormal in quality or quantity, along with a compromised mucociliary transport. In an occluded sinus, an accumulation of inflammatory cells, bacteria, and mucus exists. Phagocytosis of the bacteria is impaired with immunoglobulin (Ig)-dependent activities decreased by the low concentration of IgA, IgG, and IgM found in infected secretions.

The oxygen tension inside the maxillary sinus has significant effects on pathologic conditions. When the oxygen tension in the sinus is altered, resultant sinusitis occurs. Growth of anaerobic and facultative organisms proliferate in this environment.[83] Many factors may alter the normal oxygen tension within the sinuses. A direct correlation exists between the ostium size and the oxygen tension in the sinus. In patients with recurrent episodes of sinusitis, oxygen tension is often reduced, even when infection is not present. As a consequence, a history of recurrent acute rhinosinusitis is relevant to determine whether an implant may be at increased risk when inserted at the same time as the sinus graft.

Radiographic Appearance

The radiographic hallmark in acute rhinosinusitis is the appearance of an air-fluid level. A line of demarcation will be present between the fluid and the air within the maxillary sinus. If the patient is supine, then the fluid will accumulate in the posterior area; if the patient is upright during the imaging, the fluid will be seen on the

WWW.HIGHDENT.IR

floor and horizontal in nature. Additional radiographic signs include smooth, thickened mucosa of the sinus, with possible opacification. In severe cases the sinus may fill completely with supportive exudates, which gives the appearance of a completely opacified sinus. With these characteristics, the terms *pyocele* and *empyema* have been applied.

Treatment

Because acute rhinosinusitis is one of the most common health problems today, patients having sinus augmentation procedures should be well screened for a past history and current symptoms. Even though acute rhinosinusitis is a self-limiting disease, a symptomatic patient should be treated and cleared by the physician before grafting procedures. These patients are also more prone to postoperative sinusitis. As a result, a sinus graft is performed and allowed to mature several months before the placement of the implant. In addition, the suggested antibiotic coverage may be altered and extended, both before and after the sinus graft procedure.

Chronic Rhinosinusitis

Chronic rhinosinusitis is a term used for a sinusitis that does not resolve in 6 weeks and also has recurrent episodes. It is the most common chronic disease in the United States, affecting approximately 37 million people. Symptoms of chronic sinusitis are associated with periodic episodes of purulent nasal discharge, nasal congestion, and facial pain.

Etiology

As maxillary rhinosinusitis progresses from acute to chronic, anaerobic bacteria become the predominant pathogens. The microbiology of chronic sinusitis is very difficult to determine because of the inability to achieve accurate cultures. Studies have shown that possible bacteria include *Bacteroides* spp., anaerobic gram-positive cocci, *Fusobacterium* spp., as well as aerobic organisms (*Streptococci* spp., *Haemophilus* spp., *Staphylococcus* spp.).[84] A recent Mayo Clinic study showed that in 96% of patients with chronic sinusitis, active fungal growth was also present.[85]

Radiographic Appearance

Chronic rhinosinusitis may appear radiographically as thickened sinus mucosa, complete opacification of the antrum, and/or sclerotic changes in the sinus walls (which give the appearance of denser cortical bone in the lateral walls).

Treatment

Medical evaluation and clearance by an experienced physician in sinus pathology is highly recommended for patients with chronic maxillary rhinosinusitis before sinus grafting, because significant bacterial resistance and fungal growth is highly probable. Fungal infections may be difficult to treat and control, and serious complications may result in postoperative sinus graft patients. In this manner these patients are evaluated before surgery by the physician most likely to treat them after the sinus graft surgery, should significant complications occur.

Allergic Sinusitis

Etiology

Allergic sinusitis is a local response within the sinus caused by an irritating allergen in the upper respiratory tract. Therefore this allergen may be a cause of acute or chronic rhinosinusitis. This category of sinusitis may be the most common form, with 15% to 56% of patients undergoing endoscopy for sinusitis showing evidence of allergy. This condition often leads to chronic sinusitis in 15% to 60% of patients.[86] The sinus mucosa becomes irregular or lobulated, with resultant polyp formation.

Radiographic Appearance

Polyp formation related to allergic sinusitis is usually characterized by multiple, smooth, rounded, radiopaque shadows on the walls of the maxillary sinus. Most commonly, these polyps are located near the ostium and are easily observed on a CT scan. In advanced cases, ostium occlusion, along with displacement or destruction of the sinus walls, may be present, with a radiographic image of a completely opacified sinus.

Treatment

Special attention must be given to a patent ostium, bacterial resistance, and close postoperative supervision. The polyp, if enlarged, may be removed before the sinus graft. This may be performed through an anterior Caldwell-Luc approach or by an endoscopic procedure through the ostium.

Allergic sinusitis patients often have a greater risk of complications related to an increase in allergen production. Because sinus grafting is an elective procedure, the time of year for the surgery may be altered to decrease the postoperative infection risk. For example, if hay fever or a grass allergy is related to the patient's sinusitis, then the sinus graft surgery should be performed in the season or seasons that have least risk to aggravate the sinus mucosa (i.e., winter or fall).

Fungal Sinusitis (Eosinophilic Fungal Rhinosinusitis)

Granulomatous sinusitis is a very serious (and often overlooked) disorder within the maxillary sinus. Patients who have fungal sinusitis are thought to have had an extensive history of antibiotic use, chronic exposure to mold or fungus in the environment, or being immunocompromised.

WWW.HIGHDENT.IR

همیار دندانسازان

Etiology

Fungal infections are usually caused by aspergillosis, mucormycosis, or histoplasmosis.[87] Chronic sinusitis patients should always be evaluated for granulomatous conditions, because a high percentage of fungal growth exists in this patient population. Of concern in these patients is that eosinophils are activated that release major basic protein (MBP) into the mucus, which attacks and destroys the fungus. However, this results in the membrane being irritated and possibly irreversibly damaged, which allows bacteria to proliferate. Three possible clinical signs may differentiate fungal sinusitis from acute or chronic sinusitis; however, a positive diagnosis require mycological and histological studies.[87]

1. No response to antibiotic therapy
2. Soft tissue changes in sinus associated with thickened reactive bone, with localized areas of osteomyelitis
3. Association of inflammatory sinus disease that involves the nasal fossa and facial soft tissue

Radiographic Appearance

Granulomatous sinusitis may appear radiographically as mild thickening to complete opacification of the sinus.

Treatment

Patients with a history or current knowledge of fungal sinusitis should be referred to their physician or otolaryngologist for treatment and surgical clearance. Treatment usually involves debridement and therapy with an antifungal agent, such as amphotericin B.

CYSTIC LESIONS

Cystic lesions are a common occurrence in the maxillary sinus, and studies have reported a prevalence range of 2.6% to 20%.[88] They may vary from microscopic lesions to large, destructive, expansile pathologic conditions. They include pseudocysts, retention cysts, primary mucoceles, and postoperative maxillary cysts.

Pseudocysts (Mucous Retention Cyst)

The most common cysts in the maxillary sinus are mucous retention cysts. After much controversy, in 1984, Gardner[89] distinguished these cysts into two categories: (1) pseudocysts and (2) retention cysts. Pseudocysts are more common and of much greater concern during sinus graft surgery, compared with retention cysts. Pseudocysts reoccur in approximately 30% of patients and are often unassociated with sinus symptoms. As a consequence, many physicians do not treat this condition. However, when their size is larger than 10 mm in diameter, pseudocysts may occlude the maxillary ostium during a sinus graft procedure and increase the risk of postoperative infections.

Etiology

A pseudocyst is caused by an accumulation of fluid beneath the periosteum of the sinus mucosa. This elevates the mucosa away from the floor of the sinus, giving rise to a dome-shaped lesion. Pseudocysts have also been termed *mucosal cysts*, *serous cysts*, and *nonsecreting cysts*. Pseudocysts are not true cysts because they lack an epithelial lining. The cause of the fluid is from bacterial toxins from the sinus mucosa or from odontogenic causes (see Figure 38-16).

Radiographic Appearance

Pseudocysts are depicted radiographically as smooth, homogenous, dome-shaped, round to ovoid, well-defined radiopacities. Pseudocysts do not have a corticated (radiopaque) marginal perimeter and are usually on the floor of the sinus cavity.

Treatment

Pseudocysts are not a contraindication for sinus graft surgery, unless their approximate size is greater than 10 mm in diameter. However, when in doubt, an evaluation of even smaller "cysts" by an otorhinolaryngologist or ear, nose, and throat (ENT) physician may still be to confirm the diagnosis. If a large pseudocyst is present, then the elevation of the membrane during a sinus graft may raise the cyst to occlude the ostium. In addition, on elevation or placement of the grafting material, the cyst may be perforated, allowing fluid within the cyst to contaminate the graft. Large cysts of this nature should be drained and allowed to heal before or in conjunction with sinus elevation surgery. Most often, an otolaryngologist or ENT physician should evaluate and treat this condition before the sinus graft. If a pseudocyst is less than 10 mm, then less concern is needed and the fluid may be drained in conjunction with sinus grafting, depending on the surgeon's experience in the treatment of this condition. This should be accomplished with care to prevent membrane perforation. A recall evaluation of this area during the follow-up period of the sinus graft surgery is in order, because reoccurrence of pseudocysts are common.

Retention Cysts

Retention cysts may be located on the sinus floor, near the ostium, or within antral polyps. Because they contain an epithelial lining, researchers consider them to be mucous secretory cysts and "true" cysts. Retention cysts are often microscopic in size.

Etiology

Retention cysts result from partial blockage of seromucinous gland ducts located within the connective

WWW.HIGHDENT.IR

tissue underlying the sinus epithelium. As the secretions collect, they expand the duct, producing a cyst that is encompassed by respiratory or cuboidal epithelium. They may be caused by sinus infections, allergies, or odontogenic reasons.

Radiographic Appearance

Retention cysts are usually very small and not seen clinically or radiographically. In rare instances, they may achieve adequate size to be seen in a CT image and may resemble the appearance of a small pseudocyst.

Treatment

No treatment for retention cysts exist before or in conjunction with a sinus graft and/or implant insertion.

Primary Maxillary Sinus Mucocele

A primary mucocele is a cystic, expansile, destructive lesion that may include painful swelling of the cheek, displacement of teeth, nasal obstruction, and possible ocular symptoms.[90]

Etiology

The primary mucocele arises from blockage of the maxillary ostium by fibrous connective tissue. Because of the compromised drainage, the mucosa expands and herniates through the antral walls. This mucocele is classified as a *cyst* because it is lined by antral epithelium, which contains mucin.

Radiographic Appearance

In the early stages, the primary mucocele involves the entire sinus and appears as an opacified sinus. As the cyst enlarges, the walls become thin and eventually perforate. In the late stages, destruction of one or more surrounding sinus walls is evident.

Treatment

Surgical removal of this cyst is indicated before any bone augmentation procedures.

Postoperative Maxillary Cyst

A postoperative maxillary cyst of the maxillary sinus is a cystic lesion that usually develops secondary to a previous trauma or surgical procedure in the sinus cavity. It has also been termed a *surgical ciliated cyst*, *postoperative maxillary sinus mucocele*, or a *secondary mucocele*.[91-93]

Etiology

A postoperative maxillary cyst is a direct result of trauma or past history of surgery within the maxillary sinus. The cyst is derived from the antral epithelium and mucosal remnants that previously were entrapped within the prior surgical site. This separated mucosa results in an epithelium-lined cavity in which mucin is secreted. The antrum becomes divided by a fibrous septum in which one part drains normally, whereas the other part is composed of the mucocele. It is relatively rare in the United States; however, it constitutes approximately 24% of all cysts in Japan. At least three reported cases exist of a postoperative maxillary cyst forming after a sinus graft procedure, including one by the author of this chapter.

Radiographic Appearance

The cyst radiographically presents as a well-defined radiolucency circumscribed by sclerosis. The lesion is usually spherical in the early stages, with no bone destruction. As it progresses, the sinus wall becomes thin and eventually perforates. In later stages, it will appear as two separated anatomical compartments.

Treatment

Surgical ciliated cysts should be enucleated before any bone augmentation procedures. If observed after the sinus graft, then they should be enucleated and regrafted in the site.

NEOPLASMS

Etiology

Primary malignant tumors within the maxillary sinus are usually caused by squamous cell carcinomas or adenocarcinomas. Signs and symptoms of malignant disease are related to the surrounding sinus wall that the tumor invades and includes swelling in the cheek area, pain, anesthesia or paresthesia of the infraorbital nerve (e.g., anterior wall), and visual disturbances (e.g., superior wall). These tumors in the sinus are usually nonspecific and give a variety of consequences, including opacified sinuses, soft tissue masses in the sinus, as well as sclerosis, erosion, or destruction of the walls of the sinus. Sixty percent of squamous cell carcinomas of the paranasal sinuses are located in the maxillary sinus, usually in the lower one half of the antrum. Clinical signs in the oral cavity reflect the expansion of the tumor and an increased mobility of the involved teeth. Invasion of the infratemporal fossa is also possible.[70,94]

Radiographic Appearance

Radiographic signs of neoplasms may include various-sized radiopaque masses, complete opacification, or bony wall changes. A lack of a posterior wall on a panoramic radiograph should be a sign of possible neoplasm (Figure 38-17).

Treatment

Any signs or symptoms of a lesion of this type should be immediately referred for medical consultation. Of course, sinus grafts are contraindicated while this condition exists.

WWW.HIGHDENT.IR

همیار دندانسازان

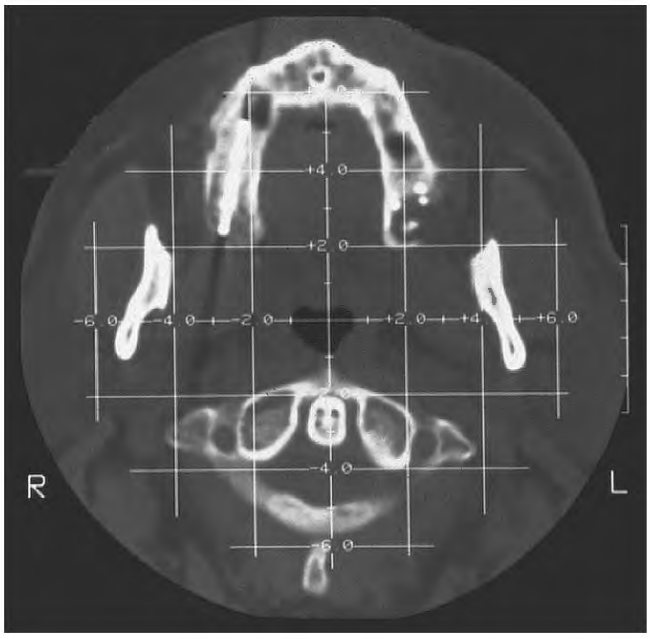

Figure 38-17 A computed tomography scan of a patient with a sinus graft and endosteal implant (blade) on the left. The right posterior maxilla has no bony wall, and the posterior sinus is radiopaque. A keratocyst was found on biopsy.

ANTROLITHS AND FOREIGN BODIES

Maxillary sinus antroliths are the result of complete or partial encrustation of a foreign body. These masses found within the maxillary sinus originate from a central nidus, which can be endogenous or exogenous.[95]

Etiology

The majority of endogenous sources are from dental origin, including retained roots, root canal sealer, fractured dental instruments, and dental implants. Additionally, bone spicules, blood, and mucus have been reported to cause antroliths.[96] Reports in the literature of exogenous sources include paper, cigarettes, snuff, and glue.[97] Although most antroliths are asymptomatic, they often are associated with sinusitis.

Radiographic Appearance

The radiographic appearance of a maxillary antrolith resembles either the central nidus (retained root) or appears as a radiopaque, calcified mass within the maxillary sinus (Figure 38-18).

Differential Diagnosis

Because the calcified antrolith is composed of calcium phosphate ($CaPO_4$), calcium carbonate salts, water, and organic material, it will be considerably more radiopaque than an inflammatory or cystic lesion.[98] The central nidus of the antrolith is similar to its usual radiographic appearance.

Treatment

Before sinus augmentation and implant placement, the antrolith should be surgically removed. If sinusitis exists, then the sinus cavity should be allowed to heal completely before sinus augmentation procedures. A nonsymptomatic condition may have the antrolith removed, sinus membrane opening sealed, and sinus graft performed at the same surgery.

CONSIDERATIONS SPECIFIC TO SINUS GRAFTS

The general contraindications for implant surgery also apply to sinus graft procedures. In addition, specific, local conditions exist that may increase morbidity, render the procedure less predictable, and/or place the patient more at risk.

Several conditions related to the maxillary sinus are a concern but are not necessarily contraindications to the sinus graft procedure. However, they should be treated before or during the sinus graft surgery. For example, root tips in the antrum, pseudocysts, an oral antral opening, extraction of hopeless teeth in the surgical site, and unerupted teeth all may be conditions that may be performed in conjunction with the sinus graft. However, less experienced clinicians should treat these conditions several months before the sinus graft surgery to improve the surgical site before the bone graft procedure. In addition, relative contraindications include patients with a narrowing of the osteomeatal complex (e.g., deviated septum, abnormal large size of middle turbinate [concha bullosa], enlargement of an air cell in the roof of the sinus [Haller cell]). An ENT consultation is warranted for these conditions, and the sinus graft surgery should be separate from implant placement surgery because a higher risk of postoperative infection exists.

Smoking

Among the factors that may negatively interfere with the final outcome of sinus grafting procedures, smoking may play a relevant role. Overall, smokers have a 7% greater failure rate in the posterior maxilla than nonsmokers.[99] Smoking is known to be associated with an increased susceptibility to allergy and infections, because it interferes with ciliary function and secretory immunity of the nasorespiratory tract. In the maxillary sinus, this may have effects on both immune exclusion and suppression, because IgA and IgM responses are reduced, whereas IgE responses are increased. Smoking is believed to disturb bone graft healing because it reduces local blood flow by increasing peripheral resistance and causing an increased platelet aggregation.[35,100] By-product chemicals of smoking, such as hydrogen cyanide and carbon monoxide, have been shown to

WWW.HIGHDENT.IR

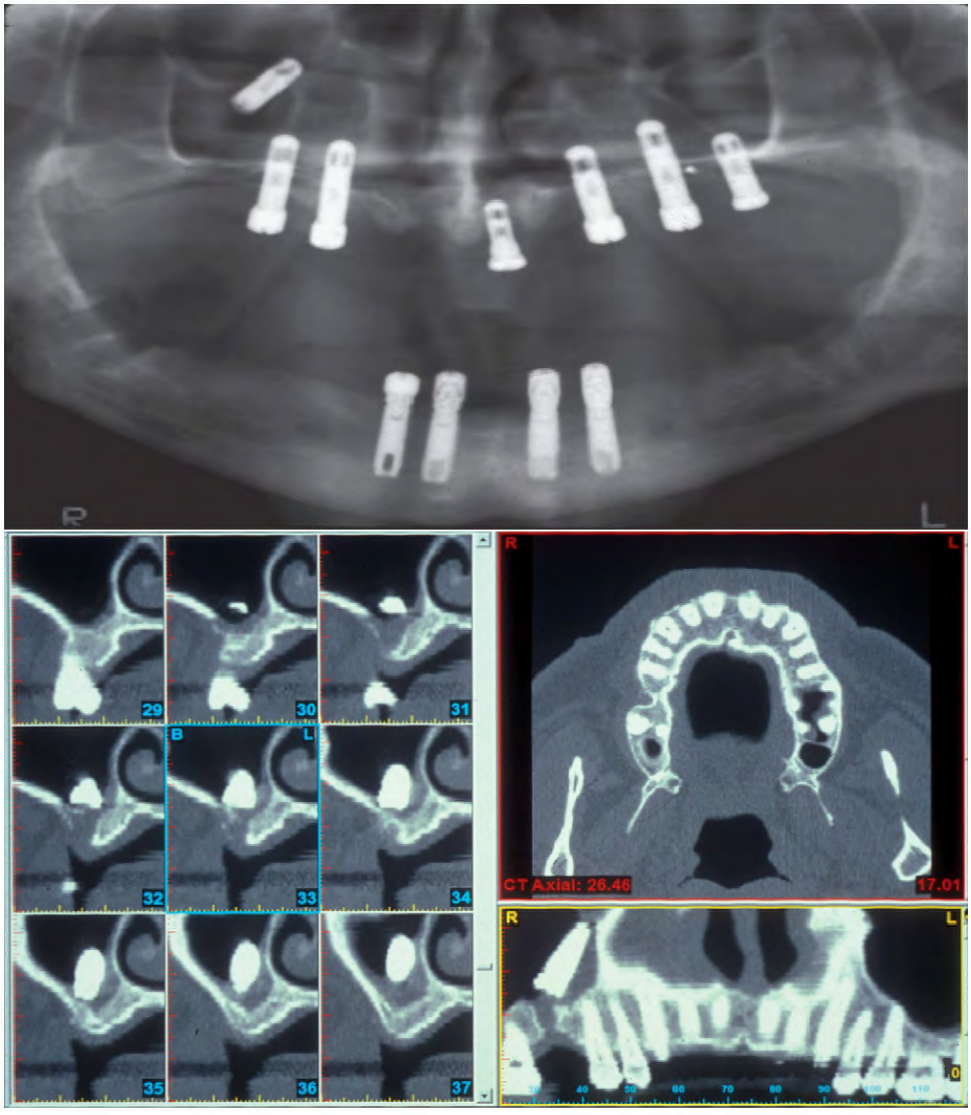

Figure 38-18 **A,** A panoramic radiograph of a patient with a history of implant stage I and stage II surgery. The patient was unaware of the implant in the right maxillary sinus (*left side of the picture*). **B,** A computed tomography scan of a patient with a sinus lift of 6 mm within the implant osteotomy and immediate implant insertion. The implant became mobile and was displaced into the sinus.

inhibit wound healing, as does nicotine, which inhibits cellular proliferation. Tobacco may interfere directly with osteoblastic function, and strong evidence exists of decreased bone formation in smokers. In addition, smokers have a significant reduction of bone mineral content. Bone mineral density can be reduced two to six times in a chronic smoker. Overall, smoking may contribute to poor available bone quality and poor healing capacity resulting from vascular and osteoblastic dysfunction.[35,100]

Although smokers have several concerns related to sinus grafting, most of these patients may be treated with sinus grafting procedures.[36,101] In a study by Dietsh-Misch et al., 50 consecutive sinus grafts were performed on 31 patients ranging from 21 to 68 years of age.[102] One third of these patients (10 patients and 15 sinus grafts) were nonsmokers, and two thirds (21 patients and 35 sinuses) smoked at least 20 cigarettes each day. The sinus graft procedures observed one perforation of sinus mucosa in nonsmokers and three perforations in smokers. Postoperative infections were zero for nonsmokers, and two sinuses became infected within 2 months of the sinus graft in smokers. However, all 50 posterior maxillae grew adequate bone height and received implants (116 implants), and all were successful. After 6 years of follow-up, zero implants and zero prostheses were lost. Therefore it appears cigarette smoking is not a strict contraindication to sinus grafting.

However, this is not to say smokers have no risk. Smoking may represent a relative contraindication because of the risk of wound dehiscence, graft infection and/or resorption, and a reduced probability of osseointegration. It is recommended, however, that if a decision to proceed with surgery has been made, then

WWW.HIGHDENT.IR

همیار دندانسازان

patients refrain from smoking at least 15 days before surgery (the time it takes for nicotine to clear systemically) and 4 to 6 weeks after surgery. Moreover, smokers should sign a detailed informed-consent form in which risks connected to smoking are clearly explained.

Chronic Maxillary Rhinosinusitis

Patients that have chronic rhinosinusitis and have a history of long-term antibiotic use are a relative contraindication for sinus graft surgery. These patients have altered sinus flora and are at greater risk of containing fungi that can lead to severe fungal-related infections. Patients at a higher risk should have a thorough preoperative examination with a CT evaluation and possible medical clearance. Furthermore, the sinus graft procedure should be performed before and separate from the implant placement surgery. In addition, when a patient is more at risk of a sinus infection during a specific time period (e.g., grass allergy in the spring), it is prudent to perform the sinus graft procedure at the time of the year with the least risk. In addition, pre- and postoperative antibiotic drugs may be extended to cover these patients around the sinus graft procedure.

In addition to relative contraindications for sinus grafting, absolute local contraindications to sinus grafting include the following (Box 38-2):

1. The patient has an active sinus infection on the day of surgery. (The patient should blow the nose, and the physician should evaluate the sample for color and thickness of mucus.)
2. The patient has a significant recurrent history of chronic sinusitis despite a history of maxillary sinus corrective surgery.
3. The patient has a significant recurrent history of fungal sinusitis.
4. The patient has uncontrolled, late-stage diabetes. (These patients are very susceptible to fungal infections.)
5. The patient has cystic fibrosis (CF), a genetic disease with a 92% to 100% chronic sinusitis rate. (In addition, patients with CF exhibit significant rates of polyp formation and fungal infections.)
6. The patient has maxillary sinus hypoplasia (MSH). (The sinus drainage system is chronically compromised and is associated with a malformed uncinate process. If implants are to be placed in patients with MSH, then the sinus cavity should not be used and SA-1 procedures are recommended.)
7. The patient has neoplasms (i.e., primary or secondary malignant tumors within the maxillary sinus).
8. The patient has inferior turbinate and/or meatus pneumatization (i.e., big nose variant).

Box 38-2 Absolute Contraindications to Sinus Grafting

- Active sinus infection day of surgery
- Significant recurrent history of chronic sinusitis
- Significant recurrent history of fungal sinusitis
- Uncontrolled, late-stage diabetes
- Cystic fibrosis (CF)
- Maxillary sinus hypoplasia (MSH)
- Neoplasms
- Inferior turbinate and/or meatus pneumatization (big-nose variant)

SURGICAL ENVIRONMENT

In a previous chapter the difference between an aseptic and "clean" surgery is addressed. Although studies have reported little (if any) difference between the two approaches for the placement of implants in existing bone volumes, care should be taken related to the surgical environment for a sinus graft.

A sinus graft surgery has a higher risk of infection than implant insertion surgery, because the maxillary sinus is often predisposed to this complication. In fact, a patient may obtain a sinus infection after the surgery that is unrelated to the sinus graft operation. However, the surgical manipulation of the antral mucosa causes an increased release of histamine, which increases the thickness of the sinus mucosa and therefore increases the risk that the osteomeatal unit will become compromised. As such, a surgical environment that includes intraoral and extraoral scrubbing with chlorhexidine, scrubbing and draping the patient, as well as gowning the doctor and assistant should be considered in addition to sterile gloves and sterile instruments. In addition, a filter to circulate and clean the air of the operating room may be advantageous to decrease the risk of allergens. The risk of postoperative sinus infection is generally less than 5% when these procedures and a preoperative and postoperative pharmacologic regimen are used.[25,103,104] However, postoperative infection occurrence has been reported to be more than 20% in conditions more prone to contribute to sinus infection.[7,105-108]

PREMEDICATIONS

Antimicrobial Medications

The risk of bacterial contamination during and after sinus graft procedures are much different than regular implant surgical procedures. Therefore the pharmacologic protocol should be effective against the organisms in this surgical site. The pharmacologic regimen includes an antibiotic drug, anti-inflammatory medications, antimicrobial rinse, and analgesic medications.

Compared with routine dental implant surgery, sinus augmentation has a greater chance of morbidity because of the possible additional routes of infection.

WWW.HIGHDENT.IR

Bacterial invasion may originate from different sources: (1) transoral surgery, (2) bone graft material, and (3) bacteria from the sinus cavity. Additionally, it has been documented that the inclusion of foreign bodies (e.g., implants, alloplasts, allografts) increases infection rates.[109,110] Because a greater chance of infection and morbidity exists with this type of surgical procedure, a strict antibiotic protocol is of benefit. Antibiotic medications have been shown to significantly reduce the number of sinus graft or implant failures caused by infection.[111]

Following the principles of prophylactic antibiotic administration, the antibiotic should be effective against the bacteria most likely to cause infection. The most likely contaminating organisms after transoral surgery are primarily streptococci, anaerobic gram-positive cocci, and anaerobic gram-negative rods. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are the three most common pathogens found with acute sinus infections.[109,112] *Staphylococcus aureus* along with anaerobic bacteria have a significant role in causing chronic rhinosinusitis disease. The organisms associated with infection of allografts such as demineralized bone in oral surgery include α-hemolytic streptococci and *S. viridans*.[113,114] *S. aureus*, *Bacteroides* spp., and endogenous bacteria cause the vast majority of postoperative infections. Therefore a pharmacologic protocol effective against these organisms is appropriate.

When evaluating various classes of antibiotic medications used for treatment of maxillary sinus infections, the antibiotic class of choice is the β-lactam antibiotic drugs. However, bacterial resistance has become a significant problem in the treatment of these pathogens. With the wide range of possible routes of bacterial invasion and types of bacteria, the antibiotic drug must be broad spectrum to account for all these possibilities. Bacterial resistance is initiated by two common mechanisms: (1) production of antibiotic-inactivating enzymes (*S. aureus, H. influenzae*, and *M. catarrhalis*) and (2) alteration in target site *(S. pneumoniae)*. Studies have shown the following resistance results[115]:

- *H. influenzae*—36.8%
- *M. catarrhalis*—98%
- *S. pneumoniae*—28.6%

Because of the high rate of bacterial resistance, amoxicillin (the drug of choice for many years) is no longer used for antibiotic prophylaxis for the sinus graft surgery. Instead, amoxicillin-clavulanate (Augmentin) is used, because the addition of clavulanic acid enhances amoxicillin's activity against the β-lactamase–producing strains of bacteria.

The patient with a history of nonanaphylactic allergic reaction to penicillin may take cefuroxime axetil (Ceftin) as an alternative.[116] Ceftin possesses good potency, efficiency, and strong activity against resistant *S. pneumoniae* and *H. influenzae.*

If a patient has a history of anaphylactic reaction to penicillin, recurrent sinus infections, or a recent history of antibiotic use, then levofloxacin (Levaquin) may be indicated. This newer type of quinolone antibiotic exhibits superior activity against most types of involved bacteria, along with resistant strains.

Maximum effectiveness of prophylactic antibiotic drugs occurs when the antibiotic is in adequate concentrations in the tissue before bacterial invasion. Because the sinus mucosa has limited blood supply to combat possible bacterial invasion from the sinus surgery, antibiotic medications should be administered at least 1 full day before surgery and extended for 5 days after surgery. Recommended systemic antibiotic drugs are shown in Box 38-3.

Local Antibiotic Medications

The antibiotic concentration within a blood clot of the sinus graft depends on the systemic blood titer. After the clot stabilizes, further antibiotic drugs do not enter the area until revascularization.[117] The bone graft is a dead space with minimum blood supply and absence of protection by the host's cellular defense mechanisms.

Box 38-3 Recommended Prophylactic Antibiotic Drugs for Sinus Grafting Procedures

Systemic Antibiotic Prophylaxis

No History of Sinus Pathologic Condition/No Antibiotic Use in Last 6 Weeks

1. Augmentin (amoxicillin-clavulanic acid) (825 mg/125 mg)
   One tablet twice a day (bid) starting 1 day before surgery and 5 days after surgery
2. Ceftin (cefuroxime axetil) (500 mg), nonanaphylactic allergy to penicillin
   One tablet bid starting 1 day before surgery and 5 days after surgery

History of Sinus Pathologic Condition/Antibiotic Use in Last 6 Weeks/Anaphylactic Reaction to Penicillin

1. Levofloxacin (Levaquin 500 mg)
   One tablet 1 day before surgery and 5 days after surgery

Antibiotic in Graft

Ancef (1 g)
Dilute with 2 mL Saline (500 mg/mL)
0.2 mL or 100 mg: add to collagen membrane
0.8 mL or 400 mg: add to graft material

Clindamycin 150 mg/1 mL
0.2 mL or 30 mg: add to collagen membrane
0.8 mL or 120 mg: add to graft material

WWW.HIGHDENT.IR

همیار دندانسازان

This leaves the graft prone to infections that would normally be eliminated by either the host defenses or the antibiotic. The osteogenic induction of autografts and allografts is greatly retarded when contaminated with infectious bacteria.[118] To ensure adequate antibiotic levels in a SA graft, it is recommended to add antibiotic to the graft mixture.[69,119,120] This local antibiotic may protect the graft from early contamination and infection. Numerous studies have shown that an antibiotic added to graft material has no deleterious effects on bone growth. Antibiotic drugs such as penicillin, cephalosporin, and clindamycin, even in high concentrations, have not been found to be destructive to bone-inductive proteins.[119-121]

The locally delivered antibiotic should have efficacy against the most likely organisms encountered. Because the incidence of allergy is so high with β-lactam antibiotic drugs, the parenteral form of cefazolin (Ancef) or clindamycin is selected. Orally administered capsules and tablets should not be used within the graft, because they contain fillers that are not conducive to osteogenesis. When the parenteral form of antibiotic is a liquid, the volume of liquid added to the graft should be minimized to allow adequate handling of the graft mixture. (See Box 38-3 for the recommended amount of antibiotic that should be added to sinus graft material).

Clinical experience indicates that less risk of infection exists when preoperative and postoperative antibiotic drugs are used both orally and in the graft. Because infection considerably impairs bone formation for patients undergoing sinus graft procedures, oral antibiotic coverage is continued for 5 days after the surgery.

Oral Antimicrobial Rinse

An additional antimicrobial medication is chlorhexidine gluconate. This category of mouth rinse has been shown to successfully decrease infectious episodes and minimizes postoperative complications from the incision line. Gentle oral rinses of chlorhexidine gluconate 0.12% should be used twice daily for 2 weeks after surgery.

Glucocorticoid Medications

The pharmacodynamics of glucocorticoid medications are discussed in Chapter 21. The decrease in inflammation of the soft tissue decreases postoperative pain, swelling, and incision line opening. In addition, the clinical manifestations of surgery on the sinus mucosa can also be decreased by use of a steroid.[122] Therefore the usual surgical protocol for most implant surgeries, including sinus grafts, includes a short-term dose of dexamethasone (Decadron) (Box 38-4). To ensure patency of the ostium and minimize inflammation in the sinus before surgery, steroid medications are initiated 1 full day before surgery. This medication should also be extended 2 days postoperatively because edema peaks at 2 days.

Decongestant Medications

Sympathomimetic drugs that influence α-adrenergic receptors have been used as therapeutic agents for the decongestion of mucous membranes. Both systemic and topical decongestant medications are useful in reopening a blocked sinus ostium and facilitating drainage. Oxymetazoline 0.05% (Afrin or Vicks Nasal Spray) and phenylephrine 1% are useful topical decongestant medications. The vasoconstrictor action of oxymetazoline lasts approximately 5 to 8 hours, which is preferred in comparison with 1 hour for phenylephrine. However, decongestant drugs have many disadvantages. Topical decongestant drugs can cause a rebound phenomenon and the development of rhinitis medicamentosa if used more than 3 to 4 days. The effectiveness of the topical decongestant is markedly enhanced by proper position of the patient's head during administration of the drug. It should also be noted that the pulse amplitude and blood flow in the sinus mucosa is reduced with decongestant drugs, such as oxymetazoline. This may, in turn, decrease the defense mechanism of the tissues.[123]

Caution is advised in pseudoephedrine administration to patients with high blood pressure, heart disease, diabetes, thyroid disease, and/or prostatic enlargement. The use of this decongestant should be avoided in patients taking antihypertension or antidepressant drugs containing a monoamine oxidase inhibitor because of a potentiation of the action of the sympathomimetic amine. Patients receiving digitalis may experience an increase in ectopic pacemaker activity. Side effects of this systemic decongestant also include nervousness, dizziness, or sleeplessness.

As a consequence of the medical and local risks of decongestant medications, the modified sinus graft pharmacologic protocol extended the use of corticosteroid medications (1 day prior) and discontinued the preoperative or postoperative dose of oxymetazoline. Decongestant medications should only be used for 1 to 3 days if signs and symptoms of postoperative sinusitis are present and the ostiomeatal complex is obtunded from the surrounding mucosa.

Box 38-4 Glucocorticoid Protocol

Dexamethasone (4 mg)

- Two tablets (8 mg) in the morning, the day before surgery
- Two tablets (8 mg) the morning of surgery
- One tablet (4 mg) in the morning, the day after surgery
- One half to one tablet (2 to 4 mg) in the morning, the second day after surgery

WWW.HIGHDENT.IR

Analgesic Medications

Any analgesic combination containing codeine, such as Tylenol 3, is prescribed postoperatively because codeine is a potent antitussive, and coughing may place additional pressure on the sinus membrane and introduce bacteria into the graft. The patient is instructed to cough (if necessary) with the mouth open so that no air pressure through the ostium occurs.

Cryotherapy

With sinus elevation procedures, postoperative inflammation in the posterior maxilla is very common. Because postoperative swelling can adversely affect the incision line, measures should be taken to minimize this condition. Application of cold dressings and cold oral liquids, along with elevation of the head and limited activity for 2 to 3 days, will help minimize the swelling. The applied cold dressing and liquids will cause vasoconstriction of the capillary vessels, thus reducing the flow of blood and lymph, resulting in a lower degree of swelling. Ice or cold dressings should only be used for the first 24 to 48 hours. After 2 to 3 days, heat may be applied to the region to increase blood and lymph flow, to help clear the area of the inflammatory consequences. This also helps reduce any ecchymosis that may have occurred from the tissue reflection.

SURGICAL TECHNIQUE

Preparation and Antisepsis

Because of the extent of tissue reflection, technique sensitivity of the surgery, and need for antisepsis, oral or conscious sedation is recommended for sinus graft procedures. After sedation and adequate infiltration anesthesia (i.e., posterior and middle alveolar nerve, greater palatine nerve) are obtained, the patient is prepared for surgery. Preparation of the surgical site is important in sinus manipulation surgery to reduce contamination by the patient's own normal flora. The mouth cannot become a sterile environment for surgery. However, intraoral preparation before surgery may significantly reduce the bacterial count in the mouth. Studies reveal a significant reduction in bacteremia during extractions and implant surgery complications after preparation with antiseptic mouth rinse.[124,125]

Iodophor compounds (Betadine) are a most effective antiseptic. However, because the iodine is complexed with organic surface-active agents, it has been shown to inhibit the osteoinduction of demineralized bone. Therefore care is taken to avoid contamination of the graft. As a consequence, intraoral preparation of the surgical site requiring a bone graft, a 0.12% chlorhexidine gluconate (Peridex) scrub, and rinse is most often used. Extraoral presurgical scrubbing of the skin should also be performed with chlorhexidine antiseptics.

SINUS SURGERY: HISTORY

In the early 1970s, Tatum[3,4] began to augment the posterior maxilla with autogenous rib bone to produce adequate vertical bone for implant support. He found that onlay grafts below the existing alveolar crest would decrease the posterior intradental height significantly, yet very little bone for endosteal implants would be gained. Therefore in 1974, Tatum developed a modified Caldwell-Luc procedure for SA grafting. The crest of the maxilla was infractured to elevate the maxillary sinus membrane. Autogenous bone was then added in the area previously occupied by the inferior third of the sinus. Endosteal implants were inserted in this grafted bone after approximately 6 months. Implants were then loaded with final prostheses after an additional 6 months.

In 1975, Tatum developed a lateral-approach surgical technique to elevate the sinus membrane and place the implant simultaneously. The implant system used was a one-piece ceramic implant, and a permucosal post was required during the healing period. Early ceramic implants were not designed adequately for this procedure, and results with the technique were unpredictable. In 1981, Tatum[126,127] developed a submerged Ti implant for use in the posterior maxilla and achieved predictable results (Figure 38-19).

From 1974 to 1979, the primary graft material for sinus grafts was autologous bone. In 1980, Tatum[126,127] further expanded the application of the SA augmentation technique with a lateral maxillary approach, with the use of synthetic bone. The same year, Boyne and James[5] first reported on the sinus graft technique using autogenous bone for SA grafts. Most of the publications in the 1980s were anecdotal or based on very small sample sizes.

TREATMENT CLASSIFICATIONS FOR THE POSTERIOR MAXILLA

In 1984, Misch[69] organized a treatment approach to the posterior maxilla based on the amount of bone below the antrum, and in 1986 he expanded the treatment approach to include the available bone width that was related to implant design (see Figure 38-12). In 1987, Misch[69] included the technique of the sinus floor elevation through the implant osteotomy before implant placement. He reported on 170 sinus graft cases, with two complications and an uneventful resolution.

In the Misch SA classification, the treatment modality is dependent on the available bone height between the

floor of the antrum and the crest of the residual ridge in the region of the ideal implant locations. The SA protocol also suggested a surgical approach, bone graft material, and a time table for healing before prosthetic reconstruction. In 1995, Misch[41] modified his 1987 classifications to include the lateral dimension of the sinus cavity; this dimension was used to modify the healing period protocol, because smaller-width sinuses (0 to 10 mm) form bone faster than larger-width (>15 mm) sinuses. The Division A–width ridge was also increased to 6 mm to permit more bone to flank the implant on each side. Jensen[128] and Chiapasco[129] and Misch et al.[130] proposed other classifications of the sinus graft procedure.

SURGICAL TECHNIQUE

Subantral Option One: Conventional Implant Placement

The first Misch SA treatment option, SA-1, occurs when sufficient bone height is available to permit the placement of endosteal implants following a usual surgical protocol. Because the quality of bone in the posterior maxilla often is D3 or D4 bone, bone compaction to prepare the implant site is common. This permits a more rigid initial insertion of the implant and also increases the BIC after initial healing.

In the abundant bone volume (Division A), root form implants are used for prosthetic support. The minimum ideal bone height is related to implant design and bone density; however, at least a 12-mm implant in height is suggested for a 4-mm-diameter threaded implant (Figure 38-20).

The goal of the sinus graft in the posterior maxilla is to augment the antral floor and gain additional bone in height. As a result, the sinus graft procedure results in an SA-1 condition after bone formation. Therefore after successful sinus grafts, the patient is placed in the SA-1 category and surgical approach. Often the softer bone type after sinus graft indicates bone compression rather than bone extraction techniques (Figure 38-21).

Because the maxillary sinus is not invaded during an SA-1 approach, it is less critical to evaluate the sinus before implant insertion. Therefore the contraindications for sinus graft surgery do not apply for implant insertion when adequate bone is present below the sinus for implants of adequate size to support the load of the prosthesis. Although a common axiom in implant dentistry is to remain 2 mm or more from an opposing landmark, this is not necessary in the SA region.

Narrower bone volume patients (Division B) in SA-1 may be treated with osteoplasty or augmentation to increase the width of bone. The insertion of smaller surface area implants (as small-diameter root form implants) is not suggested because the forces are greater in the posterior regions of the mouth, and the bone density is less than in most regions. In addition, the narrow ridge is often more medial than the central fossa of the mandibular teeth and will result in an offset load on the restoration, which will increase the strain to the bone.

Osteoplasty in the SA-1 posterior maxilla may change the SA category if the height of the remaining bone is less than 12 mm after the bone modification is completed. Augmentation for width may be accomplished with bone spreading, autogenous onlay, and/or appositional grafts. Larger-diameter implants are often required in the molar region, and bone spreading to place wider implants is the most common approach when the bone density is poor. If less than 2.5 mm of width is available in the posterior edentulous region (C–w), then the most predictable treatment option is to increase width using onlay autogenous bone grafts. After graft maturation the

area is reevaluated to determine the proper treatment plan classification.

Endosteal implants in the SA-1 category are left to heal in a nonfunctional environment for approximately 4 to 8 months (depending on bone density) before the abutment post or posts are added for prosthodontic reconstruction. Care is taken to ensure that the implants are not traumatized during the initial healing period. Progressive loading during the prosthetic phases of the treatment is suggested in D3 or D4 bone.

Subantral Option Two: Sinus Lift and Simultaneous Implant Placement

The second SA option in the Misch SA classification, SA-2, is selected when 10 to 12 mm of vertical bone

WWW.HIGHDENT.IR

همیار دندانسازان

is present (2 mm less than the minimum height in SA-1) (Figure 38-22). To obtain the 12 mm of vertical bone necessary for improved implant survival in ridges of adequate width (Division A), the antral floor is elevated through the implant osteotomy 0 to 2 mm. Tatum[3,4,126] originally developed this technique in 1970, and Misch[69] first published it in 1987. Summers[131] published a similar procedure in 1994, 24 years after Tatum's first presentation.

The SA-2 surgical approach modifies the floor of the maxillary sinus. Therefore a preexisting pathologic condition of the sinus should not be present, because it may affect the implant site by retrograde infection.

Incision and Reflection

In an edentulous posterior maxilla, a full-thickness incision is made on the crest of the edentulous ridge from the tuberosity to the distal of the canine region.

WWW.HIGHDENT.IR

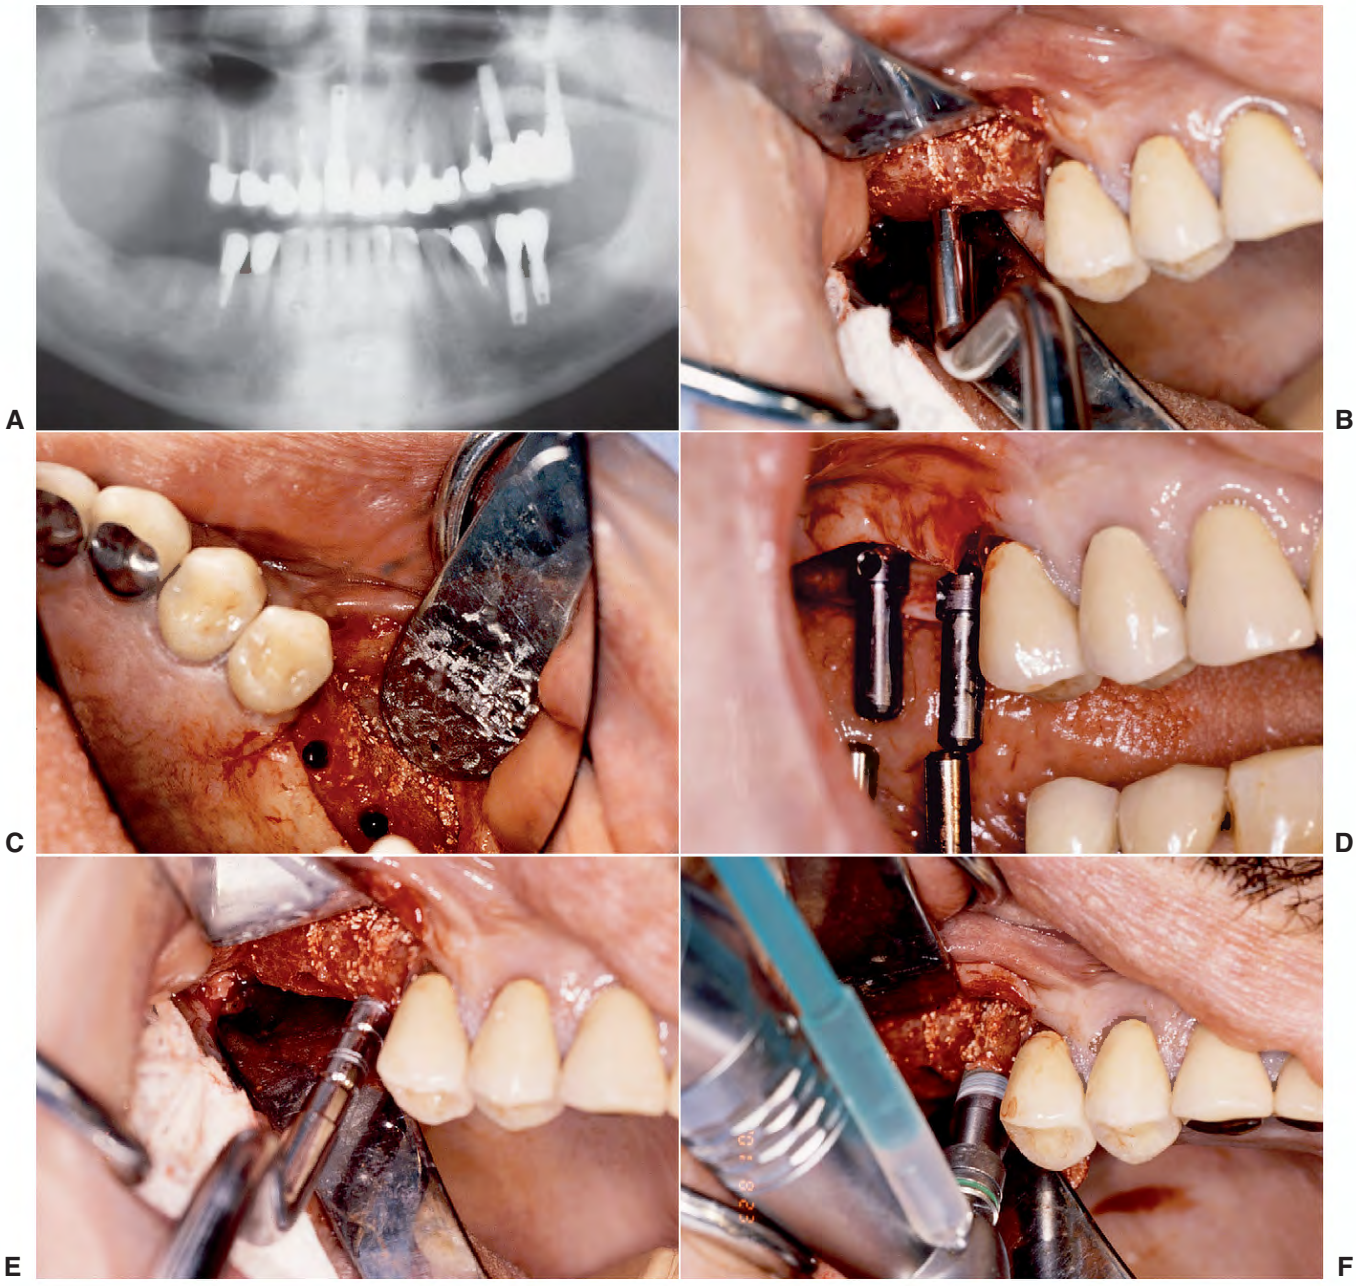

Figure 38-21 **A,** A panoramic radiograph of a maxillary right posterior region after a sinus graft has healed 6 months. **B,** A bone compression technique is used to prepare the osteotomy. **C,** The initial osteotomies with adequate final bone for implant insertion. The bone compaction technique is used to compress the bone, not expand the facial plate. **D,** Direction indicators indicate the osteotomies are parallel to each other and perpendicular to the occlusal plane. They are also over the direction indicators of the implant osteotomies in the mandibular arch. **E,** A larger-diameter osteotome prepares the mesial site. **F,** A threaded implant is inserted with a slow-speed hand piece at 30 rpm. *Continued*

A vertical, lateral relief incision is made at its distal and anterior extension of the crestal incision for approximately 5 mm. If minimal attached tissue exists on the crest of the ridge, which is more often observed in the premolar region, then the primary incision is made more palatal to place more keratinized tissue on the facial aspect. When teeth are present in the region, the crestal incision extends at least one tooth beyond the edentulous site. When one tooth is missing, the reflection is similar to a single-tooth replacement option, and even a direct (flapless technique) may be used.

A full-thickness palatal flap is first reflected because the palatal dense cortical plate facilitates soft tissue reflection. Special attention is given to avoid the pathway of the greater palatine artery or to remain completely subperiosteal so that this structure remains in the soft tissue. The labial mucosa is pulled off the edentulous ridge, rather than elevating the tissue from the bone.

WWW.HIGHDENT.IR

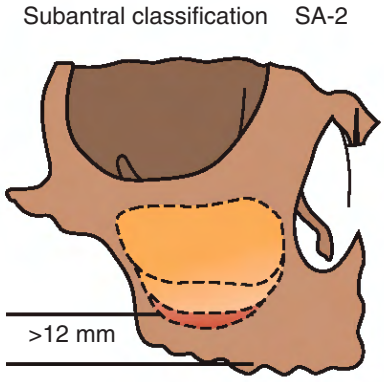

Figure 38-22 A subantral (SA)-2 option is indicated when 10 to 12 mm of bone is present below the maxillary sinus. The goal is to elevate the antral floor 0 to 2 mm within the osteotomy and simultaneously place an endosteal implant.

The crest is not used to leverage the tissue, because the ridge may have minimal cortical bone. This could result in damage to the residual ridge or possibly even penetrate the sinus cavity. Once the tissue is reflected, the width of the available bone is evaluated to ensure that it is greater than 6 mm wide and allows the placement of Division A root form implants.

Osteotomy and Sinus Lift (SA-2)

The endosteal implant osteotomy is prepared as determined by the density of bone protocol, which is usually D3 bone. The depth of the osteotomy is approximately 1 to 2 mm short of the floor of the antrum (Figure 38-23). When in doubt of the height dimension, the osteotomy should err on a shorter length. The implant osteotomy is prepared to the appropriate final diameter, short of the antral floor, following the established protocol for bone density.

A flat-end or cupped-shape osteotome of the same diameter as the final osteotomy is selected. It is of a different end shape than osteotomes used for bone spreading. The osteotome is inserted and tapped firmly in 0.5- to 1.0-mm increments beyond the osteotomy until reaching its final vertical position, up to 2 mm beyond the prepared implant osteotomy (Figure 38-24). A slow elevation of the sinus floor is less likely to tear the sinus mucosa. This surgical approach compresses the bone below the antrum, causes a greenstick-type fracture in the antral floor, and slowly elevates the unprepared bone and sinus membrane over the broad-based osteotome. If the osteotome cannot proceed to the desired osteotomy depth after tapping, then it is

WWW.HIGHDENT.IR

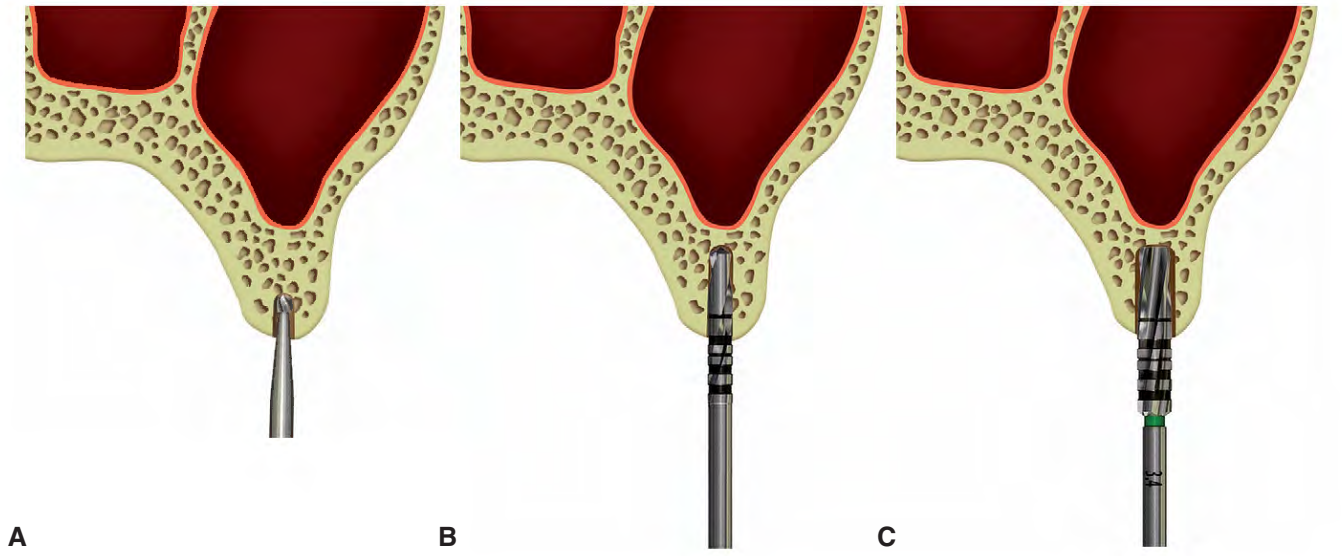

Figure 38-23 **A,** The subantral (SA)-2 technique begins with a pilot bur to mark the implant site. **B,** A 2-mm twist drill prepares the osteotomy 1 to 2 mm short of the sinus floor **C,** A final osteotomy width is sequentially obtained, remaining 1 to 2 mm short of the antral floor.

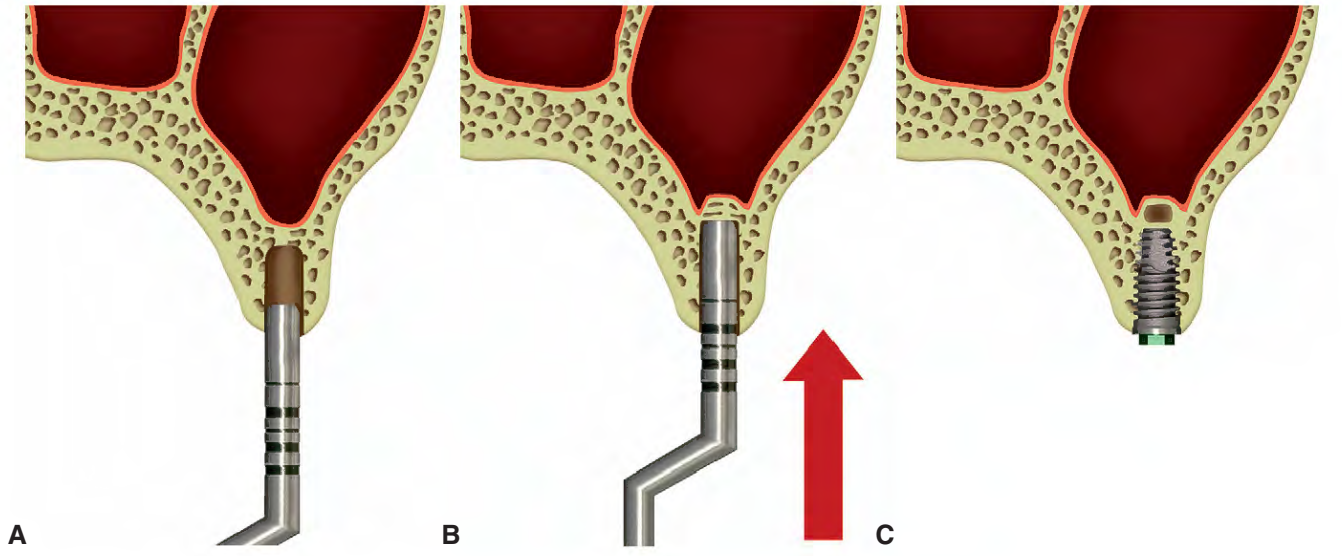

Figure 38-24 **A,** A flat-ended osteotome, the same diameter as the final osteotomy size, is used within the site. **B,** A surgical mallet is used to gently and slowly tap the osteotome 1 to 2 mm through the sinus floor. The osteotome raises the floor and 1 to 2 mm of bone with the sinus mucosa over the implant site. **C,** An implant is inserted into the osteotomy and extends 0 to 2 mm above the surgical sinus floor.

removed and the osteotomy is prepared again with rotary drills an additional 1 mm in depth. The osteotome is then reinserted to attempt the greenstick fracture of the antral floor. Extraction forceps may be used to rotate and remove the osteotome from the osteotomy. The osteotome is not luxated, because this will increase the width of the final osteotomy.

Once the osteotome prepares the implant site, the implant may then be threaded into the osteotomy and extend up to 2 mm above the floor of the sinus. The implant is slowly threaded into position so that the membrane is less likely to tear as it is elevated. The apical portion of the implant engages the more dense bone on the cortical floor, ideally with bone over the apex, and an intact sinus membrane. The implant may extend 0 to 2 mm beyond the sinus floor, and the 1 mm of compressed bone covering over the implant apex results in as much as a 3-mm elevation of the sinus mucosa (Figure 38-25).

Some authors have used the SA-2 sinus lift procedure to gain more than 2 mm of implant vertical height and/or place bone graft materials in the osteotomy site before implant insertion. These blind surgical techniques increase the risk of sinus membrane perforation. When the sinus mucosa is perforated, the graft material may extrude into the atrum and increase the risk of postoperative infection, because it may occlude the ostium and alter the environment of the

Continued

sinus proper. If a sinus infection occurs, then a bacterial smear layer may accumulate on the implant apex. This prevents future BIC and may contribute to future sinus infections.

The success of the intact sinus membrane lift cannot be confirmed before or at the time of implant placement. Attempts to feel the elevation of the membrane from within an 8-mm-deep implant osteotomy that is approximately 3 mm in diameter may easily cause tearing of the sinus lining. Four to 6 months after the surgical procedure, a radiograph that demonstrates bone over the implant apex may be used to indicate the success of the 0- to 2-mm increased vertical height. The patient's prosthodontic treatment may proceed similar to that in the SA-1 category.

It is not unusual for the maxillary sinus to drape over the apices of a maxillary molar. When the tooth is extracted, the sinus often resides too close to the crest

for implant insertion, without grafting the sinus floor. Rosen et al.[132] developed a modification to the SA-2 treatment approach for use at the time of an extraction of a maxillary molar.

The technique is indicated when the maxillary molar is extracted, the surrounding walls of bone are intact, and no periapical pathologic condition extends into the antrum. The crest of the ridge to the antral floor should be 7 mm or more in height. Once the tooth is extracted and the surrounding boney walls confirmed, a modification of the SA-2 technique is in order. A 5- to 6-mm trephine bur is used in the center of the extraction site and prepares the bone 1 to 2 mm below the antral floor. A 5- to 6-mm-diameter, flat-ended or cup-shaped osteotome and mallet intrudes the core of bone 2 mm above the sinus floor, creating 9 mm or more of vertical bone. A socket graft may be used within the extraction socket but is not pushed into the surgical space of the

sinus, because it may perforate the sinus mucosa. After 4 months, an implant may be inserted, often with a SA-1 or SA-2 approach.

If sinus membrane perforation occurred during the initial implant placement procedure, then increased bone height is not likely. This is the primary reason why only 0 to 2 mm of additional bone height is attempted with this technique. However, even when membrane perforation occurs and/or no bone grows around the apical end of the implant, the SA-2 technique is of benefit, because the apical end of the implant is surrounded by denser bone. This enhances rigid fixation during healing and increases BIC, leading to improved loading conditions. As a result of the less predictable outcome, one additional implant may be placed or a larger-diameter implant is suggested. If inadequate bone is formed around the apical portion of a implant, then a progressive-loading protocol for D4 bone is suggested during prosthetic reconstruction.

Worth and Stoneman[133] have reported a comparable phenomenon of bone growth under an elevated sinus membrane called *halo formation*. They observed the

WWW.HIGHDENT.IR

natural elevation of the sinus membrane around teeth with periapical disease. The elevation of the membrane resulted in new bone formation once the tooth infection was eliminated. In an article by Palma et al.,[134] the elevation of the sinus membrane in implant insertion, with or without a graft material below the mucosa, gave similar results in primates regarding implant stability or BIC after healing. As a result of the autologous bone present above the apical portion of the implant with an SA-2 technique, and the sinus floor fracture (which increases the regional accelerated phenomenon of bone repair and formation), new bone formation over the implant apex is predictable.

When more than 2 mm of bone is desired above the sinus floor, a lateral-access opening to the antrum, with direct vision and access to elevate the sinus mucosa on the floor, is suggested. Because the lateral-access opening to the sinus is often 10 × 10 mm or larger and the lateral maxilla over the sinus is only 1 mm thick, the sinus mucosa is more readily elevated. If the mucosa is torn, then it may also be sealed with collagen before the sinus floor augmentation. Attempting to elevate the sinus mucosa more than 2 mm through an implant osteotomy 3 to 4 mm wide and 8 mm deep is not predictable. Reiser et al.[135] reported that when the sinus elevation was 4 to 8 mm in cadavers, almost 25% resulted in sinus perforation. The implant osteotomy sinus floor augmentation technique is often attempted because of the perceived ease of surgery of an SA-2 technique versus an SA-3 lateral-access procedure. However, the few extra minutes needed to gain access from the maxillary lateral wall and direct vision to the antral floor present obvious benefits.

Subantral Option Three: Sinus Graft with Immediate or Delayed Endosteal Implant Placement

The third approach to the maxillary posterior edentulous region, SA-3, is indicated when at least 5 mm of vertical bone and sufficient width are present between the antral floor and the crest of the residual ridge in the area of a needed prosthodontic abutment (Figure 38-26). A Tatum lateral maxillary wall approach is performed just superior to the residual alveolar bone. After the lateral-access window and membrane are rotated in and upward to a superior position, a mixture of autogenous bone, alloplast, and/or allograft material is placed in the space previously occupied by the sinus. When the original ridge is greater than 5 mm in width, the implant may be inserted at the same time as the sinus augmentation or delayed 2 or more months before implant insertion.[53,55-60] The short delay between graft placement and implant insertion ensures the graft is more stable and is healing without compromise related to postoperative sinus infection. When the original ridge width is Division B or C–w, an onlay graft in conjunction with the sinus augmentation is a possible treatment option (Table 38-2).

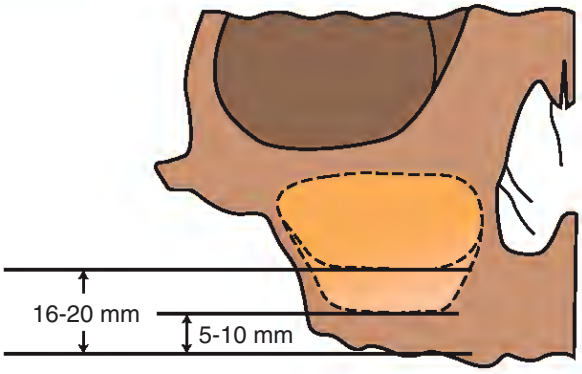

Figure 38-26 A subantral (SA)-3 sinus category exists when 5 to 10 mm of bone exists below the antrum. A Tatum lateral-wall sinus membrane elevation and sinus graft to obtain 16 to 20 mm of bone height is indicated.

The author has chosen a residual height of 5 mm for the SA-3 category for two main reasons: (1) this height (in adequate bone width and quality) can be considered sufficient to allow primary stability of implants placed at the same time of the sinus graft procedure; (2) this height may allow the use of alloplastic materials, because

Table 38-2 Healing Times for Treatment Categories

Figure 38-27 The second division block of the fifth cranial nerve (V2; deep in the pterygomaxillary space) is used for anesthesia.

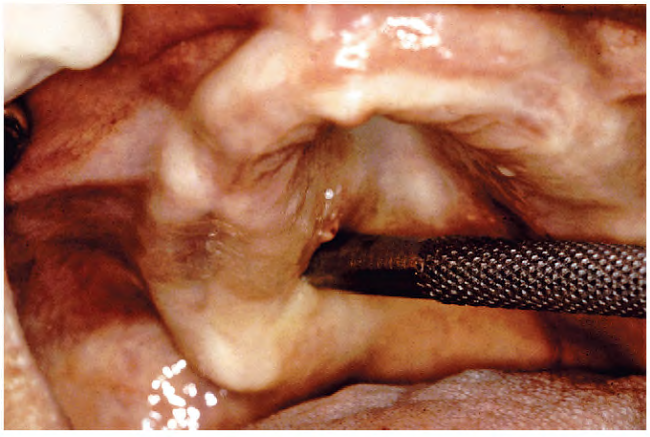

Figure 38-28 An injection deep within the greater palatine foramen may obtain V2 block anesthesia.

adequate amounts of bone may be harvested from the tuberosity to augment the alloplastic component of the graft.

Anesthesia

Infiltration anesthesia has been used with success for sinus graft surgeries in the past; however, more profound regional anesthesia is achieved by blocking the secondary division of the maxillary nerve (V2). The sinus graft surgery often requires the reflection of the soft tissue to the zygomatic process. In addition, several branches of the maxillary branch of the fifth cranial nerve innervate the sinus mucosa. As such, a V2 block is advantageous for patient comfort, and this achieves anesthesia of the hemimaxilla, side of the nose, cheek, lip, and sinus area.

Two options exist for V2 block anesthesia: (1) high and within the pterygomaxillary tissue behind the posterior wall of the maxilla (Figure 38-27) or (2) at the depth of approximately 1 inch with a long-gauge needle within the greater palatine foramen (Figure 38-28). The first method is easier to perform but may injure the pterygoid plexus or the maxillary artery and result in hematoma, or it may fail to reach the proper landmark. With the second option, it is more difficult to find the foramen and negotiate up the canal.[136] It may also injure the greater palatine artery or nerve. Too deep an administration with a greater palatine approach may result in the penetration of the orbit floor. Possible sequelae include periorbital swelling and proptosis, diplopia, retrobulbar block with dilated pupil, corneal anesthesia, motionless eye, retrobulbar hemorrhage, and optic nerve block with transient loss of vision. However, the success rate is greater, and the clinical risks appear minimal. Therefore most often, the first attempt for block anesthesia is within the greater palatine foramen; if unsuccessful, then the high posterior approach is used. Prevention of these complications is ensured by reduction of the needle depth measurement for smaller patients and the strict application of the technique. Proper angulation during penetration prevents the penetration into the nasal cavity through the medial wall of the pterygopalatal fossa.

Infiltration anesthesia is first administered to the posterior and middle alveolar nerve and greater palatine nerve. Scrubbing, gowning, and draping of the patient is next. Then after the infiltration is effective, the V2 block is administered. A long-acting anesthetic such as bupivacaine 0.5% (Marcaine) or etidocaine 1.5% (Duranest) with epinephrine 1:200,000 is preferred. Block anesthesia with these agents is longer acting than infiltration in the maxilla.[136]

Of benefit to find the greater palatine foramen is an open-bore instrument, (i.e., the handle of a mouth mirror with the mirror portion removed). Pressure is applied with this instrument along the palatal tissue, at the union of the residual ridge and hard palate, in the region of the second molar (Figure 38-29). Most often,

Figure 38-29 A blunt open bore instrument determines the greater palatal foramen.

WWW.HIGHDENT.IR

the open-bore handle will feel and recede into the foramen. Slight pressure for a few seconds then marks the tissue over the opening of the foramen. A long, 1 1/2-inch needle is introduced into the foramen from the opposite side of the mouth and negotiates the canal for approximately 1 inch.

Incision Line and Reflection

A crestal incision is made on the palatal aspect of the maxillary posterior edentulous ridge from the tuberosity to one tooth anterior to the anterior wall of the maxillary sinus, leaving at least 3 mm of attached tissue on the facial aspect of the incision. Because ridge resorption occurs toward the midline at the expense of the buccal dimension, the incision is made with awareness of the greater palatal artery, which proceeds close to the crest of the ridge in the severely atrophic maxilla. If bleeding from the palatal flap occurs, a hemostat may be used to constrict the blood vessels distal to the bleeding, pressure may be applied over the greater palatine foramen with a blunt instrument, or electrocoagulation at the bleeding site may be used.

A vertical relief incision is made on the distal of the incision to enhance surgical access to the maxillary tuberosity. A broad-base anterior vertical relief incision is also made at least 10 mm anterior to the anterior vertical wall of the antrum. This may mean that the incision is made on the distal aspect of the first bicuspid or canine when the anterior wall of the antrum is very close to the roots of the anterior teeth. The facial soft tissue flap is designed, following general principles, with a base wider than the crest to ensure proper blood supply. The palatal portion of the flap is first reflected, followed by the facial crestal tissue, which is lifted off the crest.

The facial full-thickness mucoperiosteal flap is reflected to expose the complete lateral wall of the maxilla and a portion of the zygoma. The facial flap should be reflected to provide complete vision and access to maxillary lateral wall. The reflection is usually excessive if the infraorbital nerve (fan-shaped appearance) emerging from the infraorbital foramen is visualized. Aggressive reflection of the facial flap may cause damage to this exposed nerve structure. The reflected labial tissue can be tied to the cheek mucosa with 2-0 silk sutures, carefully avoiding the parotid duct. All fibrous tissue should be removed from the future lateral wall access site to avoid soft tissue contamination of the bone graft. A wet surgical sponge can be used for this purpose (Figure 38-30).

Access Window

The overall design of the lateral-access window is determined after the review of the CT scan, which helps determine the thickness of the lateral wall of the antrum, the position of the antral floor from the crest of the ridge, the posterior of the anterior wall in relationship to the teeth (if present), and the presence of septa on the floor and/or walls of the sinus.

The outline of the Tatum lateral-access window is scored on the bone with a rotary hand piece under copious cooled sterile saline. It is often easier to perform this step at 50,000 rpm, but it is possible even at 2000 rpm, depending on the lateral-wall bone thickness. With experience, the first bur is usually a No. 6 round carbide, which scratches the bone and designs the overall window dimension. This bur is followed with a No. 4 round diamond, which "polishes" away the bone within the groove made by the carbide bur. A No. 6 round diamond bur for the entire process is of benefit for an early learning curve, because carbide burs more readily tear the sinus membrane if the bur inadvertently comes in contact with it. The inferior score line of the rectangular access window on the lateral maxilla is placed approximately 2 to 5 mm above the level of the antral floor (which is 5 to 10 mm from the crest). If the inferior score line is made at or below the level of the antral floor, then infracture of the lateral wall will be very difficult, leading to possible membrane perforation. If the inferior score line is made too high (>5 mm) above the sinus floor, then a ledge above the sinus floor will result in a blind dissection of the membrane on the floor. When available bone height is almost 10 mm, the sinus graft requires only 5 to 6 mm of additional bone. Under these conditions, the lateral access is more limited, and the inferior score line may be 1 to 2 mm above the antral floor.

The most superior aspect of the lateral-access window should be approximately 8 to 10 mm above the inferior score line. A soft tissue retractor placed above the superior margin of the lateral-access window helps retract the facial flap and prevents the retractor's inadvertent slip into the access window, which may damage the underlying membrane of the sinus.

The anterior vertical line of the access window is scored approximately 5 mm distal to the anterior vertical wall of the antrum. If the sinus access window outline is difficult to determine in relation to the sinus cavity, then it should err over the antrum rather than over the bone around this structure. The distal vertical line on the lateral maxilla is approximately 15 mm in the edentulous posterior maxilla from the anterior limit of the window and is usually in the region of the first molar, which is within direct vision of the operator. A larger access window offers many advantages, including less stress on the membrane during initial elevation and ease of additional membrane elevation with instruments because of the direct access that facilitates graft placement. Excessive size of the lateral-access window is not indicated, because the outer bony wall of the maxilla helps bone grow into the sinus graft material.

The corners of the access window are usually round, rather than at right or acute angles. If the corner angles are too sharp, then membrane perforation may occur

The Tatum access window is 2 to 5 mm above the antral floor, 2 to 5 mm from the anterior wall, 15 mm long, and 10 mm in height. **C,** The carbide drill should not perforate the lateral maxilla, which will tear the sinus membrane. A paintbrush stroke is used to outline the access window. **D,** A No. 4 to 6 diamond is used in a straight or contraangle hand piece and deepens the score line of the access window until a bluish hue or bleeding is observed. **E,** A flat-ended metal punch is placed over the lateral-access window. A mallet is used to gently tap the instrument and greenstick fracture the lateral-access window from the lateral wall of the maxilla. **F,** The back, rounded portion of the curette is placed against the lateral-access window and gently pushes it medial. The sharp blade of the curette is placed against the inner wall of bone and scrapes the sinus membrane off the bone. *Continued*

from the use of a surgical curette at the corner or during the infracture of the lateral wall. Once the lateral-access window is delineated, the rotary bur continues to scratch the outline with a paintbrush stroke approach under cooled sterile saline irrigation, until a bluish hue is observed below the bur or hemorrhage from the site is observed. The expansion of the maxillary sinus after tooth loss pushes the arteries of the membrane to the outside of the structure and just below the surrounding bone. Therefore either the bluish hue of the membrane or bleeding in the area are signs of approaching the sinus membrane. This observation should be achieved circumferentially around the access window. The access window should not be overprepared in depth, because touching the membrane with rotary burs may cause it to tear (see Figure 38-30, *C, D*).

Continued

It should be noted that the largest blood vessel in the lateral wall is from an endosseous anastomosis from the posterior superior alveolar and the infraorbital artery that is approximately 1.5 mm in diameter. However, when the lateral wall is very thin in the edentulous patient, this blood vessel atrophies and often is not present. Thus excessive bleeding is rare. This vessel proceeds in the lateral wall of the maxilla 15 to 20 mm from the dentate crest. The horizontal lines of the access window should not be positioned directly over this structure. The vertical lines of the access window often cut through the artery. Because the blood supply may be from either direction, both vertical access lines may have bleeding. This is rarely a concern for vision or blood loss during the procedure. If intraosseous bleeding is a problem, the high-speed diamond used to score the window may be used without irrigation and polish the bleeding site, which cauterizes the vessel

from the heat on the bony wall. Electrocautery may also be used on this vessel, if necessary. A hemostat on the artery may be less effective, because it may fracture the lateral wall and/or perforate the sinus mucosa. Elevating the head and a surgical sponge applied to the site for a few minutes is also sufficient to control this hemorrhage in many cases.

Sinus Membrane Elevation

A flat-ended metal punch (or mirror handle) and mallet are used to gently infracture the lateral-access window from the surrounding bone, while still attached to the thin sinus membrane. The flat-ended punch is first positioned in the center of the window. If light tapping does not greenstick fracture the bone, the flat-ended

punch is placed along the periphery of the access window and tapped again. If the window does not separate easily, the punch is rotated so that only an edge comes in contact with the scored line. This decreases the surface area of the punch against the score line of the window and increases the stress against the bone. Another light tap with the mallet will most likely cause greenstick fracture of the bone along the scored line. If this still does not free the window, then further scoring of the bone with the hand piece and diamond bur is indicated, and the tapping procedure is repeated (see Figure 38-30, *E*).

A short-bladed soft tissue curette designed with two right-angle bends is introduced along the margin of the window (i.e., BioHorizons Sinus Currette No. 1). The curved portion is placed against the window, whereas the sharp edge is placed between the sinus membrane and the margin of the inner wall of the antrum for a

WWW.HIGHDENT.IR

همیار دندانسازان

depth of 2 to 4 mm. If any sharp edges of bone remain on the bone's margin, then they may be flicked off with the curette. The curette is slid along the bone margin, 360 degrees around the access window. This ensures the release of the membrane from the surrounding walls of the sinus without tearing from the sharp bony access margins. The sinus membrane may be elevated from the antral walls easily, because it has few elastic fibers and is not attached to the cortical wall. Specially designed and shaped curettes are available to facilitate this maneuver (see Figure 38-30, *F*).

A larger curved periosteal or sinus membrane elevator is then introduced through the lateral-access window along the inferior border (i.e., BioHorizons Sinus Currette No. 2). Once again, the curved portion is placed against the window, and the sharp margin of the curette is dragged along the floor of the atrum, while elevating the sinus membrane. The curette should always be maintained on the bony floor to avoid a membrane perforation. The curette is never blindly placed into the access window. The surgeon should see and/or feel the curette against the antral floor or sinus walls at all times. Once the mucosa on the antral floor is elevated, the lateral, distal, and medial wall of the sinus is addressed. The curette is pushed against the bone that easily reflects the membrane. The sinus membrane is inspected for perforations or openings into the antrum proper (see Figure 38-30, *G* to *J*).

It is easier to gain direct vision and access to the distal portions of the antrum than the anterior portions when the sinus area expands beyond the access window. Therefore whenever the periosteal elevator or curette cannot stay against the bone with good access in the anterior area, the access window should be increased in size toward the anterior. A Kerrison rongeur or a preparation similar to the initial score-and-fracture technique may be used to expand the size of the access window.

The periosteal elevators and curettes further reflect the membrane off the anterior vertical wall, floor, and medial vertical wall to a height of at least 16 mm from the crest of the ridge, or approximately 8 to 11 mm in an SA-3 procedure. It is better to err on the high side to ensure that ideal implant height may be placed without compromise (always making sure the ostium remains unobstructed). The lateral-access window is positioned as part of the superior wall of the graft site, once in final position. The SA space has the original sinus floor as the base; the posterior antral wall, medial antral wall, and anterior antral wall as its sides; and the lateral-access window and elevated sinus mucosa as its superior wall.

Sinus Graft: Layered Approach

The Top Layer: Collagen and Antibiotic. A resorbable collagen membrane (CollaTape) soaked with a parental form of antibiotic (Ancef 0.2 mL or Cleocin 0.2 mL) is then prepared. The collagen and antibiotic is placed onto the elevated antral floor region and attaches to the sinus mucosa on the superior part of the graft site.

Autogenous bone

Ideally the lateral-access window, which now is part of the superior limit, is not covered with the collagen. The collagen is a carrier for the antibiotic to decrease the risk of postoperative infection. In addition, in case of membrane tearing or separation of the sinus mucosa (with or without the awareness of the surgeon) the collagen membrane seals the opening (see Figure 38-30, *K*; Box 38-5).

The Second Layer: Sinus Graft Materials. The author and several others have investigated the components of the sinus graft using animal research clinical biopsies, case series studies, and reentry observations. Several graft materials have been proposed in single use or mixes of different combinations, which include autogenous bone,* demineralized freeze-dried bone (DFDB) powder or cortical fibers,[14,149-153] freeze-dried bone (FDBA),[33,34,154,155] β-tricalcium phosphate (β-TCP),[6,32,64,81] xenograft hydroxyapatite (HA) (bovine anorganic bone),† calcium carbonates (bioactive glass),[161-162] and all combinations of these.‡ Recently, additional research has been focusing on combining "traditional" bone substitutes with bone growth factors.[28,155,171-174] Each graft material presents a similar, yet distinct, biological approach to the sinus graft.

DFDB has minute amounts of osteoinductive material capable of inducing some undifferentiated mesenchymal cells to form osteoblasts. The mechanism for this process appears to relate to the bone morphogenic protein found primarily in cortical bone. The ideal size and shape appears to be fibers of cortical bone (Grafton). In animal and human studies, demineralized freeze-dried

WWW.HIGHDENT.IR

bone allograft (DFDBA) powder used alone in sinus grafts did not provide a satisfactory result, and the author does not use it currently. Bone was present, but not in as much volume as the graft material originally placed. Speculation exists that the material resorbes more rapidly than the bone formation process, resulting in lesser volume of bone. In addition, when DFDB is placed into an area of low-oxygen tension (hypoxic or hypocellular tissue), the material results in fibrous or cartilage tissue rather than bone.[175] Other authors have observed similar conclusions on the poor performance of DFDB used alone in animal and human studies.[152,165,167,176,177] At the Sinus Graft Consensus Conference,[13] high success rates were reported for all materials and combinations, with the exception of DFDB when used alone.

The DFDB portion of the graft appears primarily to be a source of type I collagen and a small secondary response of BMP for undifferentiated cells. It may resorb and permit blood vessels to invade the graft. Its combination with autogenous bone allows bone formation from phase I or phase II simultaneously. Researchers have postulated that this may produce more bone than when either material is used alone.[164,178-180] In the graft technique the author uses, the DFDB cortical fibers are mixed with another graft material (e.g., microporous HA or a mineralized bone allograft) and platelet-rich plasma (PRP) (not with whole blood or anesthetic solution). The toxic by-products of blood catabolism[181] and the acidic pH of anesthetic may decrease bone formation. Whole blood is drawn (10 to 20 mL) from the patient and placed into a centrifuge for approximately 10 minutes at 3400 to 5600 rpm. The blood is separated into three layers: (1) red blood cells, (2) a buffy coat of platelets and white blood cells, and (3) serum. The buffy coat and serum is then centrifuged again to increase the concentration of platelets. Platelets contain platelet-derived growth factors (PDGFs), which are involved in the cascade of bone mineralization.[28,155,171] The PRP is added to the DFDB cortical fibers and osteoconductive ceramic graft material in the intermediate layer of the sinus graft. An antibiotic is also added to the graft material when used for sinus grafts.

Osteoconduction describes the ability of a material to permit bone to grow in its presence. An osteoconductive material does not grow bone in the absence of bone or differentiated mesenchymal cells. Therefore these materials act more as fillers and may help form a future bone matrix or maintain volume and consistency for surgical placement. Microporous HA may include mixtures of calcified or mineralized cortical or trabecular bone, β-TCP, $CaPO_4$, and xenographic bone and are all osteoconductive bone graft materials.

A histomorphometric study by Froum et al.[182] at 26 to 32 weeks after grafting evaluated mineralized cancellous bone allograft (MCBA) and anorganic bovine bone material (ABBM) for sinus augmentation. Bilateral sinus grafts, one filled with MCBA and the other with ABBM, were compared. The average vital bone content of the MCBA was 28.25%; the ABBM was only 12.44%. This report is similar to studies by the author; however, when a layered approach to sinus grafting includes autogenous bone at the most inferior layer, a greater vital bone percent is obtained.[179]

The osteoconductive portion of the graft is mixed with an antibiotic for sinus grafts, because the risk of infection is greater than for most bone-grafting procedures. A parental form of antibiotic is used rather than a tablet form, because oral antibiotic drugs often have fillers in the product that are not osteoconductive. The most common antibiotic is Ancef 500 mg/mL, and 0.8 mL of solution is added to the graft.

In sinus grafts the second layer of the graft consists of either microporous HA, inorganic bovine bone, or mineralized FDBA (70%) mixed with 30% DFDB (cortical fibers), the PRP obtained from 10 cc of whole blood, and a parental form of antibiotic. The mixture forms the intermediate layer of the sinus graft, and it is placed below the collagen and antibiotic (which is on the top) and the autogenous bone on the original sinus floor on the bottom. These materials are mixed together, placed in an open 3-mL syringe that has its end removed, and placed in the sinus graft site with a forward and inferior packing motion. Because the membrane has been elevated, the sinus graft mixture can be introduced below it and condensed into position. Packing is firm but not excessive, because perforation of the medial wall is possible and spaces for blood vessels must be present to grow to form new bone (see Figure 38-30, *N* and *O*).

The Bottom Layer: Regional Acceleratory Phenomenon. Once the sinus membrane has been elevated and collagen membrane plus antibiotic has been inserted into the superior aspect of the graft site, the original antral floor and anterior wall are scratched with a sharp hand instrument. This trauma sets up a regional acceleratory phenomenon (RAP) that introduces more growth factors into the site and helps blood vessels from the bony walls to grow into the graft. These vessels allow migration of osteoclasts and osteoblasts that resorb and replace the graft with living bone. In addition, the blood vessels provide blood supply to the autologous bone portion of the graft, required for initial osteogenesis.

The medial wall and posterior wall are not aggressively scratched; because they are so thin, perforation may occur (see Figure 38-30, *L*).

The size of the antrum in the lower one third is evaluated once the membrane has been elevated. The lateral wall to medial nasal wall may be less than 10 mm (small), 10 to 20 mm (average), or greater than 20 mm (large) and noted in the surgical report. This can be correlated with the rate of graft transformation because

WWW.HIGHDENT.IR

همیار دندانسازان

the new bone forms from the surrounding walls of bone around the graft site. In general, the bone graft maturation time varies from 4 to 10 months, depending on type of graft material and size of the graft site mediolateral and anteroposterior (A-P) dimension.

Autologous Bone. An osteogenic material is capable of producing bone, even in the absence of local undifferentiated mesenchymal cells. Autologous bone predictably exhibits this activity in the sinus graft. Tatum[3,4] first developed and reported the use of autogenous bone for sinus grafts in the 1970s, and Boyne and James[5] first published the information in 1980. In primates *(Macaca fascicularis)*, Misch[178,179] found the use of iliac crest or tail bone in sinus grafts produced bone slightly denser than typical in the region, as evidenced from histology sections harvested at the reentry procedure. Similar findings have been observed during case series studies with patients undergoing sinus grafts with autologous bone from the iliac crest or intraoral donor sites.[148,152,165]

It is interesting to note that sinus grafts in the literature that have used all autogenous bone have lower success rates than sinus grafts with synthetic substitutes (e.g., Del Fabbro et al.[29] reported 87.70% versus 95.98%).[8,29,36,139,137] However, these reports are misleading. The sinus graft success is linked to the success rate of the implants inserted. Those articles that used autologous bone as the sinus graft material most often used a machine surface condition implant, whereas those articles with only bone substitutes most often used a rough implant surface condition. When success rates of implants in a sinus graft relative to implant surface condition are evaluated, smooth-surface implants were 85.64% successful versus rough surfaces at 95.98%. Therefore autogenous bone is no worse than bone substitutes as a graft material in the sinus; however, it cannot be said to be better.

All the grafts studied by the author have included at least some autogenous bone. The Tatum surgical approach, using a portion of the lateral maxilla attached to the sinus membrane to gain access to the graft region, results in at least some autogenous cortical bone in the graft. Whether the lateral-wall cortical bone is an actual medium for bone growth has not been determined, but this is a reasonable speculation. In addition, an autograft is harvested and placed on the original sinus floor. The author has performed reentry of more than 1500 sinus grafts (at implant placement) accompanied by more than 50 human histologic sections and 18 primate sinus grafts and histology. A consistent histologic and clinical finding is that bone grows into the SA region from the surrounding walls of the maxillary antrum where the sinus membrane was elevated.[178,179,183] In other words, the bone growth came from the surrounding walls of bone, similar to an extraction socket. The last regions to form bone are usually the center of the lateral-access window and the region under the elevated sinus membrane. In fact, no new bone at time intervals up to 12 months was found to grow immediately under the sinus membrane.

As a result of these observations, Misch altered the surgical approach and alloplastic and/or autologous graft placement position after 1987. Since then, the sinus membrane of the medial wall of the antrum is consistently elevated to the height of the SA augmentation. This provides an additional wall for host bone to help new bone formation. The sinus membrane of the anterior wall, and usually the posterior wall, are also elevated to the expected height of the sinus graft.

In addition to the lateral-access window, as much autogenous bone as practical is harvested and used in the graft. The most common harvest site for the SA-3 approach is the tuberosity on the same side of the patient that the sinus is being augmented. In this way, an additional surgical site is not required. Additional sources of bone to be added to the graft site may be any debris from implant osteotomies, bone cores over the roots of anterior teeth, sinus exostoses, and cores from the mandibular symphysis or ramus region. The autogenous bone is placed on the original bony floor in the area most indicated for implant insertion. A blood supply from the host bone can be established earlier to this grafted bone and maintains the viability of the transplanted bone cells and the osteogenic potential of the transplanted bone growth factors. Cancellous bone is best used after compaction of the graft to increase the cell volume.[181,183] Autogenous bone represents an important component of the sinus graft, and harvesting of at least some autogenous bone is highly encouraged.

It should be noted that the autograft layer is not mixed with any bone substitute material. When mixed with other materials, it is isolated farther from any initial source of blood vessels; as a consequence, it may not remain vital. Although the release of growth factors, space maintenance, and a calcium source are still of benefit, the primary advantage of osteogenesis is lost when the autogenous bone is mixed with other graft materials.

Once the middle layer of the graft has been placed, the maxillary tuberosity is completely exposed. The SA-3 posterior anatomy most always provides substantial amounts of autogenous bone to harvest. A rotary bur separates the tuberosity from the palatine process and sections the crestal bone distal to the second molar. A curved osteotome and mallet then separate the intact tuberosity. Another option is to harvest the tuberosity with a rongeur or trephine bur. The tuberosity bone is usually soft and therefore is compressed to form more cells per volume. Then it is used in the most inferior portion of the sinus graft, on top of the original antral floor. Additional autogenous bone may be harvested intra- or extraorally as indicated on a case-by-case basis (see Figure 38-30, *P*).

A multilayered graft is therefore placed into the antrum (see Figure 38-30, *Q*). The first material intro-

WWW.HIGHDENT.IR

Box 38-6 Sinus Graft: Immediate and Delayed Implant Placement

Immediate Implant Placement (SA-3I)

When the endosteal implants are inserted at the same time as the sinus graft, the following conditions should exist:

1. Greater than 5 mm bone height
2. Greater than 6 mm bone width
3. D3 bone quality or better
4. No sinus pathologic condition
5. No history of recurrent sinusitis
6. No relative contraindications
7. No or small sinus membrane tear during surgery, completely sealed with collagen
8. No parafunction on removable soft tissue–borne prosthesis

Delayed Implant Placement (SA-3)

Implants should not be inserted at the same time as the sinus graft when the following conditions exist:

1. Less than 6 mm bone width
2. D4 bone quality
3. Treated sinus pathologic condition within last few months
4. History of recurrent sinusitis (especially when treated with recurrent antibiotic medications)
5. Relative contraindications (smoking, medically compromised patient)
6. Medium to large tear in the sinus membrane during the graft surgery
7. Parafunction on overlying removable prosthesis

duced is a collagen membrane and antibiotic, which forms the superior layer of the graft. The next layer (and often the largest) is a 70% mixture of $CaPO_4$ (usually cortical FDBA (MinerOss) or a xenograft microporous HA (OsteoGraft N-300 or Bio-Oss), a 30% volume of DFDB cortical fiber (Grafton), PRP from 10 to 20 cc of whole blood, and antibiotic (Ancef 500 mg/mL, 0.8 mL, or Cleocin 150 mg/mL, 0.8 mL), which acts to form bone through a combination of osteoinduction and osteoconduction pathways. The last material introduced into the antrum in its most inferior position is autogenous bone, usually harvested from the tuberosity. This osteogenic portion of the graft is typically placed in the more anterior regions or in critical future implant sites.

Access Window. A resorbable membrane may be placed over the lateral-access window (see Figure 38-30, *R*). This delays the invasion of fibrous tissue into the graft and enhances the repair of the lateral bony wall. A nonresorbable membrane is not used because it may complicate the treatment of a postoperative sinus infection. A bacterial smear layer may accumulate in the nonresorbable material and contribute to the infection process. An infection with a resorbable membrane is less of an issue, because the lower pH of the infection resorbs the membrane rapidly. PRP is placed over the lateral collagen membrane to increase the amount of growth factors for bone formation and to increase the growth factors for tissue healing. If inadequate PRP is available because it was used in the second layer of the graft, then PPP may be used.

Froum et al.[182] evaluated sinus grafts with barrier membranes over the lateral-access wall compared with no barrier membrane. All sinus graft combinations in the study demonstrated higher vital bone percent on the cores when a barrier membrane was used. Misch observed a higher vital bone percent even when collagen was used over the lateral-access site compared with no collagen. Therefore either a collagen material (CollaTape), when autograft is used, or collagen barrier membrane (BioMend), when no or little autograft is available, should be placed over the lateral maxillary access window site.

Implant Insertion. A review of the literature by Del Fabbro et al.[29] notes success rates of implants placed at the same time as the graft have a survival rate of 92.17%, whereas a delayed implant insertion has a survival rate of 92.93%. The 5 to 10 mm of initial bone height in a SA-3 posterior maxilla, the cortical bone on the residual crest, and the cortical-like bone on the original antral floor may stabilize an implant that is inserted at the time of the graft and permit its rigid fixation. Therefore an endosteal implant may be inserted at this appointment and has been advocated for some years in the past by this author[69] and others.* Therefore when the conditions are ideal for the SA-3 sinus graft, the implant may be inserted (see Figure 38-30, *S*; Box 38-6).

The ideal conditions for implant insertion at the same time as the sinus graft include the following: (1) greater than 5 mm of bone below the antrum, (2) greater than 6 mm width of crestal bone, (3) D2 or D3 bone in the region, (4) no pathologic condition of the sinus is present, (5) no history of recurrent sinusitis is given by the patient, (6) no relative contraindications exist (e.g., smoking, ASA 3 patients with lowered immune responses), (7) no or only a small tear in the sinus membrane during the procedure, and (8) no parafunction on an overlying soft tissue–borne prosthesis.

Although the implant may be inserted at the same time as the sinus graft, several advantages exist to delaying implant placement for approximately 2 to 4 months:

1. The individual rate of healing of the graft may be assessed after 2 to 4 months while the implant osteotomy is being prepared and the implant

*References 10, 13, 36, 127, 128, 176.

WWW.HIGHDENT.IR

همیار دندانسازان

inserted. The healing time for the implant is no longer arbitrary, but it is more patient specific.

2. Under ideal conditions, postoperative sinus graft infections occur in approximately 3% to 5% of patients, which is greater than the percentage for implant placement surgery or intraoral onlay bone grafts. If the sinus graft becomes infected with an implant in place, then a bacterial smear layer may develop on the implant and make future bone contact with the implant less predictable. The infection is also more difficult to treat when the implants are in place and may result in greater resorption of the graft as a consequence. If the infection cannot be adequately treated, then the graft and implant must be removed. Therefore a decreased risk of losing the graft and implant exists if a postoperative infection occurs with a delayed implant insertion. Some reports in the literature indicate a slightly higher failure rate of implants when inserted simultaneously compared with a delayed approach.
3. Blood vessels within the graft are required to form and remodel bone. An implant in the middle of the sinus graft does not provide a source of blood vessels. It may even impair the vascular supply.
4. Bone width augmentation may be indicated in conjunction with sinus grafts to restore proper maxillomandibular ridge relationships and/or increase the implant diameter in the molar region. Augmentation may be performed simultaneously with the sinus graft. As a result, larger-diameter implants may be placed with the delayed technique.
5. The bone in the sinus graft is denser with the delayed implant placement. As such, implant angulation and position may be improved because it is not dictated by existing anatomical limitations at the time of the sinus graft.
6. The surgeon may access the sinus graft before implant insertion. On occasion, the sinus graft underfills a region, and the lack of awareness of the condition during implant insertion at the same time results in an implant placed in the sinus proper, rather than the graft site.
7. On reentry to a sinus graft, it is not unusual to observe a craterlike formation in the center of the lateral-access window, with soft tissue invagination. If the implant is already in place, then it may be difficult to remove the soft tissue and assess its precise extent. When soft tissue is present at a delayed implant insertion, the region is curetted and replaced with a bone graft before implant placement. The healing time for the implant is related to the developing bone assessed at the delayed surgery, not an arbitrary period that may be, on occasion, too brief.

The primary disadvantage of delaying the implant placement is the need for an additional surgery. If overall treatment time is a significant factor for the patient, then the implant may be inserted after 2 months, which considerably reduces the risk of infection after implant insertions. Otherwise, 2 to 4 months or more is typical for the reentry and implant insertion after a SA-3 technique (see Table 38-2).

Soft Tissue Closure. The soft tissues and periosteum should be reapproximated for primary closure without tension, with care to eliminate graft particles in the incision line. However, because a collagen membrane is placed over the lateral-access window, the tissues often will not reapproximate without tension. Therefore the facial flap must often be expanded. A tissue pickup holds the facial flap to the height of the mucogingival tissues junction. The flap is then elevated, and a No. 15 blade is used to incise the tissue 1 mm deep through the periosteum above the mucoperiosteum. Tissue scissors are then introduced into the incision parallel to the facial flap at a depth of 3 to 5 mm. A blunt dissection under the flap releases the periosteum and muscle attachments to the base of the facial flap. The flap may then be advanced over the graft site to the palatal tissues.

It should be noted that horizontal vascular anastomoses occur lateral to the maxilla, within the soft tissue, and approximately 20 mm above the crest of the ridge. A blunt dissection does not violate these vessels. No tension should exist on the facial flap with primary closure of the site. Interrupted horizontal mattress or a continuous suture (3-0 polyglycolic acid [PGA]) may be placed. Suturing is more critical with this procedure than with many other implant placements. Incision line opening may contribute to infection, contamination, or loss of graft materials. The borders and flange of an overlaying soft tissue–borne denture or partial denture are aggressively relieved to eliminate pressure against the lateral wall of the maxilla.

Subantral Option Four: Sinus Graft Healing and Extended Delay of Implant Insertion

In the fourth option for implant treatment of the posterior maxilla, SA-4, the SA region for future endosteal implant insertion is first augmented. This option is indicated when less than 5 mm remains between the residual crest of bone and the floor of the maxillary sinus (Figure 38-31). The SA-4 corresponds to a larger antrum and minimal host bone on the lateral, anterior, and distal regions of the graft, because the antrum generally has expanded more aggressively into these regions. The inadequate vertical bone in these conditions decreases the predictable placement of an implant at the same time as the sinus graft, and less recipient bone exists to act as a vascular bed for the graft (see Figure 30-8). In addition, less autologous bone exists in the tuberosity for harvesting, and fewer septa or webs usually exist in the sinus (and typically exhibit longer mediodistal and

WWW.HIGHDENT.IR

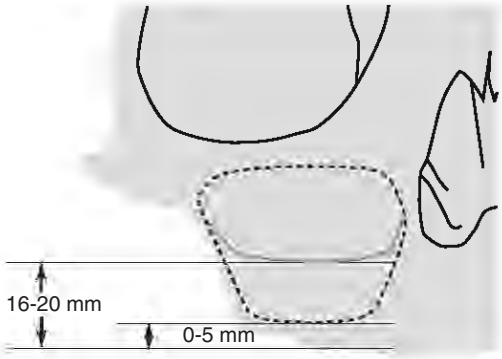

Figure 38-31 The subantral (SA)-4 classification has 0 to 5 mm of bone below the maxillary sinus floor. A sinus graft before an extended delay and before implant placement is in order.

wider lateromedial dimensions). Therefore the fewer bony walls, less favorable vascular bed, minimal local autologous bone, and larger graft volume all mandate a longer healing period and slightly altered surgical approach.

The Tatum lateral-wall approach for sinus graft is performed as in the previous SA-3 procedure (Figure 38-32). Most SA-4 regions provide better surgical access than the SA-3 counterparts because the antrum floor is closer to the crest, compared with the SA-3 maxilla. However, in Division D maxillae it is usually necessary to expose the lateral maxilla and the zygomatic arch. The access window in the severely atrophic maxilla may even be designed in the zygomatic arch. The medial wall of the sinus membrane is elevated at least 16 mm from the crest so that adequate height is available for future endosteal implant placement. This means the elevation is 11 to 16 mm from the sinus floor. The combination of graft materials used and their placement are similar to those for the SA-3 technique. However, because less autogenous bone is often harvested from the tuberosity, an additional harvest site may be required, most often above the roots of the maxillary premolars or from the mandible (i.e., from the ascending ramus).

The width of the host site for most edentulous posterior maxillae is Division A. However, when Division C–w to B exists, an onlay graft for width is indicated. When the graft cannot be secured to the host bone, it is often better to perform the sinus graft 6 to 9 months before the autogenous graft for width. Then after the onlay graft maturation, the implants may be inserted.

VASCULAR HEALING OF THE GRAFT

Healing of the sinus graft takes place by several vascular routes, including the endosseous vascular anastamosis and the vasculature of the sinus membrane from the sphenopalatine artery. In mildly resorbed ridges, the host bone receives its blood supply from both centromedullary and mucoperisosteal vessels. However, as age and the resorption process increases, the bone gradually becomes totally dependant on the mucoperiosteum for the blood supply. The periphery of the graft is mainly supplied by vessels of the sinus membrane and by intraosseous vascular bundles. The central portions of the graft receive blood from collateral branches of the endosseous anastomosis. The extraosseous vascular anastomosis may enter the graft from the lateral-access window.

Many local variables are related to sinus graft maturation, including healing time, the volume of the SA graft, the distance from the lateral to medial wall (small, average, or large), and the amount of autologous bone in the multilayered approach, all of which relate to the speed and amount of new bone formation.

The time of evaluation of the sinus graft is perhaps the greatest variable of all. When the sinus graft is reentered at 2 months, the amount of new bone is minimal. At 4 to 6 months, more new bone in the sinus graft is observed; at 8 to 10 months, more vital bone is evident.* Froum et al.[182] evaluated a sinus graft from the same patient at 4 months, 6 months, 12 months, and 20 months. The amount of new bone continuously increased, compared with the amount of graft material in the antrum. In addition, the additional time allowed the graft to mature into a type of bone typical of the region. It is clear that the more time that elapsed from sinus graft to implant loading, the more vital bone was available to support the occlusal load. Unfortunately, no study is available to date to determine when the ideal bone volume and quality is obtained in a sinus graft or lift relative to elapsed time from initial surgery.

The materials in the sinus graft affect the rate of bone formation. Bone formation is fastest and most complete within the first 4 to 6 months with autogenous bone, followed by the combination of autogenous bone, porous HA, and DFDB (6 to 10 months); alloplasts only (i.e., TCP) may take 24 months to form bone.† In 2003, Merkx et al.[185] reported more new bone formed in a shorter time frame with autogenous bone, whereas HA and bone allograft gave lower vital bone percent values.

A sinus graft site, which is the inferior third of the maxillary sinus, may be 5 to 30 mm in mediolateral depth and 5 to 40 mm in mesiodistal length. The time required to form new bone in this region is related to the volume of the graft. Therefore the time required before implant insertion for SA-4 or implant uncovery in SA-3 is dependent on the volume of the sinus graft. Delayed implant placement for 4 months or more in a small sinus permits the evaluation of the graft and indicates the further time required for direct bone fixation of the implant. If the sinus graft volume is moderate in size, then 6 months before reentry is

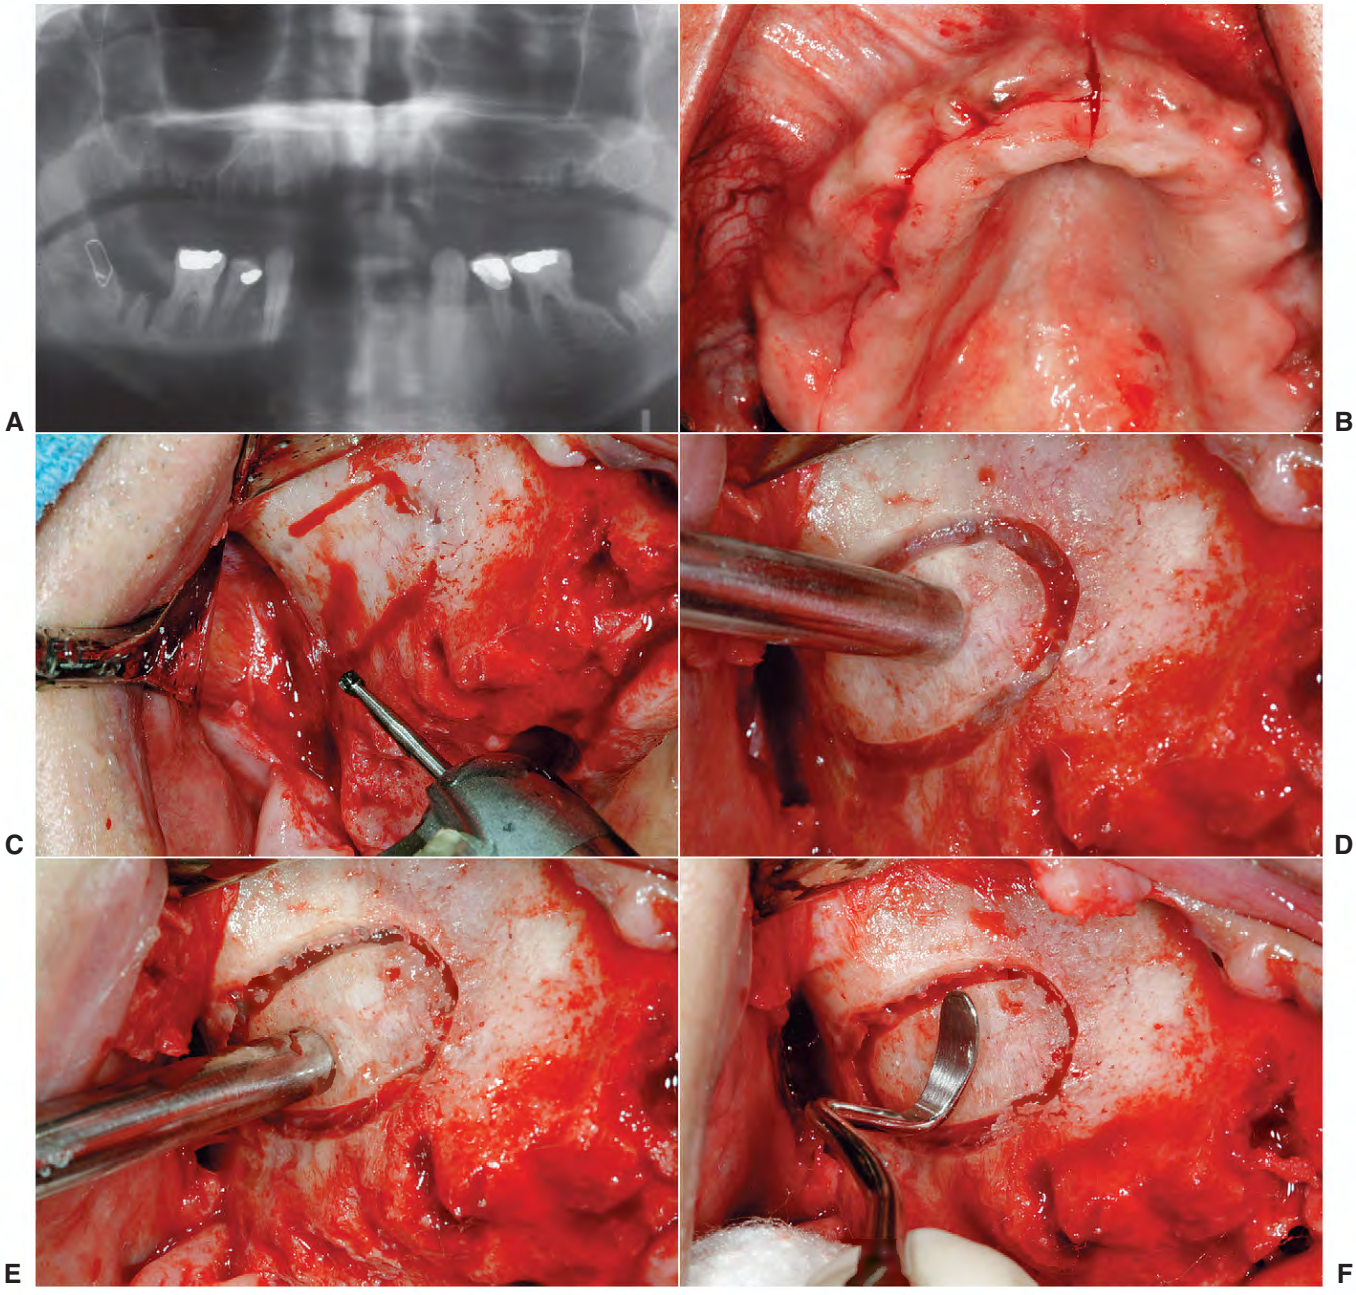

Figure 38-32 **A,** A panoramic radiograph of a completely edentulous maxilla with less than 5 mm of available bone height below the maxillary sinuses (subantral [SA]-4 category). **B,** A crestal incision is made slightly toward the palate and extends from the maxillary right tuberosity region to the midline. Vertical-release incisions are made at both ends of the crestal incision. **C,** A No. 6 round carbide bur with an extended shank in a 5:1 hand piece is used to score the lateral maxilla and represents the initial outline of the Tatum lateral-access window to the maxillary sinus. **D,** A blunt instrument is placed on the lateral-access window and gently tapped with a mallet to greenstick fracture the access window from the lateral maxilla. **E,** The window separates from the lateral maxilla and may be depressed 1 to 2 mm toward the antrum. Because the window is large, a reduced amount of stress is applied to the sinus membrane. Because the sinus membrane has few elastic fibers connected to bone, the membrane is elevated from the rim of the access window. **F,** The round back of the double-action sinus curette is placed against and depresses the access window 1 to 2 mm. *Continued*

suggested. A large antrum (>20 mm wide and >30 mm A-P) may require 8 months before the implant insertion or uncovery. If the bone density was D4 at implant placement, the graft site was large, and/or little autologous bone was used in the graft, then the time before uncovery or placement of the implants may be as long as 10 months.

POSTOPERATIVE INSTRUCTIONS

The postoperative instructions are similar to those for most oral surgery procedures that include sinus manipulation. Rest, ice, pressure, and elevation of the head are particularly important. Strict adherence to the pharmacologic protocol is of major importance.

WWW.HIGHDENT.IR

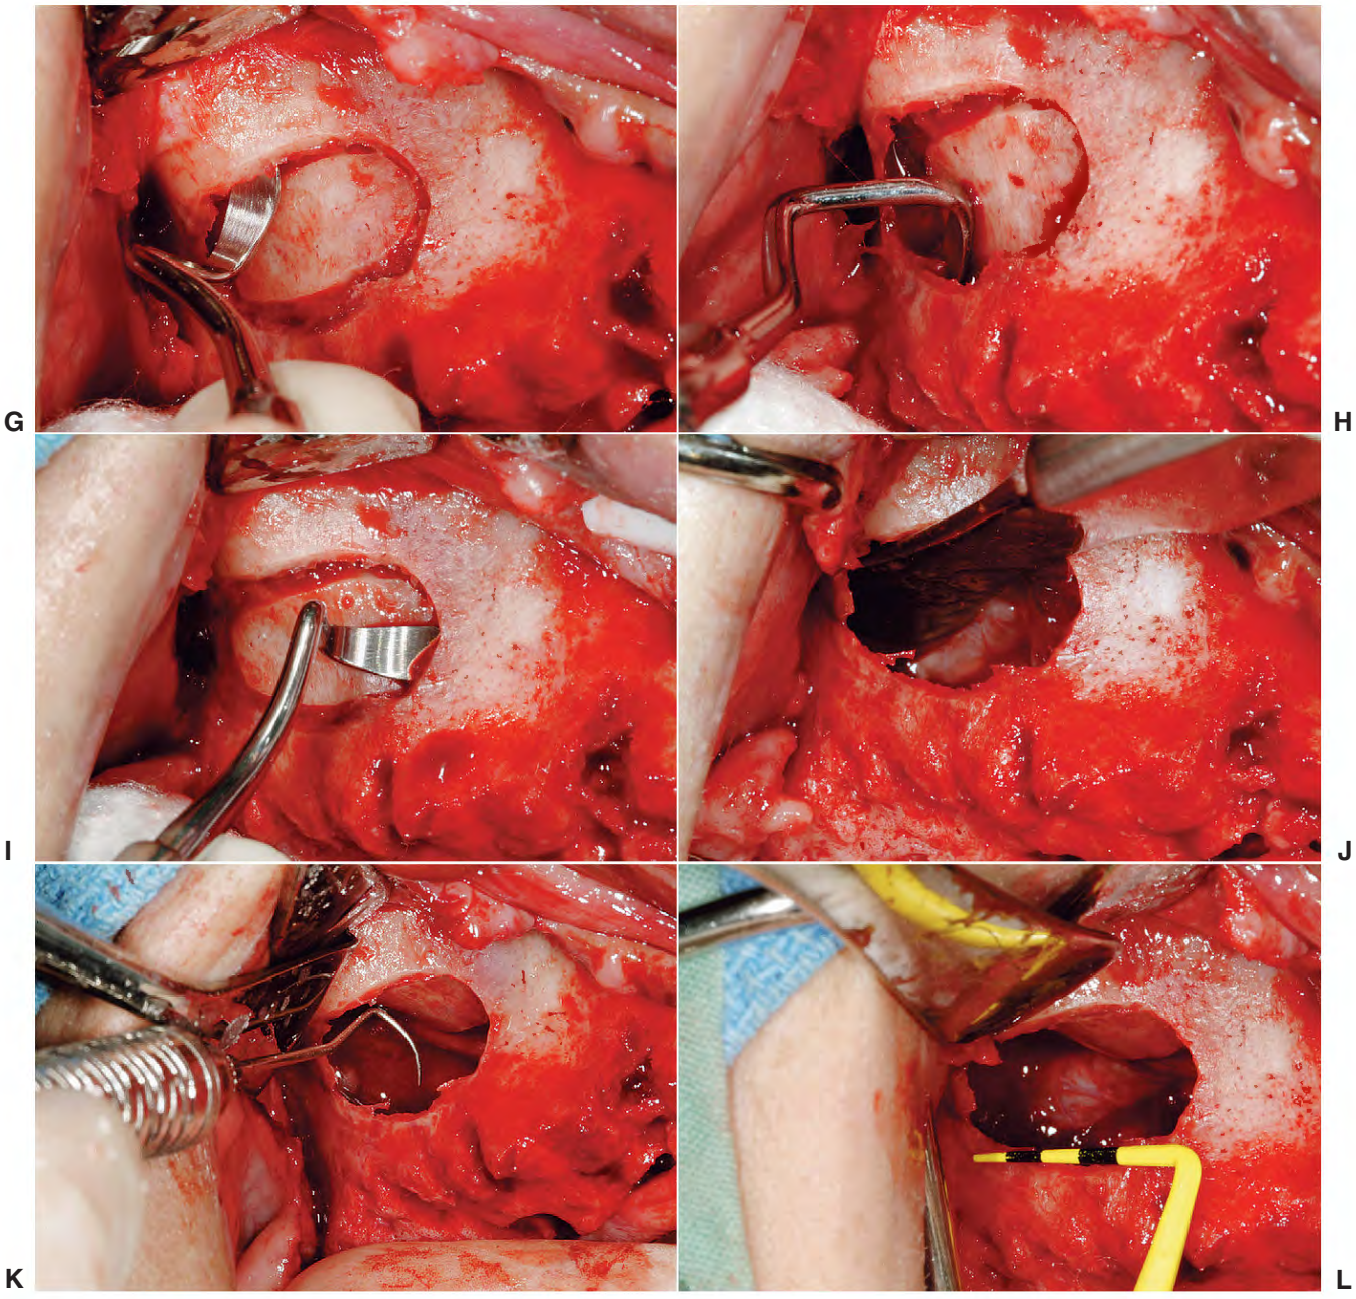

Figure 38-32, cont'd **G,** The blade of the sinus curette is slid along the inner bony wall a few millimeters and scrapes the sinus membrane along the top of the access window from the lateral wall of bone and around the sinus. **H,** The sinus curette slides along the floor of the antrum approximately 5 mm from the access window. **I,** The anterior portion of the access window is engaged. The curette must remain on bone. If it does not scratch the bony wall, then the membrane will be separated. The most common location of a sinus membrane tear is anterior to the access window, because direct vision of the membrane is not possible and the hand position to remain along the bone depends on the double bend of the sinus curette. **J,** The sinus mucosa is gently elevated off the medial wall of the maxillary sinus so that 16 mm of bony walls exist above the crest of the residual ridge. **K,** A sharp explorer is used to scratch the inner sinus bony walls below the elevated sinus mucosa. This increases the regional acceleratory phenomenon and helps to encourage blood vessels from the walls of bone to grow into the sinus graft. **L,** The length of the Tatum lateral-access window approximates 15 mm. The corners are round, rather than square or acute.

In addition, several other instructions are significant (Box 38-7). Although smoking is not an absolute contraindication for sinus grafting, smoking during the days immediately after the procedure is contraindicated because it may compromise the healing from both the intraoral and SA graft region.

In studies by Dietsh-Misch et al.[102] and Levin and Schwartz-Arad,[100] the risk of complications related to smoking and sinus grafts were reported. The complications of nonsmokers and smokers related to sinus graft procedures were similar (two infections out of 35 sinus grafts[102] in nonsmokers versus zero

infections in 25 sinus grafts in smokers; 55.7% versus 63.3%, respectively).[100] A similar report by Peleg et al.[36] also found no statistical difference in implant failure rates in sinus grafts between smokers and nonsmokers up to a 9-year postoperative period. This is not to say smoking is not a concern. For the health of the patient and the potential risk of sinus infection, the patient is encouraged to cease smoking before, during, and after the sinus graft and implant insertion.

Blowing the nose and/or creating negative pressure while sucking through a straw or cigarette should also be eliminated for the week after surgery. Block and Kent[176] reported on a patient who lost the entire sinus graft 2 days after surgery from blowing the nose. Sneezing, if it occurs, should be done with the mouth open to relieve pressure within the sinus. Swelling of the region is common, but pain is usually less severe than after anterior implants in an edentulous mandible.

In addition, the patient should be warned against lifting and pulling on the lip to observe the surgical site or during oral hygiene procedures, to reduce the risk of incision line opening. The patient should be notified that small bone particles or synthetic bone found in the mouth or expelled from the nose with bleeding is not unusual (see Box 38-7).

IMPLANT INSERTION

The implant surgery at reentry after successful sinus grafts is similar to SA-1, with a few exceptions. The periosteal flap on the lateral side is elevated to directly allow inspection of the previous access window of the sinus graft. The previous access window may appear

completely healed with bone, soft and filled with loose graft material, or with cone-shaped fibrous tissue ingrowth (with the base of the cone toward the lateral wall).

If the graft site on the lateral-access wall appears clinically as bone, then the implant osteotomy and placement follow the approach designated by the bone density. If soft tissue has proliferated into the access window from the lateral-tissue region, then it is curetted and removed. The region is again packed to a firm consistency with autologous bone from the previously augmented tuberosity, with DFDB cortical fibers (Grafton), and with resorbable HA (similar to the original graft). The implant osteotomy may then be prepared and the implant placed following the D4 bone protocol. An HA-coated, threaded implant offers an advantage when the bone density is D4 at implant insertion. Additional time (6 months or more) is allowed until the stage II implant uncovery is performed and progressive bone loading is used during prosthetic reconstruction.

The time interval for stage II uncovery and prosthetic procedures after implant insertion of a sinus graft is dependent on the density of bone at the reentry of implant placement (see Box 38-5). The crest of the ridge and the original antral floor may be the only cortical bone in the region for implant fixation. The most common bone density observed for a sinus graft reentry is D3 or D4. Most often, mineralized bone graft material in the sinus graft has not converted to bone. The tactile sense and the CT evaluation interprets the mineralized graft material as a more dense bone type. Therefore a tactile or radiographic D3 bone may actually be D4-like bone. Therefore it is prudent to wait longer (rather than shorter) for implant uncovery. As a result, the total time for SA-3 is 0 to 4 months before implant insertion and 4 to 6 months for uncovery, and an SA-4 sinus graft waits 4 to 6 months for implant insertion and another 4 to 8 for implant uncovery. Therefore the overall graft maturity time is 4 to 10 months for SA-3, and SA-4 healing time is 8 to 14 months before prosthetic reconstruction. Progressive loading after uncovery is most important when the bone is particularly soft and less dense. Inadequate bone formation after the sinus graft healing period of SA-4 surgery is a possible, but uncommon, complication. When observed, the SA-3 technique may be used to place additional SA graft before the implant placement surgery 4 months later.

INTRAOPERATIVE COMPLICATIONS RELATED TO SURGERY

Membrane Perforations

The most common complication during sinus graft surgery is tearing or creation of an opening in the sinus membrane (Box 38-8). This has several causes, which include a preexisting perforation, tearing during scoring of the lateral window, existing or previous pathologic condition, and elevation of the membrane from the

bony walls. This complication occurs about 10% to 34% of the time. It has been reported with a higher frequency in smokers. If membrane perforation occurs more often than this, then the surgeon should give consideration to alter or reevaluate the surgical technique used in sinus grafting.

Sinus membrane perforation usually does not affect the sinus graft. However, in a report of the Sinus Consensus Conference of 1996, analysis of failed sinus grafts found 48% (79 of 164 failures) were attributed to perioperative complications, of which 48% (38) were found in patients that had sinus membrane perforations.[13] In an endoscopic evaluation after sinus grafts, macrolaceration of the sinus membrane resulted in a typical sinusitis appearance, even when clinical conditions of infection were not present.[186] Once the tear or perforation is identified, the continuation of the sinus elevation procedure is modified. The sinus membrane should be elevated off the bony walls of the antrum, despite the mucosal tear. If a portion of the membrane is not elevated away from a sinus wall, then the graft material will be placed on top of the membrane, thus preventing the bone graft from incorporating with the bony wall.

The perforation of the sinus membrane should be sealed to prevent contamination of the graft from the mucus and contents of the sinus proper and to prevent the graft material from extruding into the sinus proper. When graft materials enter the sinus proper, they may become sources for infection or may migrate and close off the ostium to the nose and create an environment for an infection.

However, numerous studies have shown a very low probability of sinus infections after perforations in the sinus membrane. Jensen et al.[10] reported that graft maturation occurred and no sinus infections were observed despite a 35% incidence of sinus perforation during the procedure in 98 patients.

The surgical correction of a perforation is initiated by elevating the sinus mucosal regions distal from the opening. Once the tissues are elevated away from the opening, the membrane elevation with a sinus curette should approach the tear from all sides so that the torn region may be elevated without increasing the opening size. The antral membrane elevation technique decreases the overall size of the antrum, thus "folding" the membrane over on itself and resulting in closure of the perforation. A piece of resorbable collagen membrane (e.g., CollaTape) is placed over the opening to ensure continuity of the sinus mucosa before the sinus bone graft is placed. The collagen sticks to the membrane and seals the SA space from the sinus proper (Figure 38-33).

If the sinus membrane tear is larger than 6 mm and cannot be closed off with the circumelevation approach, then a resorbable collagen membrane, but of a longer resorption cycle (BioMend), may be used to seal the opening. The remaining sinus mucosa is first elevated as described previously. A piece of collagen matrix is cut to cover the sinus tear opening and overlap the margins more than 5 mm. It should be noted that when a sinus tear occurs, it is sealed with a dry collagen membrane so that it may be rotated into the lateral-access opening, gently lifted to the mucosal tissue around the opening, and allowed to stick to the mucosa. Because no antibiotic is used on the collagen to make this procedure easier to perform, additional antibiotic is added to the graft material. Therefore 1 mL of Ancef 500 mg/mL or Cleocin 150 mg/mL is added to the graft material. Once the opening is sealed, the sinus graft procedure may be completed in routine fashion. However, care should be taken when packing the sinus with graft material. After a perforation, the graft is easily pushed through the collagen-sealed opening and into the sinus proper, and a periosteal elevator may be placed at the top of the graft site and under the perforation. The graft material is then gently inserted and pushed toward the sinus floor and sides but not toward the top of the graft (Figure 38-34).

A sinus perforation may cause an increased risk of short-term complications. A greater bacterial penetration risk exists into the graft material through the torn membrane. Therefore additional antibiotic is added to the particulate graft material. In addition, mucus may invade the graft and affect the amount of bone formation. Graft material may leak through the tear into the sinus proper, migrate to and through the ostium, and be eliminated through the nose or obstruct the ostium and prevent the normal sinus drainage.

WWW.HIGHDENT.IR

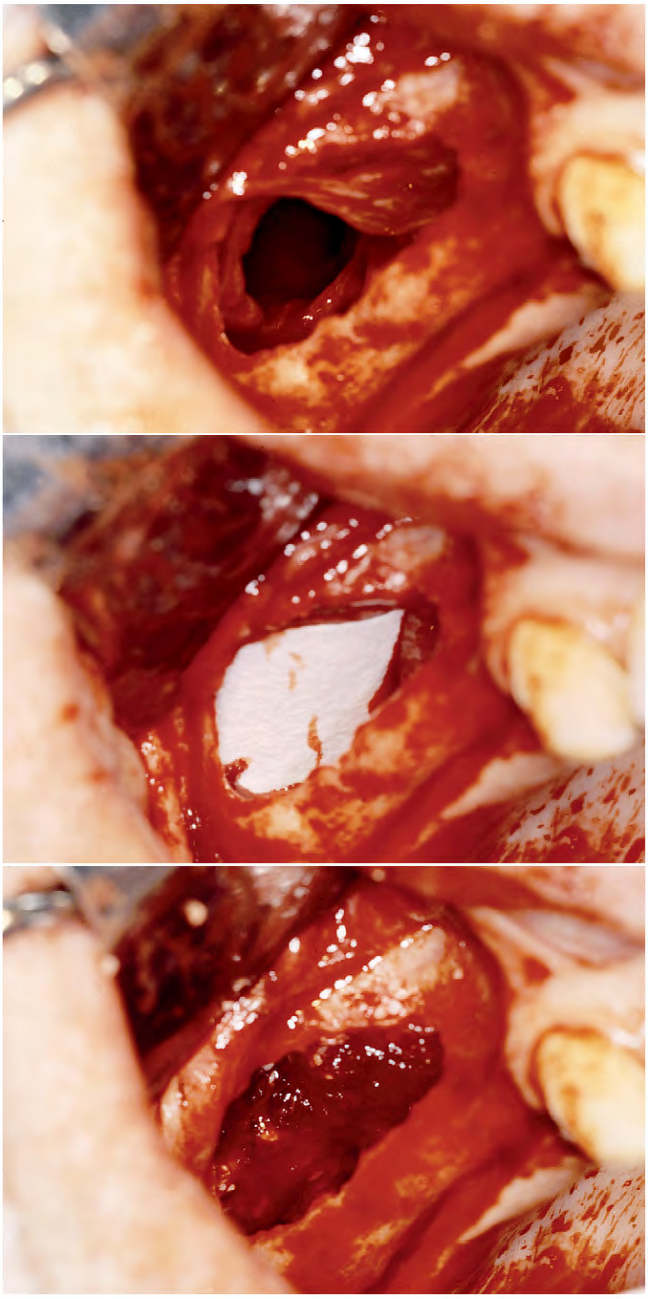

Figure 38-34 **A,** When the opening in the sinus mucosa is greater than 6 mm, the tissues distal are elevated, but often the remaining mucosal margins do not approximate each other. **B,** A dry piece of collagen (BioMend) is placed over the sinus membrane opening. **C,** A parental form of antibiotic moistens the collagen barrier once in place, or extra antibiotic is mixed into the graft material.

Ostium obstruction is also possible from swelling of the membrane related to the surgery. These conditions increase the risk of infection. However, despite these potential complications, the risk of the infection is low (less than 5%); therefore the sinus graft surgery should continue, and the patient should be monitored postoperatively for appropriate treatment.

When a larger sinus membrane perforation has occurred during a SA-3 approach, it is prudent to delay implant insertion. Placement of implants is deferred for at least 2 months (in a SA-3 option) to allow for healing of the membrane and the gingival tissues on the edentulous crest. Risks of the sinus graft entering the sinus proper increase when implants are pushed into the grafted site. Therefore the waiting period before implant insertion permits assessment of postsurgical complications and graft consolidation before the implants are inserted.

Antral Septa

Antral septa (of buttresses, webs, and struts) are the most common osseous anatomical variant seen in the maxillary sinus. Underwood, an anatomist, first described maxillary sinus septa in 1910. He postulated that the cause of these bony projections derived from three different periods of tooth development and eruption. Krennmair et al.[187] further classified these structures into two groups: primary, which are a result of the development of the maxilla, and secondary, which arise from the pneumatization of the sinus floor after tooth loss.

Misch[179] postulated that septa might be bone reinforcement pillars from parafunction when the teeth were present. He noticed these structures occur more often in SA-3 sinuses and after a shorter history of tooth loss. Long-term edentulous sites and SA-4 sinuses have fewer septa. The prevalence of septa has been reported to be in the range of 33% of the maxillary sinuses in the dentate patient and as high as 22% in the edentulous patient.[187,188] The septa may be complete or incomplete on the floor, depending on whether they divide the bottom of the sinus into compartments. The septa may also be incomplete from the lateral wall or, the medial wall, or it should extend from the floor.

The shape of an incomplete maxillary sinus septum often resembles an inverted gothic arch that arises from the inferior or lateral walls of the sinus. In rare instances, they may divide the sinus into two compartments that radiate from the medial wall toward the lateral wall (Figure 38-35).

The most common location of septa in the maxillary sinus has been reported to be in the middle (second bicuspid–first molar) region of the sinus cavity. CT scan studies have shown that 41% of septa are seen in the middle region, followed by the posterior region (35%) and the anterior region (24%). For diagnosis and evaluation of septa, CT scans are the most accurate method of radiographic evaluation.[188,189] Panoramic radiography has been shown to be very inaccurate with a high incidence of faulty diagnoses.

Sinus septa may create added difficulty at the time of surgery. Maxillary septa can prevent adequate access and visualization to the sinus floor; therefore inadequate or incomplete sinus grafting is possible. These dense projections complicate the surgery in

WWW.HIGHDENT.IR

همیار دندانسازان

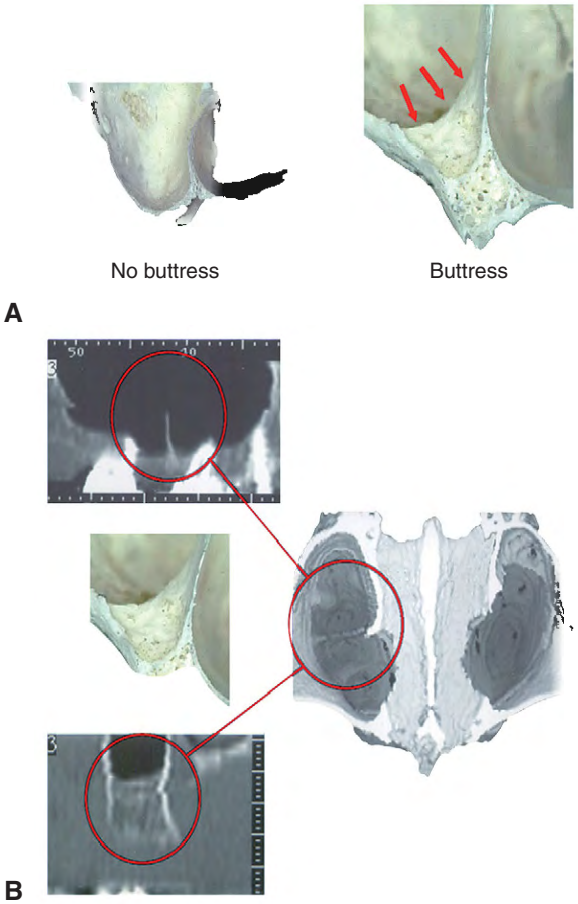

Figure 38-35 **A,** Septa or buttresses are frequently found on the floor and/or walls of the maxillary sinus. Looking down into the sinus on the left shows a smooth floor and walls. This is the most common location for a septum.

several ways. After scoring the lateral-access window in the usual fashion, the lateral-access window may not greenstick fracture and rotate into its medial position. The strut reinforcement is also more likely to tear the membrane during the releasing of the access window. The sinus membrane is often torn at the apex of the buttress during sinus membrane manipulation, because difficulty exists in elevating the membrane over the sharp edge of the web, and the curette easily tears the membrane at this position. However, because septa are mainly composed of cortical bone, immediate implant placement may engage this dense bone, allowing for strong intermediate fixation. Moreover, septa allow for faster bone formation because they act as an additional wall of bone for blood vessels to grow into the graft.

Management of Septa Based on Location

The use of CT radiographs before sinus graft surgery permits the surgeon to observe and plan the necessary modifications to the sinus graft procedure as a result of the septa. The modification to the surgery is variable depending on its location. The septa may be in the anterior, middle, or distal compartment of the antrum. When the septum is found in the anterior section, the lateral-access window is divided into sections: one in front of the septa and another distal to the structure. This permits the release of each section of the lateral wall after tapping with a blunt instrument. The elevation of each released section permits investigation into the exact location of the septa and to continue the mucosal elevation.

The mucosal tissue may often be elevated from the lateral walls above the septa. The curette may then slide down the side walls and release the mucosa from the bottom half of the septum on each side. The sinus curette should then approach the crest of the buttress from both directions, up to its sharp apex. This permits elevation of the tissue over the web region without tearing the membrane (Figure 38-36).

When the strut is located in the middle region of the sinus, it is more difficult to make two separate access windows within the direct vision of the surgeon. As a result, one access window is made in front of the septa. The sinus curette then proceeds up the anterior aspect of the web, toward its apex. The curette then slides toward the lateral wall and above the septa apex. The curette may then slide over the crest of the septum approximately 1 to 2 mm. A firm, pulling action fractures the apex of the septum. Repeated similar curette actions can fracture the web off the floor. Once the septum is separated off the floor, the curette may proceed more distal along the floor and walls (Figure 38-37).

When the septum is in the posterior compartment of the sinus, it is often distal to the last implant site. When this occurs, the posterior septum is treated as the posterior wall of the sinus. The sinus membrane manipulation and sinus graft is placed up against and anterior to the posterior septum.

Bleeding

Bleeding from the lateral-approach sinus elevation surgery is rare; however, it has the potential to be troublesome. Three main arterial vessels should be of concern with the lateral-approach sinus augmentation. Because of the intra- and extraosseous anastomoses that are formed by the infraorbital and posterior superior alveolar arteries, intraoperative bleeding complications of the lateral wall may occur. The soft tissue vertical-release incisions of the facial flap in a resorbed maxilla may sever the extraosseous anastomoses. The extra-osseous anastomosis on average is located 23 mm from the crest of the dentate ridge; however, in the resorbed maxilla, it may be within 10 mm of the crest. When this artery is severed, significant bleeding has been observed. These vessels originate from the maxillary artery and have no bony landmark to compress the vessel. Therefore vertical release incisions in the soft tissue should be kept to a minimum height with delicate reflection

WWW.HIGHDENT.IR

همیار دندانسازان

of the periosteum. Hemostats are usually difficult to place on the facial flap to arrest the bleeding. Significant pressure at the posterior border of the maxilla and elevation of the head to reduce the blood pressure to the vessels usually stops this bleeding. The elevation of the head may reduce nasal mucosal blood flow by 38%.[190,191] When this is not effective, pressure against the fourth cervical vertebra (C4) in the neck to reduce blood flow to the external carotid and collagen sponges in the posterior region can be used to reduce and arrest the hemorrhage. Microfibrillar purified sheep collagen (Avitene) may adhere to a wet surface and promote clot formation and stabilization.[192]

The vertical component of the lateral-access wall for the sinus graft often severs the intraosseous anastomoses of the posterior alveolar artery and infraorbital artery, which is on average approximately 15 to 20 mm from the crest of a dentate ridge. Methods to limit this bleeding, which is far less of a risk, have been addressed and include cauterization by the hand piece and diamond bur without water, electrocautery, or pressure on a surgical sponge while the head is elevated.

The third artery of which the implant surgeon should be cautious is the posterior lateral nasal artery. This artery is a branch of the sphenopalatine artery that is located within the medial wall of the antrum. As it courses anteriorly, it anastomoses with terminal branches of the facial artery and ethmoidal arteries. A significant bleeding complication may arise if this vessel is severed during elevation of the membrane off the thin medial wall.

If the excessive bleeding occurs while the medial wall is elevated, then the sinus may be packed with Avitene, followed by packing with large 4 × 4-inch surgical sponges, elevation of the head, and pressure on the C4 space on the same side as the sinus to stop the bleeding. Once the bleeding is arrested, the sponges are removed, the layered graft materials may be inserted, and the procedure is completed.

Epistaxis (active bleeding from the nose) is a common disorder; however, it has been reported that 6% of patients who experience this in the general population require medical treatment to control and stop the hemorrhage because it lasts longer than 1 hour. Of these patients, 15% are on anticoagulant therapy. Treatment options to treat epitasis include nasal packing, electrocautery, and the use of vasoconstrictive drugs. Vessel ligation and/or endoscopic surgery are necessary on rare occasion.

The most common site (90%) of nasal bleeding is from a plexus of vessels at the anteroinferior aspect of the nasal septum and the anterior nasal cavity (which is anterior to the sinus cavity and within the anterior projection of the nose). The posterior nasal cavity accounts for 5% to 10% of epitasis events and is in the region of the sinus graft. If the orbital wall of the sinus is perforated, or if an opening into the nares is already present from a previous event, then the sinus curette may enter the nares and cause bleeding. The arteries involved in this site are composed of branches of the sphenopalatine and descending palliative arteries, which are branches of the internal maxillary artery. The posterior half of the inferior turbinate has a venous network, the Woodruff plexus. Lavage of the nares with warm saline and oxymetazoline decongestant sprays provides excellent vasoconstritive activity to treat the condition. A cotton roll with silver nitrate or lidocaine with 1:50,000 epinephrine is also effective.

Bleeding from these arteries during the sinus graft procedure may also be controlled by nasal packing with bovine collagen, electrocautery, head elevation, or packing the sinus with surgical sponges (gauze). Pressure against the C4 (at the level of the thyroid cartilage) on the same side as the bleeding may also be of benefit.

Bleeding from the nose may also be observed after sinus graft surgery. Placing a cotton roll, coated with petroleum jelly with dental floss tied to one end, within the nares may obtund nose bleeding after the surgery. After 5 minutes the dental floss is gently pulled and removes the cotton roll. The head is also elevated, and ice is applied to the bridge of the nose. If bleeding cannot be controlled, then reentry into the graft site and endoscopic ligation by an ENT surgeon may be required.

SHORT-TERM POSTOPERATIVE COMPLICATIONS

Short-term complications are defined as those that occur within the first few months after surgery.

Incision Line Opening

Incision line opening is uncommon for this procedure because the crestal incision is in attached gingiva and at least 5 mm away from the lateral-access window. Routinely, the soft tissue requires release before primary approximation and suturing. Because a collagen membrane is placed over the window, the soft tissue will not approximate without tension unless the surgeon expands the facial flap by releasing the periosteum above the mucogingival junction (where the tissue becomes thicker). Incision line opening occurs more commonly when lateral-ridge augmentation is performed at the same time as sinus graft surgery, or when implants are placed above the residual crest and covered with the soft tissue. It may also occur when a soft tissue–supported prosthesis compresses the surgical area during function before suture removal.

The consequences of incision line opening are delayed healing, leaking of the graft into the oral cavity, and increased risk of infection. However, if the incision line failure is not related to a lateral onlay graft and is only on the crest of the ridge and away from the

WWW.HIGHDENT.IR

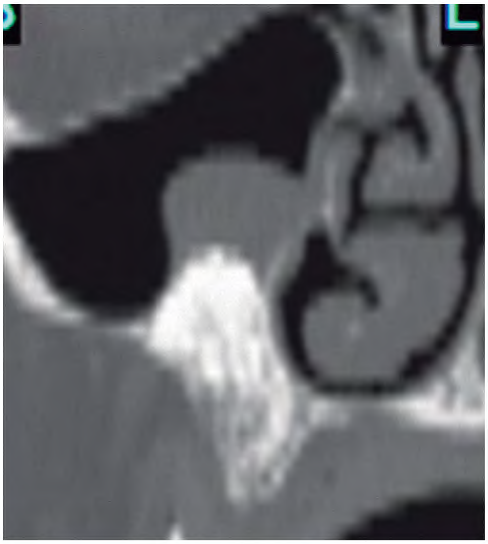

Figure 38-38 Ostium blockage caused by a sinus graft procedure resulting in the blockage of the maxillary osteomeatal complex.

sinus access window, then the posterior crestal area is allowed to heal by secondary intention. During this time, a soft tissue–borne restoration should be aggressively relieved, with no reline material in contact with the ridge. If incision line opening includes a portion of a nonresorbable membrane (i.e., for lateral-ridge augmentation), then the membrane should be cleaned at least twice daily with an abrasive devise and oral rinses of chlorhexidine. If the incision line is not closed after 2 months, then a surgical procedure should reenter the site, expand the tissues, remove the bone regeneration membrane, and reapproximate the tissue.

Nerve Impairment

Special attention must be given to the course of the infraorbital nerve. As described previously, the infraorbital nerve lies within the orbital floor and exits the foramen approximately 6.1 to 7.2 mm from the orbital rim. However, anatomical variants have been reported to be as far as 14 mm from the orbital rim in some individuals. In the severely atrophic maxilla, the infraorbital neurovascular structures exiting the foramen may be close to the intraoral residual ridge and should be avoided when performing sinus graft procedures to minimize possible nerve impairment. This is of particular concern on soft tissue reflection and the bone preparation of the superior aspect of the window. Because the infraorbital nerve is responsible for sensory innervations to the skin of the molar region between the inferior border of the orbit and the upper lip, iatrogenic injury to this vital structure can result in significant neurosensory deficits of this anatomical area. Most often, the nerve is not severed, and a neurotmesis is present. This paresthesia usually resolves within 1 month after the surgery.

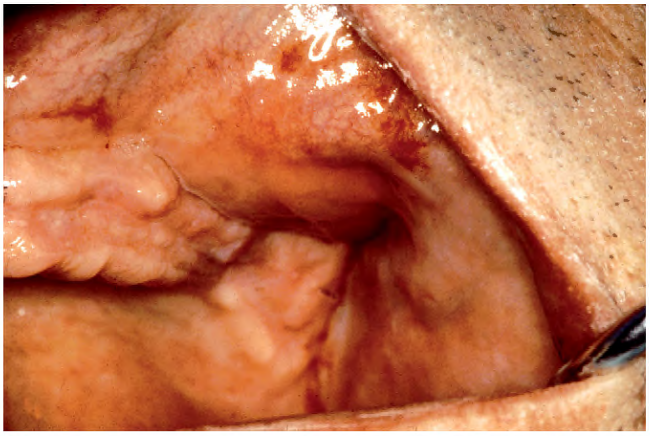

Figure 38-39 The most common clinical sign of a maxillary sinus infection after a sinus graft is a swelling from the lateral-access window.

Acute Maxillary Rhinosinusitis

The manipulation and altering of the sinus membrane shows no significant long-term changes. This has been seen clinically and reported through in-depth studies. However, mild inflammatory mucosal changes do occur immediately postoperatively. This is a temporary reaction to the normal physiologic activity of the mucosal airway defense mechanism. According to the literature, acute postoperative sinusitis occurs as a complication in approximately 3% to 20% of sinus graft procedures,* and it represents the most common short-term complication. Most often, the infection begins more than 1 week after surgery, although it may begin as soon as 3 days later. Because the surgical field is close to several vital structures, postoperative infections may arise and spread very rapidly with possible life-threatening complications.

Maxillary sinusitis is the most widely reported postoperative complication after sinus augmentation procedures. This disorder should be considered if the patient postoperatively complains of any of the following symptoms: headache, pain or tenderness in the area of the maxillary sinus, and rhinorrhea. Studies have supported the fact that patients who had predisposing factors for sinusitis were more at risk of developing postoperative transient sinusitis. The wide range of reported percentages (3% to 20%) may be the result of different methods used for diagnosis (i.e., clinical, radiographic, endoscopic) (Figures 38-38 and 38-39).

Sinus Physiology

Elevation of the sinus mucosa and bone grafting does alter the overall maxillary sinus environment by reducing the size of the sinus and repositioning the mucociliary transport system. In spite of this, only short-term clearance impairment exists, resulting in only subclinical effects on the sinus physiology. However, in cases of preoperative sinusitis histories, sinus

*References 8, 13, 69, 76, 105, 106, 127.

WWW.HIGHDENT.IR

همیار دندانسازان

elevation surgery may predispose a patient to sinus-related complications. It has been shown that these procedures do alter the microbial environment. Studies reveal that at 3 months after surgery, positive sinus cultures were present compared with cultures taken for the same patients preoperatively. However, after 9 months the cultures were similar to the preelevation results. The key is maintenance of the osteomeatal opening between the maxillary sinus and the nasal cavity.

Very few cases of long-term pathologic symptoms have been reported in the literature after sinus graft surgery. However, numerous case studies in the medical literature have reported on postoperative sinusitis after sinus surgery. Resolution of these conditions has been accomplished with the use of antibiotic drugs and/or Caldwell-Luc procedures. No long-term chronic sinusitis cases have been reported or documented.

Prophylactic antibiotic medications and sound surgical principles minimize postoperative infections and complications.[48] However, autogenous bone, allografts, and alloplasts in the sinus graft may be subject to infection. The resistance to contamination is low and may be increased if contaminated by intraoral or sinus pathogens.

Cases of maxillary sinusitis after dental implant surgery have rarely been reported in the dental literature. However, recently in the medical literature, numerous cases of minor to severe complications after sinus surgery have been documented. Although very infrequent, severe infections may lead to more severe complications, such as orbital cellulitis, optic neuritis, cavernous sinus thrombosis, epidural and subdural infection, meningitis, cerebritis, blindness, osteomyelitis, and, although rare, brain abscess and death.[79] Therefore it is recommended to develop a professional relationship with an otolaryngologist before the dental surgeon's first sinus graft is performed. After infections are eliminated, oroantral fistulas are possible that may be difficult to correct, possibly requiring numerous surgical procedures that include soft tissue and bone grafts. In addition, prosthetic obturators may be required until the oral antral fistula is corrected.

Although the incidence of infection after the procedure is usually low, the damaging consequences on osteogenesis and the possibility of serious complications require that any infection be aggressively treated. In case of postoperative infection, it is recommended that the clinician perform a thorough examination of the area by palpation, percussion, and visual inspection to identify the area primarily affected. Infection follows the path of least resistance and is observed by changes in specific anatomical sites to which it spreads[66] (see Table 38-1).

Clinical Evaluation

Radiographic evaluation of acute rhinosinusitis is both expensive and often inaccurate (Figure 38-40). As such, a patient history for acute sinusitis is a benefit and is diagnostic when two or more of the following factors are present: (1) facial congestion or fullness, (2) nasal obstruction or blockage, (3) nasal discharge, (4) purulence or discolored postnasal discharge, (5) facial pain or pressure, (6) hyposomia or anosmia (decrease or no ability to detect an odor), (7) purulence in the nares on physical examination, (8) fever, (9) headache, (10) halitosis, (11) dental pain, (12) cough, and (13) ear pain. When multiple symptoms are evident, antibiotic drugs for acute rhinosinusitis are in order. In addition, when associated with unresolved symptoms after a sinus graft, a CT scan may be necessary.

Therapeutic Treatment of Postoperative Infections

If infection occurs postoperatively, then treatment must be aggressive because of the possible complications and morbidity of the graft material. Antibiotic therapy is the first line of treatment for these related symptoms. Diagnosis is often presumptive without microbiological confirmation and usually based on empirical evidence. Identification of the causative pathogen is usually difficult, requiring either an antral puncture or endoscopy to obtain an uncontaminated specimen for culture.

When selecting antibiotic medications for sinus infections, a variety of factors must be evaluated. These include the most common type of pathogens involved, antimicrobial resistance, pharmacokinetic and pharmacodynamic properties, and the sinus tissue penetration of the various antibiotic drugs. The antibiotic medication of choice should be effective against respiratory pathogens and should have known activity against resistant strains of the common pathogens. Two such factors are used when evaluating sinus antibiotic medications: (1) the minimum inhibitory concentration (MIC) and (2) the concentration of antibiotic drugs penetrating inflamed diseased sinus tissue. The MIC is the lowest concentration of the antimicrobial agent that results in the inhibition of growth of a microorganism. The MIC is usually expressed by MIC 50 or MIC 90,

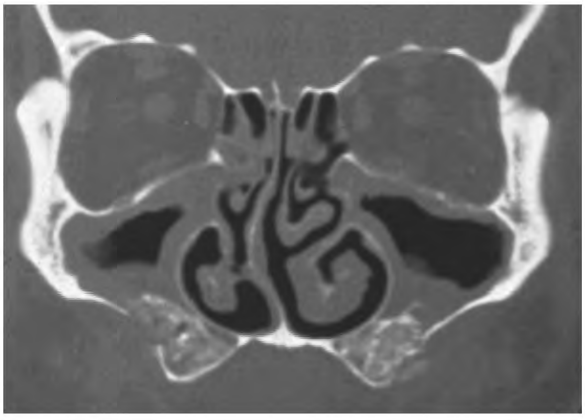

Figure 38-40 A computed tomography (CT) scan taken after sinus graft of a patient with no history of infection or complications. The maxillary sinus mucosa appears thickened, yet no infection was observed.

WWW.HIGHDENT.IR

meaning that 50% or 90% of the microbial isolates are inhibited, respectively.

Previous studies and treatment modalities used amoxicillin as the first drug of choice. However, with the increasing prevalence of penicillinase- and β-lactamase–producing strains of *Haemophilus influenzae* and *Moraxella catarrhalis*, along with penicillin-resistant strains of *Streptococcus pneumoniae*, other alternative antibiotic drugs should be selected.

Antimicrobial Classes

β-Lactam Medications. The most common β-lactam antibiotic drugs used in the treatment of sinusitis are penicillin (amoxicillin, Augmentin) and cephalosporin (Ceftin, Vantin). Amoxicillin has been the drug of choice for years to combat the bacterial strains associated with sinusitis. However, its effectiveness has been questioned recently because of the high percentage of β-lactamase–producing bacteria and penicillin-resistant *S. pneumoniae*. Augmentin (amoxicillin-clavulanate) has the added advantage of activity against β-lactamase bacteria. It has been associated with a high incidence of gastrointestinal side effects; however, with a new dosing regimen (twice a day [bid]), these complications have been significantly decreased.

Two recommended cephalosporin medications have also been suggested to treat sinusitis and include cefuroxime axetil (Ceftin) and cefprodoxime proxetil (Vantin). Other cephalosporin drugs fail to achieve adequate sinus fluid levels against the causative pathogens. Ceftin and Vantin have good potency and efficacy and exhibit strong activity against resistant *S. pneumoniae* and *H. influenzae*.

Fluoroquinolone Medications. Fluoroquinolone drugs are bactericidal antibiotic medications that are classified into four different generations. The third-generation quinolone drugs are well-suited, broad-spectrum antibiotic medications and have been labeled by the U.S. Food and Drug Administration (FDA) for use against sinus pathogens. They exhibit excellent absorption and achieve very significant sinus blood levels, even in pathologic conditions. Quinolone drugs are distributed extensively throughout the sinus, with high levels being found in inflamed tissue and maxillary sinus cysts. The tissue/blood ratio is approximately 4:1, making it extremely potent within the diseased sinus. The three most common quinolone medications used for sinus treatment include levofloxacin (Levaquin), gatifloxacin (Tequin), and moxifloxacin (Avelox).

Macrolide Medications. Macrolide drugs are bacteriostatic agents that include erythromycin, clarithromycin (Biaxin), and azithromycin (Zithromax). Macrolide medications have good activity against susceptible pneumococci; however, with the increasing rate of macrolide resistance, their use in combating sinus pathogens is becoming associated with a high likelihood of clinical failure. These antibiotic drugs are very active against *M. catarrhalis*, although their activity on *H. influenzae* is questionable. Therefore these antibiotic medications are not suggested to treat postoperative sinus infections.

Lincosamide Medications. Clindamycin (Cleocin) is the primary lincosamide drug used in clinical practice today that is considered to be bacteriostatic. However, in high concentrations, bactericidal activity may be present. Clindamycin is mainly used for the treatment of gram-positive aerobes and anaerobes. With acute sinusitis disease, clindamycin is usually not indicated because it exhibits no activity against *H. influenzae* and *M. catarrhalis*. This drug may be used in chronic sinus conditions because anaerobic organisms play a much larger role in the disease process.

Tetracycline Medications. Doxycycline (Vibramycin) is a bacteriostatic agent with adequate activity against penicillin-susceptible pneumococci and *M. catarrhalis*. This drug does not exhibit any activity against penicillin-resistant bacteria and is not effective against *H. influenzae*. Severe side effects of this medication are photosensitivity and esophageal caustic burns. As a consequence, tetracycline drugs are not used to treat postoperative sinus infections.

Sulfonamide Medications. The most common sulfonamide drug, trimethoprim-sulfamethoxazole (Bactrim), is bacteriostatic. Recently, a high rate of resistance to these drugs has been seen with *S. pneumoniae*, *H. influenzae*, *M. catarrhalis,* and other sinus pathogens. Therefore this drug is not considered to treat postoperative infections, unless a culture and sensitivity test has been performed.

Nitroimidazole Medications. Metronidazole is the most important member of the nitroimidazole group. It is bactericidal and is effective against gram-positive and gram-negative anaerobic bacteria. Its main use would be in the treatment of chronic sinus conditions; however, it should be used with another antibiotic drug to be effective against aerobic bacteria.

In the evaluation of different antibiotic drugs used for the treatment of pathologic conditions of the sinus, meticulous analysis of the activity against the most common pathogens must be evaluated. With all the antibiotic medications evaluated, amoxicillin-clavulanate, cefuroxime axetil, levofloxacin, and moxifloxacin showed significant sinonasal and MIC 90 blood levels against the most common pathogens associated with sinus infections. Moxifloxacin, a third-generation fluoroquinolone drug, has been shown to have superior qualities compared with many other antibiotic medications. It shows extensive distribution throughout the sinuses in both inflamed and noninflamed sinus tissue, with significantly high concentration within maxillary sinus cysts. The tissue/blood ratio is 4:1, with blood levels occurring 3 to 4 hours after administration. Because of the potency and expense of this medication, it is used only in the treatment for severe infections.

Decongestant Medications. If acute sinusitis symptoms are present, then a nasal decongestant may be used to maintain the patency of the ostium. These

WWW.HIGHDENT.IR

همیار دندانسازان

sympathomimetic drugs influence α-adrenergic receptors to reopen a blocked ostium and facilitate drainage. Oxymetazoline 0.05% (Afrin or Vicks Nasal Spray) is the most effective over-the-counter topical decongestant. The vasoconstrictor action of this medication will last for approximately 5 to 8 hours. However, proper administration positioning must be adhered to, which includes the patient lying down with the head down. The antimicrobial solution is then directly applied to drain into the sinus ostium area. The use of this medication is limited to 3 to 4 days to prevent a rebound phenomenon and the development of rhinitis medicamentosa.

No Response to Antibiotic and Decongestant Medications

If symptoms are not alleviated with antibiotic and decongestant medications, then possible referral to the patient's physician or otolaryngologist is warranted. Emergency consultation should be considered if the patient complains of severe headache that is not relieved by mild analgesics, as well as persistent or high fever, lethargy, visual impairment, or orbital swelling.

Saline Rinses

An important procedure for the patient with the presence of a sinus graft infection is saline rinses with a bulb syringe or a squeeze bottle in the nostril used to lavage the sinus through the ostium. The nasal saline rinse has a long history for treatment of sinonasal disease. Hypertonic and isotonic saline rinses have proven efficiency against chronic sinusitis. These techniques of nasal irrigation have been evaluated, with the best option of a positive-pressure irrigation using a squeeze bottle that delivers a gentle stream of saline to the nasal cavity (NeilMed, Santa Rosa, Calif.). The syringe or squeeze bottle should not seal the nasal opening, because this may force bacteria up toward the ethmoidal sinus. Instead, a gentle lavage with sterile saline rinses the sinus and flushes out the mucus and exudate. Ideally the head is placed down and forward so that the saline can reach the ostium in the superior and anterior portion of the sinus. The course of therapy should continue for at least 7 days.[193]

The most current, comprehensive study on the treatment of sinus disease involves guidelines established by the Sinus and Allergy Health Partnership, Centers for Disease Control and Prevention, and the FDA in 2000. With this information as a guide, the following recommendations for antibiotic use in the treatment of infections after sinus graft are suggested.

Mild Infection

Symptoms

- Purulent and nonpurulent nasal drip
- Nasal blockage
- Facial pain and pressure
- Intraoral and extraoral swelling
- Cough

Treatment

1. Amoxicillin-clavulanate (Augmentin) 825 mg/125 mg (1 tablet bid for 10 days)

   a. If nonanaphylactic allergy to amoxicillin, cefuroxime axetil (500 mg) 1 tablet bid for 10 days
   b. If anaphylactic allergy to amoxicillin, levofloxacin (500 mg) 1 tablet bid for 7 days

2. Over-the-counter decongestant (oxymetazoline 0.05% for 3 days)
3. Nasal saline rinses

NOTE: If the patient does not respond to the initial treatment for mild infections within 5 days, then the patient should immediately be placed on moxifloxacin and a Medrol dosepack. A patient still symptomatic after 3 days of moxifloxacin treatment should have a medical referral for evaluation and treatment. Removal of the graft is often indicated in those cases.

Moderate to Severe Infection

Symptoms from mild infection

- Severe headache
- High persistent fever (>102.5° F)
- Periorbital swelling
- Ocular symptoms (diplopia, proptosis)
- Altered mental status
- Infraorbital hyperesthesia

Treatment

1. Moxifloxacin (400 mg) 1 tablet bid for 10 days
2. Medrol dosepak (4 mg), as directed
3. Nasal saline rinses

NOTE: If reduction of symptoms for moderate and severe infections is not seen within 5 days after moxifloxacin treatment, then the patient should be referred for medical consultation and treatment.

Spread of Infection

Because of the anatomical and topographic location of the maxillary sinus, infections from oral or sinus pathogens may spread quickly to adjacent sites.

Sinus-related pathologic conditions are the most common cause of orbital infection, accounting for 60% to 84% of cases. Because of the seriousness of ocular infections, early diagnosis and aggressive treatment is paramount.

Various routes may predispose this area to infection from the maxillary sinus and include the following:

1. The venous plexus of the maxillary sinus drains through the posterior wall into the deep facial vein, through the pterygoid plexus, and finally into the cavernous sinus.
2. Veins also perforate the osseous roof of the maxillary sinus, entering the orbit through the superior and

WWW.HIGHDENT.IR

inferior ophthalmic vein. These veins also are connected to the pterygoid plexus and cavernous sinus.
3. Additionally, numerous veins perforate the anterior wall that drain into the superior ophthalmic vein and into the cavernous sinus. From the cavernous sinus, drainage through the deep middle cerebral vein communicates with the white substance of the brain's superficial venous system.

Because of the elaborate maxillocerebral venous anastomoses, spread of infection from the maxillary sinus may result in possible sequelae such as brain abscesses, intraorbital abscesses, orbital cellulitis, cavernous sinus thrombosis, and osteomyelitis.

Implant Penetration into the Sinus

Brånemark et al.[194] reported on animal histologic studies and 44 clinical cases of implants penetrating the maxillary sinus. They reported success rates comparable to other maxillary implants, and no postoperative signs or symptoms were found with these implants. An animal study by Boyne[22] led to the same conclusion. The assumption was that direct connection between hard and soft tissues to the integrated implant created a barrier to the migration of microorganisms. However, it should be noted these animals do not have the same incidence of maxillary sinusitis comparable to humans.

It is possible that an implant that penetrates the sinus floor may contribute to a source of periodic sinusitis, because a bacterial smear layer would be difficult to remove through regular phagocytic activity. When this is suspected, an apicoectomy of the implant apex, from a lateral-access window, may be of benefit.

Oroantral Fistula

Oroantral fistulae may develop postoperatively, especially if the patient has a history of infection. Small oroantral fistulae (<5 mm) usually will close spontaneously after treatment with systemic antibiotic drugs and daily rinses with chlorhexidine. However, larger fistulae (>5 mm) will normally require additional surgical intervention. Larger fistulae are associated with an epithelialized tract, which is the result of the fusion of the sinus membrane mucosa to the oral epithelium. When this occurs, patients will usually complain of fluids entering the nasal cavity upon eating or drinking.

Closure of oroantral fistulae can be achieved by using broad-based lingual or facial rotated flaps. Buccal flaps to close the fistula may be more difficult after sinus graft because of the location of the graft site. In addition, the buccal tissue is very thin, and rotated or expanded buccal flaps usually result in loss of vestibular depth.

Before the initiation of the flap design, the soft tissue around the fistula is excised and the sinus floor curetted to ensure direct bone contact. A tension-free rotated flap is then made for complete covering of the communication. For oroartral closure after sinus graft procedures, a lingual flap is recommended because of the abundance of keratinized mucosa with an adequate blood supply. Flap designs include island flaps, "tongue-shaped" flaps, or rotational and advanced flaps, depending on the size of the exposure.

A key to close the oroartral opening is the dissection of the buccal flap lateral to the fistula. An incision that extends 15 mm anterior and posterior to the fistula is of benefit. The fistula then has an elliptical incision on each side of the opening. The core of tissue and the fistulous tract is excised. The facial flap is underminded and expanded well into the tissues of the cheek. The palatal aspect of the incision is adjacent to the tongue-shaped flap. Placement of the incision for the pedicle flap should be split thickness and take into account the location and depth of the greater palatine artery. Once the attached palatal pedicle graft is rotated to the lateral and attached to the facial flap, horizontal mattress sutures are placed to invert the flap to achieve a watertight seal. Sutures with high tensile strength should be used and allowed to remain in place for at least 2 weeks (Figure 38-41).

Overfilling of the Sinus

The goal of the sinus graft is to obtain enough vertical height of bone to place endosteal implants with long-term success. The maximum length requirement of an implant with adequate surface of design is rarely more than 15 mm, and as a result, the goal of the initial sinus graft is to obtain at least 16 mm of vertical bone from the crest of the ridge. This usually means the bottom one half of the sinus is filled with graft material, because most sinuses approximate 35 mm in height. A CT scan of the sinus before surgery may be used to estimate the amount of graft material required for the ideal volume of sinus graft material. Care should be given to the amount of graft material placed into the sinus. Overfilling the sinus can result in blockage of the ostium, especially if membrane inflammation or the presence of a thickened sinus mucosa exists.

The majority of sinus graft overfills do not have postoperative complications. If, however, a postoperative sinus infection occurs without initial resolution, reentry and removal of a portion of the graft and changing the antibiotic protocol may be appropriate.

Postoperative Maxillary Surgical Cysts

Postoperative maxillary surgical cysts have been reported in the literature after sinus graft surgery; however, they are extremely rare. In 1992, Misch et al.[92] reported one incidence of a maxillary surgical cyst associated with a past sinus graft and blade implant. Complete enucleation was accomplished, and healing was uneventful.

In 1927, Kubo reported a postoperative maxillary cyst arising in the maxilla as a delayed complication

WWW.HIGHDENT.IR

همیار دندانسازان

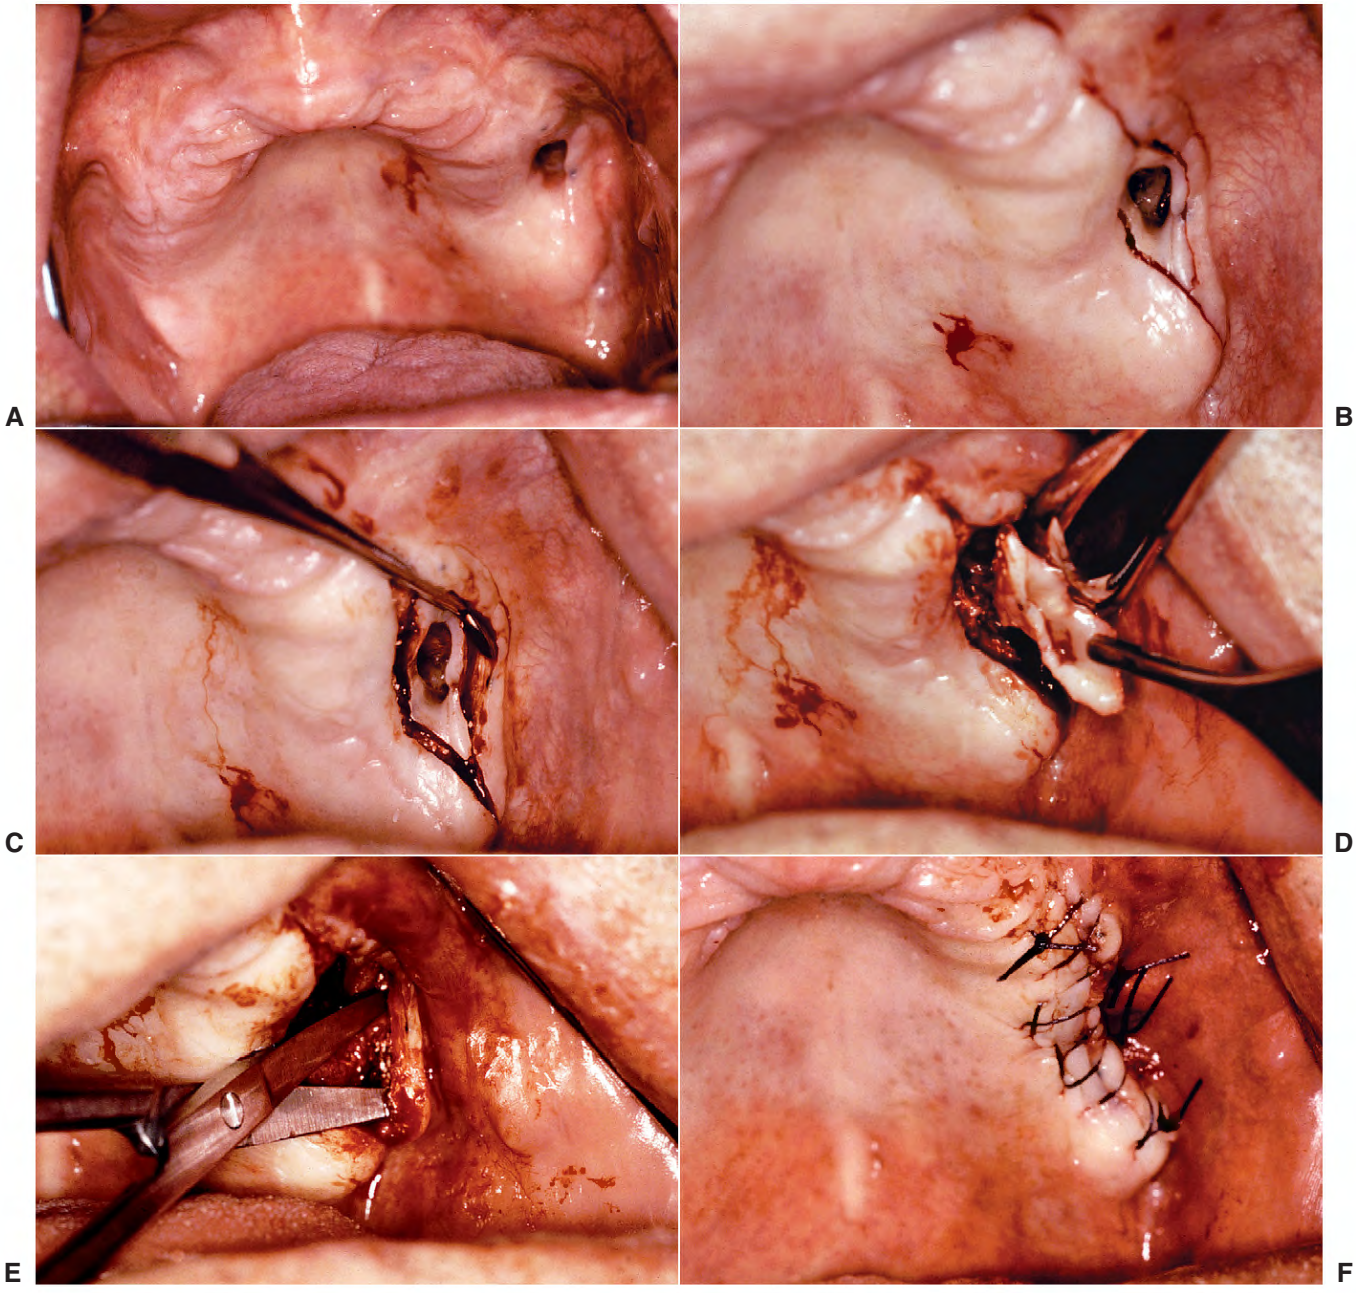

Figure 38-41 **A,** An oroantral fistula after sinus graft infection is evident on the patient's left side. **B,** An elliptical incision is made around the fistula and extends both anterior and posterior to the site. **C,** The tissues are reflected. **D,** The fistulous tract is removed, complete with the epithelial lining. **E,** The facial flap is undermined, and a submucosal space is created. **F,** Horizontal mattress sutures are used for the watertight closure.

of radical surgical intervention in the maxillary sinus.[91] Incidence reports are more common in Japan, where sinus disease is often treated aggressively with surgery,[93] but are rare in other parts of the world.

LONG-TERM RESULTS

The primary method of long-term evaluation of sinus grafts has been implant survival in these regions. Hypothetically, if the graft is composed of good-quality bone, then the endosteal implant should be maintained in health. Of course, proper implant and prosthetic procedures are required for these implants. In general, most reports in the literature contain high survival rates for all sinus graft materials and implant designs studied. The data presented at the Sinus Graft Consensus Conference reflected the high predictability of the procedure.[92] Thirty-eight clinicians provided data on 1007 sinus grafts that had received 3354 implants in function for at least 3 years. Long-term survival rates were in the 90% to 97% range. Material combinations consisted of only autogenous bone or combinations of alloplasts, allografts, and autogenous bone, yet all

WWW.HIGHDENT.IR

seemed to yield similar results. The most important factor for implant survival was the implant design, with HA-coated implants having a higher 3-year survival rate than the machined, noncoated screw design implants.

The treatment of the posterior maxillary can now be considered to be one of the most predictable regions in the mouth. Sinus grafting has been a major reason for this accomplishment. Del Fabbro et al.[29] performed a systematic review of the literature for sinus grafts and associated implants in 2004. A total of 252 articles related to this subject were reviewed, and 39 of these met inclusion criteria for a qualitative data analysis. There were 2046 patients and 6913 implants in this report, ranging from 1 to 6 years.

Implant survival was 87.7% for 100% autologous bone, 94.88% when autograft was combined with a variety of bone substitutes, and 95.98% when the bone graft was only a bone substitute mixture. The majority of articles that used autograft alone used a machined or smooth-surface implant. When surface condition was considered rather than graft materials, the smooth-surface implants had an 85.64% survival rate versus 95.98% for a rough-surface condition.

Between 1980 and 1990, the author reported on 385 human SA augmentations performed using the Tatum lateral-wall approach (SA-3 or SA-4). Of the 385 SA augmentations, only two maxillary antrum regions did not grow sufficient bone for implant placement, and the implant procedure was aborted after the 8-month healing interval. Additional data to 2005 brings these numbers to almost 2000 grafts, for which only nine antrum grew insufficient bone to place endosteal implants of adequate size. Indeed, the sinus graft surgery is the most predictable bone graft procedure available to grow adequate bone height in the mouth.

SUMMARY

In the past, implant treatment in the posterior maxilla was reported as the least predictable region for implant survival. Causes cited include inadequate bone height, poor bone density, and high occlusal forces. Past implant modalities attempted to avoid this region, with procedures such as excessive cantilevers from anterior implants or excess numbers of pontics when implants are placed anterior and posterior to the antrum.

The maxillary sinus may be elevated and SA bone regenerated to improve available bone height. Tatum began to develop these techniques as early as the mid-1970s.[3] Misch developed four options for treatment of the posterior maxilla in 1984, based on the height of bone between the floor of the antrum and the crest of the residual bone. These options were further modified to reflect the width of available bone, once adequate height was obtained. Root form implants of adequate size are indicated in the posterior maxilla. When the ridge anatomy is too narrow for root form implants, these ridges may be treated by bone spreading or with autogenous grafts. The higher forces and less dense bone often require larger-diameter implants.

It is the observation of the authors, using the sinus graft procedures described in this chapter for more than 20 years, in clinical practice, universities, and private implant institutes, that the sinus graft procedure is more than 97% effective. This region of the mouth predictably grows more bone in height than any other intraoral region.

Chapter 39

Mandibular Donor Block Bone Grafts: Symphysis and Ramus

Carl E. Misch

INTRODUCTION

Treatment plans in implant dentistry in the 1980s often used existing bone volume to determine the location and type of implant abutment. In abutment bone (Division A), root forms were inserted; in bone of moderate width (Division B), blade implants were placed; and in inadequate height of bone (Division C–h), subperiosteal implants were the treatment options (Figure 39-1). Today, the final prosthesis type and design is first determined, followed by the ideal implant position, number, and size. Often the bone available is inadequate to perform the ideal, predictable treatment and build a proper foundation. As a consequence, bone grafting has become a more frequent modality to achieve long-term success.

In addition to the biomechanical and functional needs of a prosthesis, there are often esthetic considerations. Bone grafting is often necessary to place the implant in the proper location for an ideal esthetic result. The soft tissue drape often needs enhancement in the esthetic zone. The bone foundation sets the tone for the soft tissue drape (Figure 39-2). Therefore when ideal crown contours (FP-1) and soft tissue are desired, bone augmentation is often an important aspect of the treatment.

As a result of biomechanical-based foundations and esthetic desires, a primary diagnostic consideration for implant prostheses is the available bone in the edentulous span. The placement of endosteal dental implants requires adequate bone volume at the desired locations for ideal prosthetic support. If inadequate bone exists, several surgical techniques may be used to reconstruct the deficient ridge for implant placement. The number of key factors present and the geometry of a bony defect are important considerations in the selection of a modality for ridge augmentation.[1] The fewer the number of remaining bony walls, the greater the need for osteopromotive techniques. Although allografts and guided bone regeneration techniques have been used

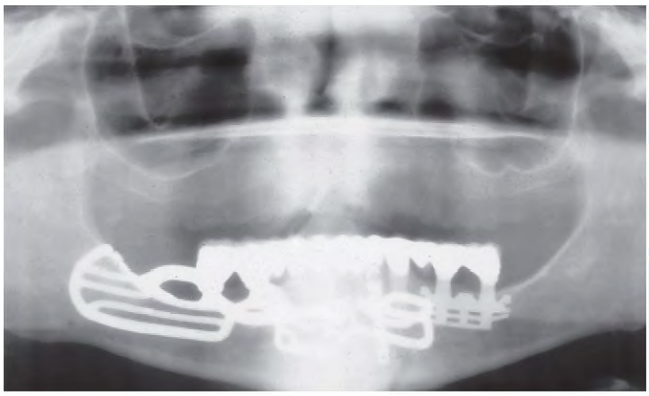

Figure 39-1 In the 1970s and 1980s, implants were often designed to adapt to the existing bone volume. Root forms were used in abundant bone (as in the anterior mandible), blade implants were inserted in narrow bone volume *(right side of radiograph)*, and subperiosteal implants were placed in inadequate bone volumes *(left side of radiograph)*.

Figure 39-2 Root form implants were placed in existing bone volumes in the 1980s. This implant prosthesis has functioned for 20 years but is an esthetic failure.

predictably in slight-to-moderate bone regeneration (primarily for inadequate width), these methods have limitations and have been found to produce less favorable results in the treatment of larger bone deficiencies.[2-13] Autologous cortical/trabecular bone grafts may be considered the gold standard in the repair of moderate to severe alveolar atrophy and bone defects.[14-28]

The use of iliac crest autologous bone blocks with osteointegrated implants was originally presented in the literature by Brånemark et al.[29] and is now a well-accepted procedure in oral and maxillofacial rehabilitation. Although the iliac crest is often used in major jaw reconstruction for implants,[30-34] it has the disadvantages of higher costs, alteration of ambulation, and the need for hospitalization and general anesthesia.[35]

Mandibular symphysis donor site grafts were originally published to correct intraoral birth defects, such as cleft palates.[36,37] Misch et al. extended the indications with mandibular symphysis and ramus block bone grafts for use of endosteal dental implants in 1992 (Figure 39-3).[38] In the repair of more localized alveolar defects, cortical bone grafts from the mandible offer several benefits.[20,38-41] The obvious advantage of intraoral versus extraoral donor grafts is their convenient surgical access. The proximity of donor and recipient sites can reduce operative and anesthesia time, making them ideal for outpatient implant surgery. There is no cutaneous scar associated with extraoral donor sites. In addition, patients report minimal donor site discomfort, and these areas may offer a decreased morbidity from graft harvest compared with extraoral locations.[19,20,38-45]

Bone harvested from the maxillofacial region appears to have inherent biological benefits for augmentation. Research suggests that this may be attributed to the embryologic origin of the donor bone.[43,46-51] The majority of bones in the skeleton are of endochondral origin (from a cartilaginous precursor). With the exception of alveolar bone, the maxilla and body of the mandible develop intramembranously, whereas the condyles develop by endochondral bone formation.[52] Experimental evidence has shown that grafts from membranous bone show less resorption than endochondral bone.[46,47,49,53-56] Although cancellous grafts revascularize more rapidly than cortical grafts,[14] cortical membranous grafts revascularize more rapidly than endochondral bone grafts with a thicker cancellous component.[48,57]

Early revascularization of membranous bone grafts has been suggested as an explanation for the improved maintenance of graft volume.[48,56-58] Another hypothesis is that bone of ectomesenchymal origin, such as the mandible, has a better potential for incorporation in the maxillofacial region because of a biochemical similarity in the protocollagen of the donor and recipient bone.[60] However, more recent research suggests that grafted bone, independent from its embryogenic origin, will mimic the properties of the recipient bone.[60] The inductive capacity of cortical grafts is explained by

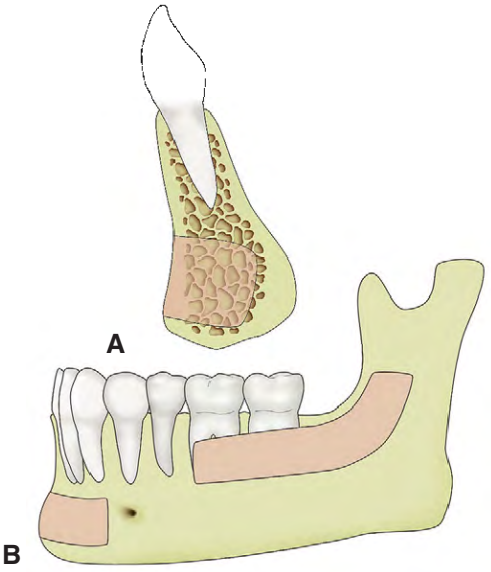

Figure 39-3 **A,** The symphysis block graft is usually 5 mm below the roots of the anterior teeth and extends to the lingual plate. **B,** The symphysis and ramus region may be harvested for intraoral defects.

their higher concentration of bone morphogenetic proteins,[61-63] and bone from the maxillofacial skeleton contains increased concentrations of growth factors, which may lead to a greater capacity for bone repair and graft retention.[64] Another hypothesis is that the improved survival of craniofacial bone grafts is simply caused by their three-dimensional structure.[65,66] Because these grafts have a thicker cortical layer, they resorb more slowly.[53,54,57,67]

An emphasis has been placed on the transplantation of viable osteoprogenitor cells from trabecular marrow grafts.[18] The concept has been that the majority of osteoblasts are present in trabecular bone. Because these cells are responsible for the formation of new bone, it is logical that trabecular grafts are advantageous. However, because of the significant resorption associated with corticocancellous block grafts from endochondral donor sites, these have lost favor in the treatment of mandibular continuity defects and ridge augmentation for soft tissue–borne prostheses.[16,18,55-57,68,69] It has been observed by Misch and others that the cortical/trabecular blocks harvested from the ilium have greater bone volume after initial healing compared with inlay trabecular grafts.[57] In addition, when endosteal implants are inserted within the first year, the bone is maintained long term. It appears the microarchitecture of the bone graft (cortical versus trabecular) and implant insertion to stimulate the bone is more important than whether the bone graft is from endochondial or mesenchymal origin.

Mandibular donor bone grafts, which are primarily cortical bone, exhibit little volume loss and show good incorporation at short healing times.[57] There are more mature bone cells (osteocytes) in the cortical bone,

WWW.HIGHDENT.IR

more growth factors, including insulin-like growth factors 1 and 2, and more bone morphogenetic protein. As important, the cortical bone acts like a barrier membrane and prevents resorption of the graft site. This permits the blood vessels from the host bone to invade the graft and bring osteoblasts into the graft along the sides of the invading blood vessels.

The cortical bone has more growth factors to encourage blood vessel growth from the host bone, including transforming growth factors. There are at least 50 known growth factors in this category (which includes bone morphogenetic proteins). Vascular endothelial growth factor is also present, which contributes to new blood vessel growth. Implant placement shortly after graft incorporation has a stimulating effect on the bone, maintaining the augmented bone volume and preventing further loss.[70-73] In addition, the dense structure of the cortical portion of the graft offers the benefit of improved implant stability during placement and healing and may even improve interfacial stress transmission upon implant loading.[74-76]

Over the years, intraoral cortical/trabecular block bone grafts have been used for residual bone augmentation prior to implant placement with extremely favorable results.[19-23,25,26,38-45,77-92] Block-type grafts may be harvested from the residual ridge, mandibular symphysis, body, or ramus area (Figure 39-4). Donor grafts may be harvested from the symphysis region of the edentulous mandible while placing implants in the region, provided there has been minimal atrophy. Implant placement in the lower jaw is then limited to the available bone superior to the graft harvest or postponed until healing of the donor site has occurred. The amount of bone available in many cases is limited only by the imagination of the surgeon. However, a common mistake in comprehensive treatment planning is to overestimate the volume of attainable bone graft from intraoral donor sites. It is prudent to consider extraoral donor sites for grafting alveolar defects, when more than a four-tooth span must be augmented (especially when height augmentation is required).

PREOPERATIVE EVALUATION OF HOST SITE

A comprehensive evaluation of the host graft site is necessary for planning of the surgery. This includes the graft size, esthetic concerns, soft and hard tissue topography, and the periodontal and endodontic health of the adjacent teeth.[38,93,94] The host site may be evaluated in width, height, and length. The most predictable bone augmentation sites require only the width dimension and extend for only one tooth. This provides mesiodistal lateral walls of bone, an apical wall, and a medial wall of host bone. A one-tooth span provides ease of soft tissue manipulation and minimal risk of incision line opening. Tooth-borne transitional restorations are easily fabricated. The donor bone harvest permits a complete fill of the region with an autograft. The least predictable bone graft sites are more than four teeth in length and require more than 5 mm of height and width of bone because the host site has primarily one wall of bone at the base and incision line complications, transitional prosthesis, inadequate autograft from the donor site combine to increase the overall risks.

The mesiodistal size of the host graft site with an intraoral harvest is most often four adjacent teeth or less in length and only deficient in width. However, in some larger mandibles with multiple harvest sites, a full-arch maxilla may be augmented in width (Figure 39-5). The mesiodistal size for a host site that requires height and width with an intraoral harvest is most often two adjacent teeth or less in length, although a span of four adjacent teeth may be restored with multiple harvest sites.

When an FP-1 prosthesis is the treatment of choice, the adjacent teeth next to the host graft site should have bone on the roots to a level within 2 mm of the cement-enamel junction. When a bone graft is placed adjacent to a tooth root (rather than bone), the graft most often resorbs to the level of the existing bone on the adjacent tooth root. Therefore, in a one-intratooth defect, a line drawn from each bone level on the adjacent roots is the most bone height that can be predictably expected.

When an ideal bone graft volume next to a tooth with vertical bone loss on the root is required, there are several options to accomplish this goal more predictably. Orthodontic extrusion of the natural tooth with bone loss can elevate the height of bone to the desired level. After orthodontic extrusion, a crown and often endodontic therapy is required. On occasion, extraction of the tooth and a bone graft extending to the next tooth (when the bone is in the correct position on that tooth) is another option.

In esthetic areas, an emphasis must be placed on not only providing adequate osseous volume, but also developing a soft tissue profile for the final implant restoration.[93] When the soft tissue region is in the esthetic zone, an increased height and thickness of keratinized mucosa before the bone graft is of benefit. A connective tissue graft is a common method to increase the desired tissue over the graft site before bone grafting. The soft tissue of the recipient site must then be completely healed for several months before bone graft surgery. Removal of foreign bodies, soft tissue surgery, or tooth extractions should be completed at least 12 weeks before bone grafting. This period allows vascularization and mature elastic fibers to be present in the soft tissue before the bone augmentation process and reduces the risk of incision line opening. Soft tissue surgical procedures may be planned in conjunction with implant placement or implant stage II uncovery when the soft tissue drape is out of the esthetic zone.

همیار دندانسازان

The width and height requirements for augmentation will influence the donor site selected from the mandible. As a general rule, when more than 4 mm of width is desired (C–w bone volume), the mandibular symphysis is the most common donor site. A mandibular ramus is selected as a donor site when the bone graft width is less than 4 mm (Division B to B–w bone volume). When an augmentation for height is required, the most common site is the mandibular symphysis and includes its cortical inferior border (Figure 39-6).

Another influencing factor for the donor site is the location of the host/recipient site. When an anterior mandible is the recipient site, the symphysis is the donor site. A posterior mandible uses the ramus site (whenever possible). A maxillary host site uses the mandibular ramus, when possible, because a ramus graft has fewer postoperative complications of the donor site.

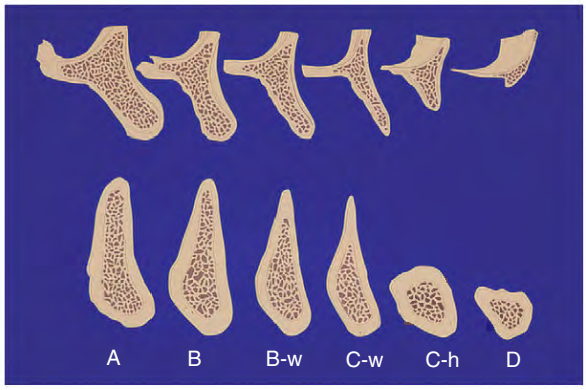

Figure 39-6 Division B and B–w bone volumes are deficient in width and are often augmented with ramus block bone grafts or barrier membranes and particulate grafts. Divisions C–w and C–h bone volumes are often grafted with symphysis block bone grafts.

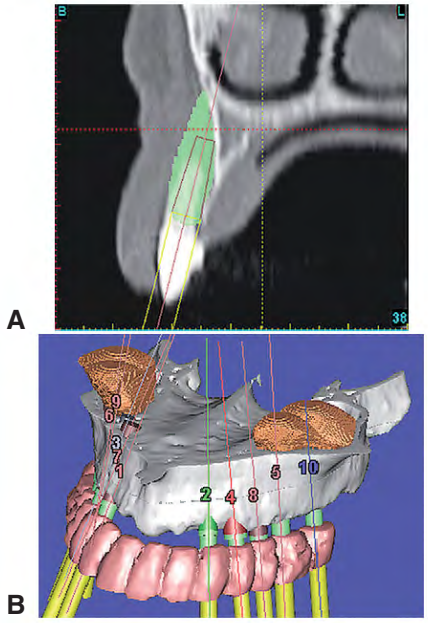

Figure 39-7 A computed tomography scan may be used to evaluate the host site volume required for proper rehabilitation.

The initial radiographic examination of the host site may include periapical, panoramic, or lateral cephalometric views and computed tomography (CT) scans. A lateral cephalometric view is useful in determining the anteroposterior (A-P) (width) dimension of the anterior mandible at the midline when an augmentation for width is required from this donor site. CT with reformatted images are most useful in preoperative planning and ridge mapping for both the host site and the donor site (Figure 39-7).[95-97] Mounted casts are also a benefit to allow the clinician to evaluate the ridge morphology in relationship to the adjacent teeth and opposing dentition. A diagnostic wax-up of the reconstructed ridge and restored dentition is advantageous in determining the graft width and position requirements and analyzing the occlusion. It is also used for fabrication of templates for CT, graft positioning, and implant surgery.[38,41,95,96] A CT model may also be generated to study the three-dimensional (3D) aspect of the host site. A mock surgery may be performed of the donor site, and this CT model may also be used to help recontour the donor bone graft to fit the model prior to the intraoral fixation (Figure 39-8).

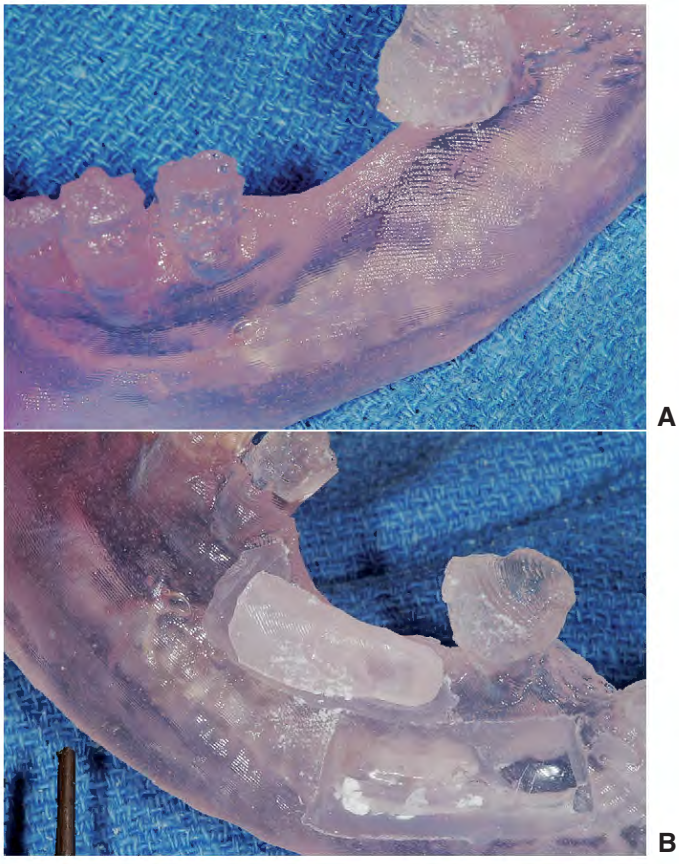

Figure 39-8 **A,** A computed tomography (CT) bone model may be used to evaluate the host donor sites before the surgery. **B,** The CT model may be used to demonstrate or practice ahead of the surgical procedure.

WWW.HIGHDENT.IR

Surgery

Preparation of Host Site

The recipient site should be completely exposed and prepared for grafting before harvesting the donor bone. In this manner, the dimensions of the graft to completely restore the bone defect may be evaluated, prepared, and measured. This approach also reduces the time period the donor graft is stored before fixation to the host site.

The concepts presented in the chapter on keys for bone grafting are incorporated into every step of the bone block grafting procedure. Incisions to surgically expose the recipient site are usually made within attached, keratinized tissue. The crestal incision in the edentulous host site is most often to the lingual aspect of the ridge, especially in the maxilla. This provides more keratinized tissue facially and reduces the risk of sutures tearing through the tissue if edema occurs after surgery, which results in incision line opening (Figure 39-9, *A*). When a block bone graft is anticipated, the vertical primary incisions usually are made one tooth distal to the tooth adjacent to the defect and include the distal interdental papilla. This provides a broader flap, which aids in primary closure and reduces incision line opening. The vertical release incision extends to the mucogingival junction (MGJ), not beyond. The soft tissue reflection of the flap distal to the graft site is a split-thickness reflection to aid the initial soft tissue healing and reduce incision line opening (see Figure 39-9, *B* to *D*).

Complete flap coverage of the block graft and tension-free wound closure are essential to achieve predictable results, and the soft tissue procedure to accomplish this goal begins before the donor graft is harvested. The traditional methods of flap release are to reflect the flap to a greater extent, exposing more host bone beyond the dimensions of the graft site, often beyond the opposing landmarks of the maxilla and including the inferior and lateral piriform rims of the nose and even the infraorbital foramen. A series of parallel incisions to the crestal incision would then be made through the periosteum of the facial flap. This procedure does allow the facial flap to advance several millimeters. However, larger grafts can not be covered without tension on the incision line. In addition, because the muscle layers are still in the facial flap, the tension and initial healing process often retract the flap and result in incision line opening, which is the most common complication of bone augmentation.

The submucosal space technique was first described by Misch to cover large block bone grafts from the iliac crest. This procedure reflects a full-thickness flap over the graft site and at least 5 mm above the height of the MGJ. The periosteum and tissues 5 mm above the MGJ remain on the bone and are not reflected. The facial flap is then lifted and 3 to 5 mm above the depth of the MGJ and a scalpel incises through the periosteum 1 to 2 mm deep, parallel to the crestal incision and extends over and beyond the vertical release incision. After the incision is made through the periosteum, pointed tissue scissors (Metzenbaum) may be introduced into the periosteal incision for 10 to 15 mm or more, parallel to the surface mucosa with the blades of the scissors closed, so the facial flap thickness is 3 to 5 mm. The tissue scissors are then opened, and this blunt dissection of the tissue allows the muscles to be separated from the flap and creates a submucosal space. With the periosteum, tissues and muscles attached to the bone on one side and a 3- to 5-mm-thick facial flap on the other side, the facial flap may now advance the depth of the submucosal space, 10 mm or more. This dramatically increases the ability to advance the soft tissue flap over a block graft (see Figure 39-9, *E* to *I*).

The advantage of the submucosal space technique is that a split-thickness flap is created and maintains the muscles on the periosteum, which is attached to the bone above the contours of the host site. Because the muscle attachments are the primary source of vascularization to the periosteum and the periosteum is the primary source of blood supply to the cortical bone, the blood supply of the cortical bone beyond the graft remains undisturbed. Muscle healing is a primary cause of flap retraction and incision line opening. With this technique, the muscles are no longer attached to the facial flap and the initial soft tissue is reduced. Because the flap may be advanced more than 10 mm, there is no tension on the incision line and sutures, which also reduces the risk of incision line opening.

Soft tissue procedures to enhance graft coverage will result in a loss of vestibular depth. The reduced vestibular depth is rarely an esthetic concern, and when the restoration is implant retained, the prosthesis does not rely on a valve seal for primary retention (as in a complete denture). Advancement of the facial flap for graft coverage will also often result in a reduction in keratinized mucosa over the facial of the ridge crest. In some cases, soft tissue grafts may be necessary, or more often, the attached mucosa may be repositioned facially at the stage II implant uncovery surgery.

The next step in the preparation of the host site is perforation of the lateral and crestal aspects of the host bone with a small-diameter drill, equal to or smaller than the drill size that corresponds to the bone screws used to fixate the donor bone (1.4 mm diameter). The holes are 3 to 5 mm apart in the entire area of the desired augmentation (Figure 39-9, *J*, *K*). The perforations in the bone are created under copious amounts of saline at 2500 rpm and penetrate both the facial and lingual plates of bone in the region of the graft, especially when augmentation is desired on both sides of the residual ridge. This procedure increases the availability of osteogenic cells, accelerates revascularization, increases the regional acceleratory phenomenon (RAP), and improves graft union.[97-99]

WWW.HIGHDENT.IR

همیار دندانسازان

The drill sites perforate the lingual plate. So that the fixation screw does not bottom out and strip the host bone and the dense, a cortical lingual plate ensures that the bone screws secure the bone block during the initial healing period. The host site is also recontoured with a large, pear-shaped carbide bur to improve the graft-to-recipient congruency. Ideally, the donor bone block should be slightly recessed in the host bone 1 to 2 mm, surrounded by a bony margin (Figure 39-9, *L*). After the block bone graft harvest and fixation, the tissues are approximated for primary closure (Figure 39-9, *M* to *S*). After a healing period of 4 to 6 months, the implants may be inserted (Figure 39-9, *T* to *V*).

MANDIBULAR SYMPHYSIS DONOR SITE

The ideal goal of a donor block harvest is to obtain sufficient bone, so the entire bone defect/augmentation dimensions are composed of the block autograft. The

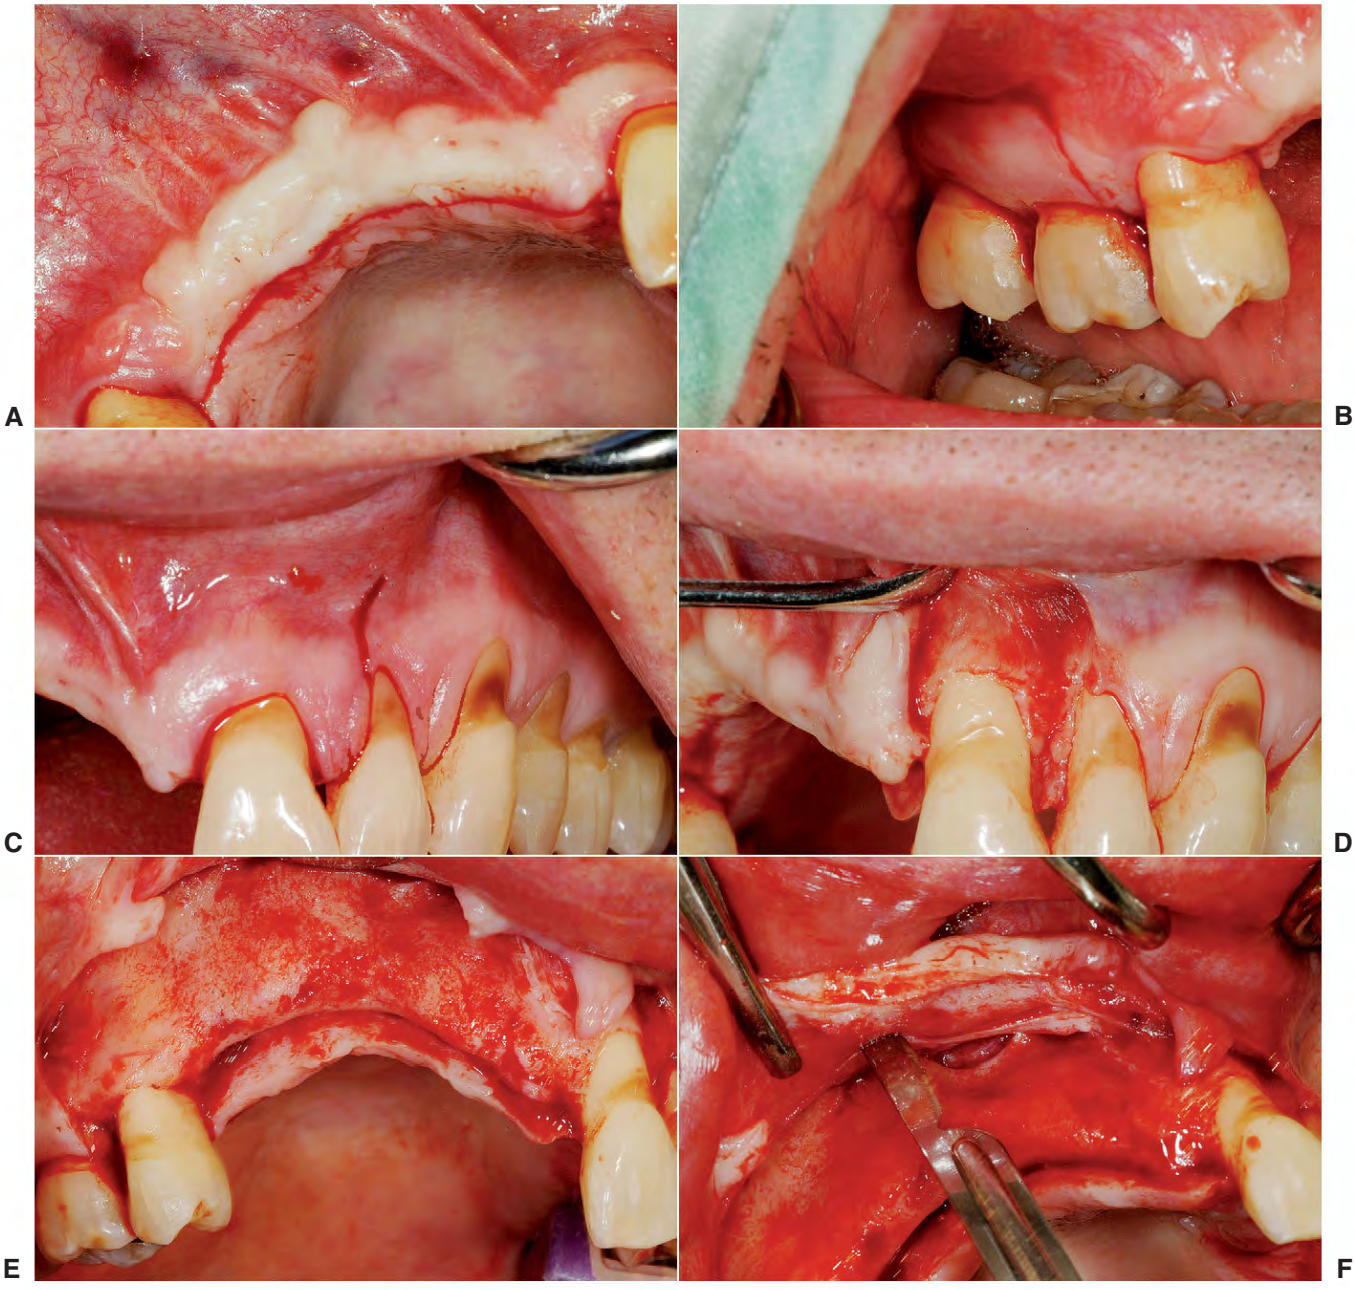

Figure 39-9 **A,** In the recipient site, incisions are designed primarily in attached, keratinized mucosa. The crestal incision is slightly toward the palate. **B,** The vertical release incision stops at the mucogingival junction and is one tooth distal to the edentulous site. **C,** The vertical release incision is distal to the interdental papilla. **D,** A split-thickness flap is reflected distal from the bone graft site. **E,** A full-thickness mucoperiosteal flap is reflected over the graft site and at least 5 mm above the level of the mucogingival junction. **F,** An incision 1 to 2 mm deep is made though the periosteum, 3 to 5 mm above the level of the mucogingival junction (which is on the other side of the flap), for the full length of the tissue flap. *Continued*

WWW.HIGHDENT.IR

mandibular ramus donor site has several advantages over a symphysis donor, including: easier graft harvest, less postoperative discomfort, less neurosensory complications, less incision line opening, less anesthesia, more profound local anesthesia with fewer drugs, and less concern of changes in facial morphology. As a consequence, it is the harvest site of choice, when possible.

Disadvantages of the ramus site include less width of bone in some patients and less length of bone on some patients. As a result, when inadequate bone is present in the ramus site, attention is brought to the mandibular symphysis region.

The mandibular symphysis exhibits a slight curved triangular shape in the midline, and this morphology is often well suited for reestablishing the arch form in maxillary anterior ridges.[100-104] The average interforaminal distance is greater than 4 cm; therefore bone deficiencies requiring larger intraoral grafts may be managed with the symphysis as a donor site. In most cases, sufficient block grafts may be harvested from the symphysis for deficiencies in width involving a span up to four teeth or sites involving up to three teeth that require gains in both vertical height and width.*

A panoramic radiograph is used initially to evaluate the available bone in this donor site. A panoramic radiograph may provide an approximate length of the mandibular teeth, the distance between the foramina, and the vertical height of bone between the root apices and the inferior border of the mandible. Periapical radiographs of the lower anterior teeth may be required for more exact measurements of their length to prevent damage to the roots. CT imagery is used to measure the bone width below the apices of the lower anterior teeth, confirm adequate donor bone volume (especially width), and assess the geometry and angulation of the symphysis.

The basal bone thickness of an anterior mandible ranges from 5 to 15 mm below the roots of the anterior teeth. However, the lingual plate should usually not be violated, so the donor graft thickness is 2 to 3 mm less than the total mandibular width. The width of the mandible in the midline is the greatest dimension. Therefore a lateral cephalogram only demonstrates the greatest bone thickness, not the prospective dimension of the graft. Most often the mandibular symphysis width is several millimeters narrower in the region of the premolar and canines compared with the midline. As a result, when an aggressive or large bone block harvest is desired, CT images of the symphysis should confirm adequate width is present for the host site reconstruction. The CT images are also more accurate than the panoramic radiographs to determine the vertical and horizontal dimension of the graft site.

The average dimension of an anterior mandible between the foramina is 44 mm, with black males having the greatest distance, followed by white males, black females, and white females having the least available donor bone between the foramen.[108] A general rule is to stay at least 5 mm mesial to the mental foramen on each side for a donor bone harvest. Because the average mesiodistal dimension for an implant is 7 mm, a 35-mm bone length between a 45-mm mental foramen length would be necessary for five teeth. In a study by Montazem et al.,[101] dentate cadaver mandibles were harvested from the mandibular symphysis. When two symmetric blocks were measured from each site, the average was 21 × 10 × 7 mm, the largest was 25 × 13 × 9 mm, and the smallest measured 21 × 6.5 × 6 mm.[101]

The vertical height of bone in the symphysis for a donor harvest is variable and ranges from 5 to 20 mm from one person to another. A general rule is to remain 5 mm from the root apices and 5 mm from the inferior border of the mandible. The inferior landmark dimension may be violated and the inferior border of the mandible may even be incorporated into the block graft when necessary.

Surgical Harvest

Anesthesia

The anterior symphyseal region of the mandible is innervated by the mandibular branch of the fifth cranial nerve (V3) and cervical nerves from C-3 and C-4. As a result, several injections are required. Bilateral dental or Akinosi blocks with lidocaine 2% (1:100,000 epinephrine) and marcaine 0.5% (1:200,000 epinephrine) accomplish anesthesia for the V3 innervation. Infiltration anesthesia with lidocaine 2% (1:100,000 epinephrine) is then performed with one-third carpule in front and below each mental foramen and one-third carpules in the midline at the base of the mental protuberance. Another carpule of anesthetic is divided in half with an injection on each side of the superior general tubercle near the base of the mandible.

Surgical access to the symphysis is obtained via a crestal incision, vestibular incision, mid-keratinized tissue incision, or sulcular approach, depending on the anatomy. Most often mandibular anterior teeth are present above the donor site.[109] The vestibular approach is used when there is 4 to 8 mm of keratinized tissue height around the lower anterior teeth, when subgingival crown margins are present in the area, when dehiscent roots are suspected, when root coverage is part of the history, or when sulcus depths around the mandibular anterior teeth are greater than 4 mm deep. In these situations, reflection of the soft tissue around the anterior teeth may result in tissue recession and root exposure soft tissue healing.

The vestibular incision is made in the mucosa at least 1 cm beyond the mucogingival junction and extends to each distal region of the canines. An inferior vertical

*References 21, 23, 26, 38, 101, 103, 105-107.

WWW.HIGHDENT.IR

همیار دندانسازان

release is made for approximately 10 mm between the canine and first premolar. Therefore this incision is anterior and above the mental foramen. A full-thickness mucoperiosteal flap is reflected toward the base of the mandible to the level of the pogonion, leaving the most inferior aspect of the periosteal attachment of the mentalis muscle intact (Figure 39-10).

The vestibular incision has the most intraoperative bleeding and the highest risk of incision line opening, but the least risk of soft tissue changes around the teeth and root exposure after healing. It also creates easier access to the chin. It is the easiest incision line to suture.

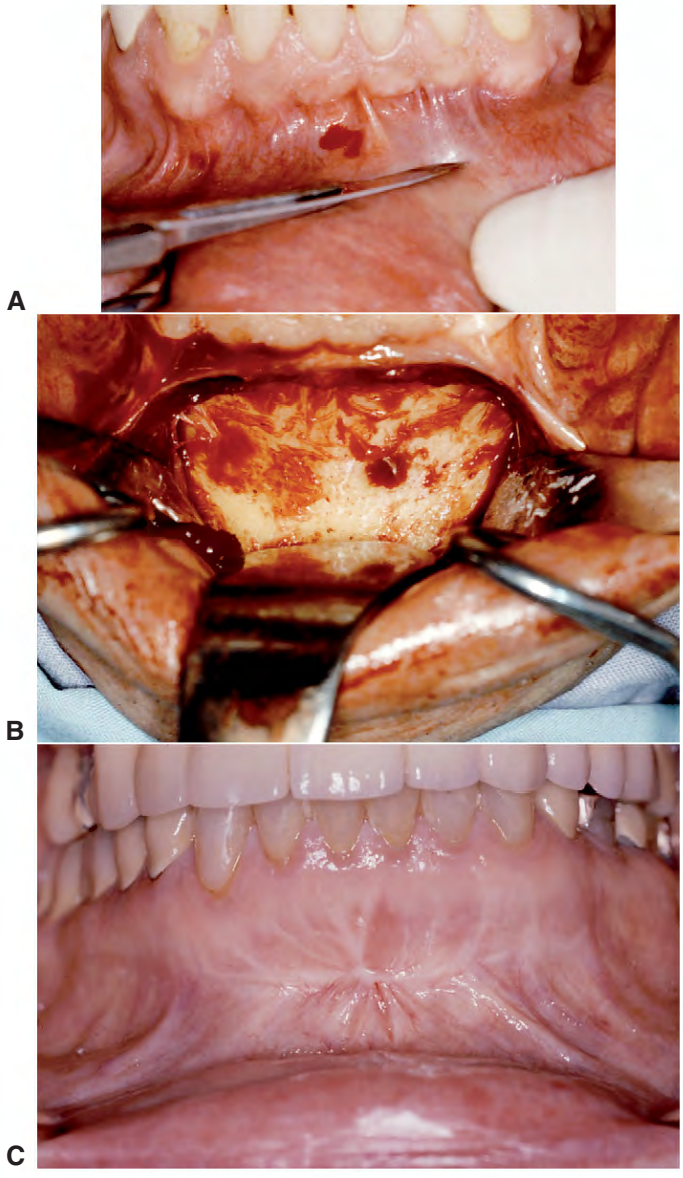

Figure 39-10 **A,** A vestibular incision is made 5 to 10 mm below the mucogingival junction when 4 to 9 mm of keratinized tissue height is observed on the facial of the mandibular anterior teeth. **B,** The incision extends to the distal of the canines and a vertical release incision is made for approximately 10 mm (above the height of the mental foramen). A full-thickness mucoperiosteal reflection exposes the mandibular symphysis. **C,** Vestibular incisions often heal with scar formation.

Limiting the distal extent of the vestibular incision to the canine tooth area will reduce the incidence of mental nerve paresthesia.[38,39,44]

An incision is made within the mandibular anterior keratinized tissue when it is 9 mm or greater in height. This condition is rarely observed. However, when present, this is the incision line of choice, because it reduces intraoperative bleeding, eliminates the risk of root exposure after healing, and soft tissue healing conditions are ideal. The incision is made from the distal of each canine and a vertical release is made 10 mm in front of and above the mental foramen (Figure 39-11).

A sulcular incision is made when there is less than 4 mm of keratinized mucosa in height around the lower anterior teeth. These conditions are associated with a high mucogingival junction and high muscle attachments. Under these conditions, incision line opening is a greater risk. This is especially observed when the mentalis muscle is large and parafunctional forces of this region exist. The sulcular incision carries the least risk of incision line opening after healing, but has an increased risk of root exposure after soft tissue healing. It is also the most time consuming for suturing (Figure 39-12).

Symphysis Donor Harvest (for Division B–w to C–w)

After the symphysis is exposed, the osteotomy for graft harvest is planned. The dimensions of the block are determined by the size of the bone defect. The osteotomies may be performed with a surgical fissure bur (557, 702) or oscillating saw. This is usually done under copious sterile irrigation with a 1:1 to 1:5 contraangle or straight hand piece. The most superior bone cut is made first, because the position of this border is less flexible. The superior osteotomy is ideally made

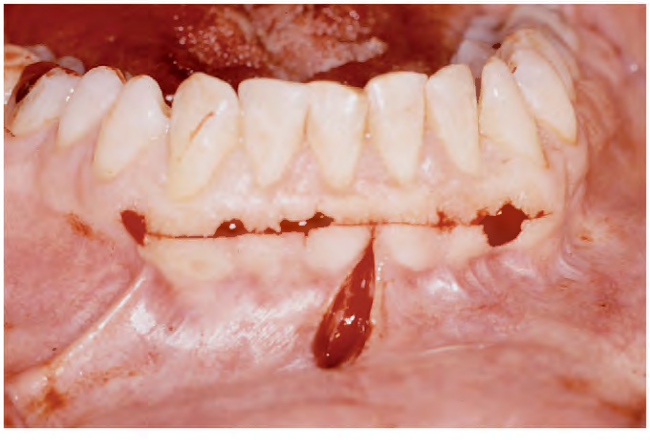

Figure 39-11 When the attached keratinized tissue on the facial aspect of the lower anterior teeth is greater than 9 mm, an incision in the keratinized tissue is of benefit. The incision is made to the distal of the canines. In this case, a midline vertical incision was made, because the symphysis harvest was limited in size.

WWW.HIGHDENT.IR

Figure 39-12 **A,** Sulcular incisions are usually made in the anterior mandible for a symphysis harvest when the keratinized tissue is less than 4 mm in height or when a heavier musculature is observed. **B,** The incision extends distal to the canines, and a vertical release incision is made anterior and above the height of the mental foramen. A full-thickness mucoperiosteal flap reflection exposes the symphysis for the harvest. **C,** A sulcular incision has less risk of postoperative incision line opening; however, there is a greater risk of root exposure after healing.

at least 5 mm below the root apices. The angulation of this cut is perpendicular to the cortex to prevent injury to the roots. The depth of the osteotomies should be at least through the outer cortex and to the opposite cortical plate. Perforation of the lingual cortex may inadvertently occur, but it is not encouraged. The osteotomy may slope below the longer canine roots when more mesiodistal distance is necessary for the host site (Figures 39-13 and 39-14).

In most cases, the inferior cortex of the mandible is maintained unless a block graft for vertical augmentation is harvested. When adequate size permits, the inferior cut is 5 mm or more above the inferior border. The inferior margin has a cut perpendicular or angled upward, so the block harvest may be lifted out of the jaw with an osteotome. This also may protect the inferior portion of the mandible from fracture during the harvest, because more cortical bone along the inferior border is maintained (Figure 39-15, *A*). The vertical cuts are made in relation to the topography needs of the host site and may extend 5 mm in front of the foramen, when necessary. A larger mesiodistal dimension harvest rarely fits the host site in one piece. Instead, two blocks of bone are usually easier to mortice into place. In addition, two blocks of bone are easier to harvest than is one long block. Therefore most often the blocks are divided into 15- to 17-mm-long pieces and three vertical cuts are often made to trim the block harvest (see Figure 39-15, *A* to *C*).

A straight bone chisel is tapped along the osteotomy to ensure the cuts have been made to the lingual cortical plate. The bone chisel is then introduced at an angle and attempts to slide along the lingual plate of bone as the mallet firmly taps the bone segment. The chisel is not positioned to leverage the bone block from the site along the inferior border, because the chin may fracture down rather than the bone block fracturing off. During this tapping and leverage process, the mandible should be closed and braced against the maxillary teeth, so the mallet force is not generated toward the condyles and temporomandibular joint (see Figure 39-15, *D*, *E*).

Often more than one piece of bone is harvested from the symphysis, which facilitates adaptation of the graft to the recipient site geometry. Two bone blocks are often easier to harvest, because the second larger segment may be removed with improved access to the lingual plate to harvest the second piece after the first segment has been removed. This also often allows the harvest of a thicker block of bone.

Additional cancellous bone may be procured from around the block of bone with a small gouge, rongeur, or chisel after the blocks are removed. This particulate bone can be used for augmentation or to fill discrepancies between the block graft and host bone. However, the volume of obtainable cancellous bone in the symphyseal area is usually meager.[105] Bone cores ranging from 4 to 10 mm in diameter may be harvested with a trephine bur for use in alveolar augmentation.[110] The trephine bur prepares the bone core to the inner aspect of the lingual cortical plate. A Molt elevator is placed into the circular osteotomy and is used to fracture the bone core off its lingual base and elevate it from the bone. The cores of bone may be transferred in toto to the recipient site or shaped to fit a defect. It is critical

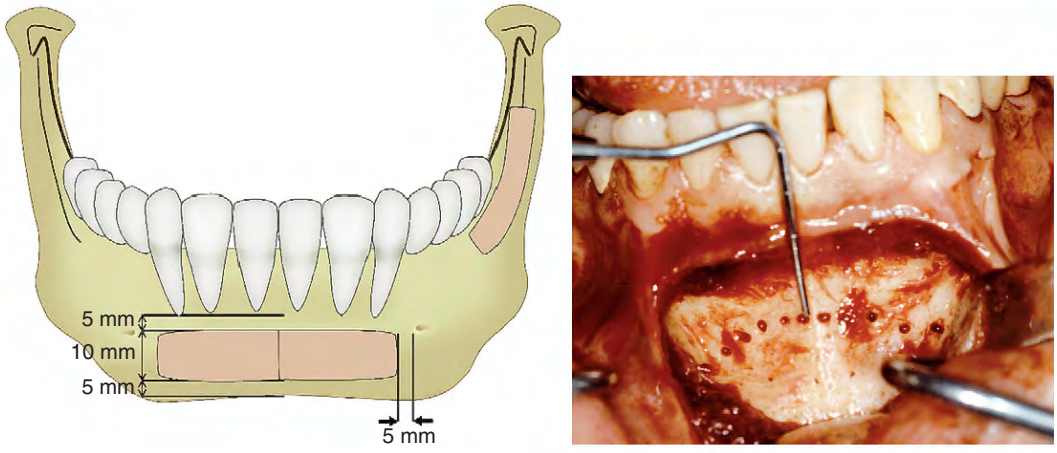

Figure 39-13 **A,** The guidelines for the symphysis block harvest is usually 5 mm from each mental foramen, 5 mm below the roots of the anterior teeth, and 5 mm from the inferior border of the mandible. **B,** The superior osteotomy for the bone block is made 5 mm from the apex of the mandibular anterior teeth. The block margin slopes down in the canine region because of the longer roots.

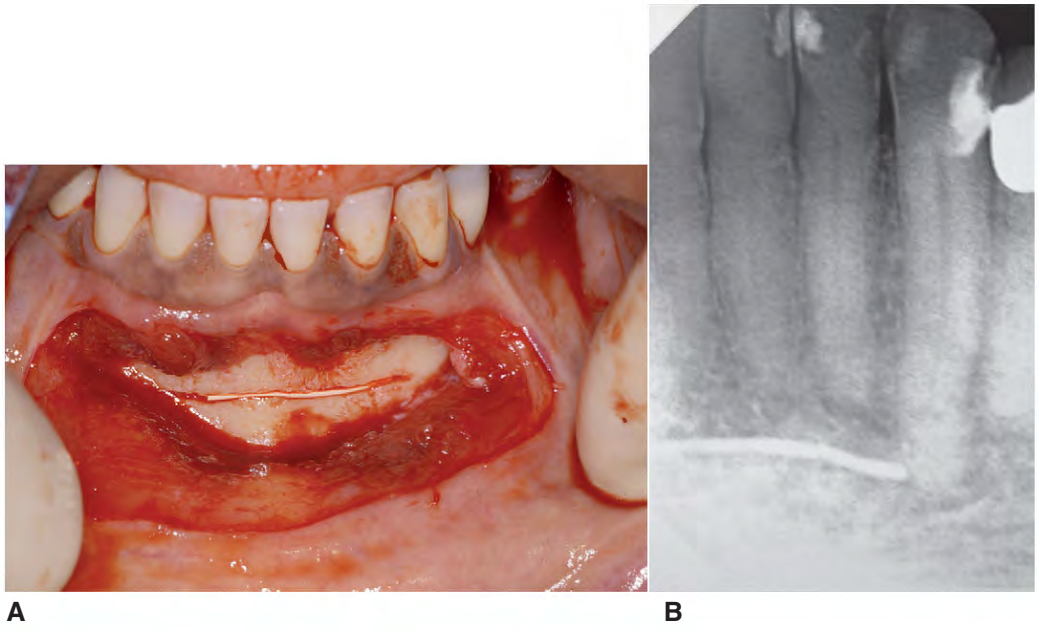

Figure 39-14 **A,** When in doubt, a piece of gutta percha may be placed into the initial osteotomy, and a radiograph of the site is made. **B,** The radiograph reveals the initial osteotomy is too close to the canine root and should be 6 mm more apical in this region.

that the bone cores or graft particles be fixated and immobilized during the healing phase when larger than 3×5 mm. This may be accomplished by mortising the bone into the defect, securing it with a membrane, or placing it into a protected space.

A branch of an artery from the submandibular complex enters the lingual cortex of this symphysis in the midline region, just above the superior genial tubercle. On occasion, this vessel bleeds with profusion. A blunt bone tap (or mirror handle with mirror removed) placed over the bleeder and a firm tap with a mallet crushes the bone over the foramen and arrests the bleeding. On occasion, the incisive branch of the mandibular nerve, artery, and vein are seen entering the bone block or is associated with slight hemorrhage. When possible, this nerve complex should stay intact. If bleeding is present, pressure with a hemostat or surgical sponge most often solves the problem.

WWW.HIGHDENT.IR

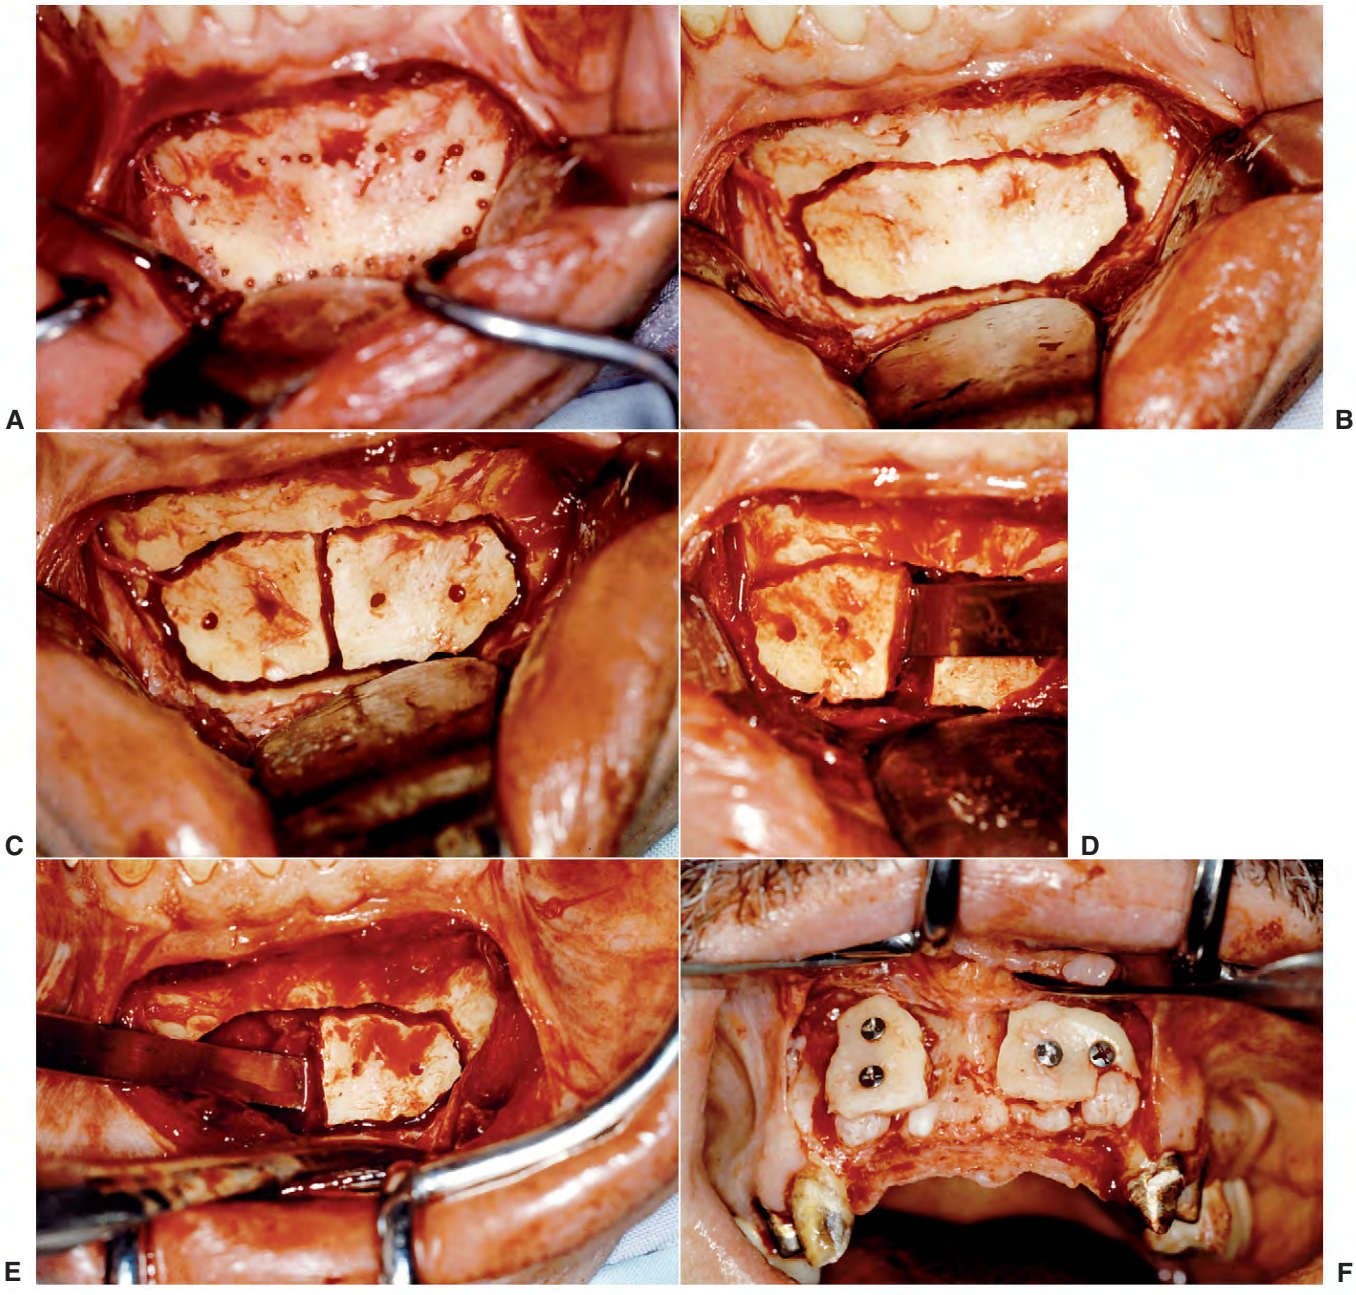

Figure 39-15 **A,** The inferior osteotomy is planned and is usually 5 mm above the inferior border of the mandible when a harvest is primarily for an increased width of bone. **B,** A fissure bur may be used to connect the dots of the planned bone block. **C,** The block is usually designed to be harvested in two pieces. **D,** After an osteotome is used to ensure the osteotomy is made up to the lingual plate, the chisel is angled to shear the one block from this landmark. **E,** The second bone block is easier to harvest, because the bone chisel can slide along the lingual plate with direct access. **F,** The bone blocks are positioned in key implant regions, with at least two fixation screws. *Continued*

The block bone grafts are then fixated to the host site in key implant positions (see Figure 39-15, *F* to *I*). The block graft may be reentered after 4 to 6 months for implant insertion (see Figure 39-15, *J* to *M*). After an additional 4-month period, the implants may be restored (see Figure 39-15, *N*).

Hemostatic materials (collagen, gelatin, sponge, oxidized regenerated cellulose) can be placed into the symphysis area after the bone harvest. Bone wax should only be used for heavier osseous bleeding because bone replacement may be inhibited.[111] Larger donor defects should be grafted with allogenic bone or resorbable hydroxyapatite (HA).

The donor site is closed after the block graft is fixated to the recipient site and the soft tissues are sutured. Before suturing the donor site, the soft tissue superior to the initial access incision (vestibular or within the keratinized tissue) is elevated a few millimeters to reduce

WWW.HIGHDENT.IR

tension on the flap from edema and lip movement. This also allows the suture needle to enter the superior flap without tearing the periosteum. A two-layered closure is recommended for suturing. The submucosal suture is a vertical or horizontal mattress with resorbable PMA or Vicryl suture on each side of the midline.

Postoperative pressure dressings can reduce the development of hematoma formation, incision line dehiscence, and infection. The patient wears a chin pressure bandage for at least 24 hours, and a large harvest should have 3 days of pressure. The patient is warned against pulling the lip to look at the site until the sutures are removed 2 weeks later. One of the most common complications is incision line opening of the donor site, which may become very painful and even infected. The patient should not suck on a straw or move the lower lip as part of any parafunctional activity.

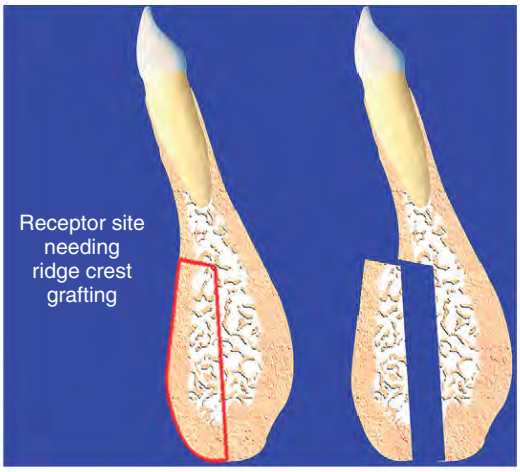

Figure 39-16 A mandibular symphysis block harvest to augment a C–h bone volume in height may include the inferior border of the anterior mandible.

C–h Symphysis Donor Harvest (for Division C–h Host Sites)

The anterior mandible may also be used as a donor site to an augment height of bone in an edentulous site, when the defect is three adjacent teeth or less. To obtain adequate donor bone volume, the inferior border of the mandible is included as part of the graft (Figures 39-16 and 39-17). A lateral cephalogram may be used to evaluate the bone height and width in the anterior mandible (Figure 39-18).

The initial incision and reflection of the anterior mandible is similar for the symphysis bone harvest for width. However, when the inferior border is included, the tissues must reflect beyond the facial line angle of the inferior border and include the inferior border and the lingual line angle of the mandible. When possible, 5 mm of the midline tissue may be maintained to help decrease the risk of ptosis after healing (Figure 39-19, *A* to *D*).

The most superior bone cut is made 5 mm from the apex of the teeth. The vertical bone cuts are made from this point through the inferior border of the mandible. The bone blocks are usually harvested in two pieces, with a midline section of 4 to 6 mm maintained. This segment decreases the risk of altering the postoperative appearance of the chin, especially when prominent. Therefore four vertical cuts are made through the inferior border of the mandible, two near the midline and two distal in relation to the recipient site requirement (see Figure 39-19, *E* to *I*).

The inferior bone cut is often the most difficult to perform. Rotary saws offer an advantage for access. However, most rotary bone saws cut less than 5 mm deep, because the blades are less than 10 mm in diameter. Because the cortex of the inferior border of the mandible is offer greater than 6 mm, attempts to fracture the bone block from the inferior border as the block is harvested are often challenging. The inferior bone cut should allow 3 mm or more of bone to remain on the lingual aspect so that the lingual plate does not fracture off during the harvest.

A small-width chisel is most often used in the inferior bone cut parallel to the lingual plate and tapped firmly with a mallet. The smaller size increases the stress (stress = force ÷ area) and more easily penetrates the cortical bone remaining on the inferior border. The bone chisel may become locked and difficult to dislodge after it is tapped into the site. Several chisels may be required, so if one is difficult to remove from the bone, another chisel adjacent is tapped and often frees the first one from the site. After the inferior border bone block is harvested, the defect is filled with microporous HA and a collagen membrane, to help restore the contour of the mandible (see Figure 39-19, *J* to *R*).

Pressure dressing should be worn for 3 days to reduce postoperative bleeding and ptosis of the chin. Sutures should remain in place for at least 2 weeks. Cortical steroid dosages may be increased (Decadron 12 mg/day 1, 6 mg/day 2, 3 mg/day 3). Antibiotics, pain medication, and ice protocol to the face for 3 days are also warranted.

Mandibular Ramus Donor Site

The limits of the ramus area are more often dictated by clinical access and variable anatomy. The overall anatomic limitations include the coronoid process, molar teeth, inferior alveolar canal, and width of the posterior mandible (Figure 39-20). There are three dominant landmarks that are variable, should be evaluated on a case-by-case basis, and require clinical radiographic and CT analysis (A-P width of the ramus, distance from external oblique of the ramus, and body to inferior alveolar nerve complex [IAN] and width of the posterior mandible and ramus). Harvesting bone

Figure 39-18 A lateral cephalogram may be used to evaluate the mandibular symphysis for adequate height and width.

from this region requires knowledge of the mandibular canal anatomy to prevent nerve injury (Figure 39-21).

The clinical evaluation deals with the presence of molars and the width and length of the external oblique in the body of the mandible. When all three molars are missing, the surgical access is easier and the width of the bone block harvest is often greater. The A-P length of the external oblique and prosthetic "buccal shelf" ranges from no presence from the third to first molar side, to a dominant projection lateral to the body of the mandible. An index finger may be placed on the external oblique of the ascending ramus and slid down the lateral aspect of the mandible. Often a ledge is felt lateral to the second molar region and begins to disappear at the medial of the first molar. The wider the "ledge" lateral to the molars or body of an edentulous mandible, the wider the ramus block bone harvest. Some mandibles have almost no "buccal shelf," whereas others have a 7-mm ledge. Most often the buccal shelf disappears at the mid-first molar region to the anterior and to the third molar region on the posterior aspect. The ramus length is variable, with the most common vertical limit below the coronoid process, as this structure is so thin that a block section would remove the entire segment.

Although the buccolingual position of the mandibular canal is variable, the distance from the canal to the medial aspect of the buccal cortical plate (medullary bone thickness) was found to be greatest at the distal half of the first molar.[112] Therefore when larger grafts are planned, the anterior vertical bone cut may be made in this area. The vertical bone cuts are progressively deepened until bleeding from the underlying cancellous bone is visible.[113,114]

The second variable is the distance from the external oblique and ramus to the IAN. The mean A-P width of the ramus is 30.5 mm, with the mandibular foramen located about two thirds of the distance from the anterior border.[113] A panoramic radiograph may be used to initially asses this dimension. The lingula on the medial of the ramus is the entry point of the IAN. It may be at the occlusal plane (most often), above the occlusal plane, or below the occlusal plane. The lingula may be in the anterior third of the ramus, the middle third, or the distal third of the width of the ramus. As a general rule, the higher and farther forward the lingula, the closer the IAN runs adjacent to the external oblique. As a result, the ramus block harvest must be lateral to the IAN and is less than 3 mm thick. The lower and more distal the lingual is in the ramus on the panoramic film, the lower the IAN is to the external oblique. As a result, the ramus block may be 6 mm in width.

The distance the IAN is from the external oblique in the body of the ramus (buccal shelf regions) is the anterior part of the second variable. When the dimension is greater than 10 mm in height, the surgical access is easier, there is less risk of paresthesia, and the block can usually be wider because the block harvest may include bone above the IAN. When the distance from the external oblique to the height of the IAN is less than 5 mm, the entire harvest site must be lateral to the IAN. Therefore the graft width is often limited to 3 mm.

The third variable of the ramus region is the width of the posterior ramus. In general, females have a thinner body and width of ramus compared with males. The best method to evaluate ramus width before surgery is a reformatted CT image.

As a result of these variables, a rectangular piece of cortical bone from 3 to 6 mm in thickness may be harvested from the ramus.[114] The length of the rectangular graft may range from 1 to 3.5 cm, and the height usually is not much greater than 1 cm.[20,44,115] These dimensions accommodate width deficiencies involving a span of three to four tooth sites. Although use of the coronoid process as an autologous graft has been reported,[116-118] the amount of bone for ridge augmentation is negligible considering the potential postoperative disability of a coronoidectomy.[119,120]

This morphology conforms especially well as a veneer graft to gain additional ridge width. The anatomic proximity makes the ramus well suited for augmentation to the posterior mandible inadequate in width.[42]

Surgery

The surgical procedure to harvest a block bone graft from the ramus presents many features similar to a sagittal split ramus osteotomy.[114,121-127] An incision begins on the midcrest of the ridge in the posterior

edentulous patient, beginning at the retromolar papilla, or base of the retromolar pad. In the dentate patient, a buccal sulcular incision from the retromolar papilla to the second premolar is first made. The retromolar pad is then identified. An incision up the ramus is made, lateral to the retromolar pad to the height of the occlusal plane. The incision is on the middle of the bone of the ascending ramus lateral to the pad. The pad is often to the lingual of the ascending ramus and is not a bony landmark. On rare occasions (but possible), the lingual nerve is present in the retromolar pad, and incising in this region leads to paresthesia or dysphasia of the lingual nerve, the chordi tympani, and a sympathetic branch of the parasympathetic nerve to the submandibular gland (Figure 39-22).

At the height of the occlusal plane, the buccal artery crosses the ramus. The maxillary artery extends anteriorly and laterally to the retromolar pad. If severed, profuse bleeding is observed. Hemostats should be readily available to clamp this vessel on the lingual aspect of the incision. Starting the incision on the ascending ramus no higher than the level of the occlusal plane minimizes the possibility of severing the buccal artery or exposing the buccal fat pad.[114] The incision continues anteriorly into the buccal sulcus of the molar teeth or posterior ridge area.

A mucoperiosteal flap is reflected from the mandibular body, exposing the lateral aspect of the ramus. The attachment of the buccinator muscle is usually observed first. A periosteal elevator is placed medial to this structure and directly on the bone of the external oblique and slid along the ramus. The flap is elevated superiorly along the external oblique ridge. After the facial flap is reflected, the incision in the mid ramus may be extended to the attachment of the temporalis muscle, with one tendon on each side of the ramus. The periosteal elevator slides along the ramus 15 mm deep, down the ramus toward the first premolar region, and

identifies the mental foramen (see Figure 39-22, *C* to *F*). The host site is reflected and prepared for the block graft (see Figure 39-22, *G* to *I*).

The donor site is evaluated and includes the ramus and body of the mandible (Figure 39-23). The anterior vertical cut may then be made and begins in relation to the existence and width of the buccal shelf (extend oblique ridge). Usually, the mid-first molar is in the position of the anterior vertical cut. A No. 557 surgical bur (or saw) may be used through the cortical bone and to the horizontal cut 2 mm above the IAN position. After the vertical cut approximates the position of the IAN, the cut is limited to the thickness of the cortical plate, usually 3 to 4 mm thick. Therefore the cut is progressively deepened until bleeding from the underlying trabecular is observed.

The anterior cut is usually 10 to 12 mm in length (Figure 39-24, *A*).

The posterior cut is then addressed and is usually above and lateral to the IAN (in front of the linguali on the lingual of the ramus). The posterior cut may be full thickness through the cortical plate to the horizontal cut. Because the nerve in this region is usually below or posterior, the cut is made through the entire depth of the cortex (see Figure 39-24, *B*).

The width of the ramus and the external oblique lateral of the mandibular body are identified. A straight hand piece and a small round drill (No. 2 to 4) punctures the bone 3 to 6 mm from the lateral aspect of the ramus and external oblique for the superior cut. The holes should allow at least 3 mm of bone on the lingual of the ramus and 2 mm of bone adjacent to the molar teeth (when present). The length of the graft is determined, as dictated by the host site (previously reflected and prepared). The penetrating holes, just through the cortical bone, are then connected with a fissure bur (No. 557 surgical length). The depth of the osteotomy may be 2 mm above the IAN (see Figure 39-24, *C, D*).

The inferior osteotomy connecting the posterior and anterior vertical cuts may be performed with an oscillating saw or a large round bur (No. 8) in a straight

hand piece. Because access and visibility are limited when making the inferior osteotomy, a more shallow cut may be extended into the cortex only, to create a line of fracture. This inferior cut should not be made completely through the cortex, as it may be located over the mandibular canal (see Figure 39-24, *E, F*).

A thin chisel is gently tapped along the entire length of the external oblique osteotomy, taking care to parallel the lateral surface of the ramus to avoid inadvertent injury to the inferior alveolar nerve. A wider wedge chisel or Potts elevator may then be inserted and levered to pry the bone block segment free and complete the greenstick fracture of the graft from the ramus. After removal of the block, any sharp edges around the ramus are smoothed with a bur or file. Bone wax is reserved for heavier osseous bleeding (see Figure 39-24, *H*). The block graft is then fixated to the host site (see Figure 39-24, *I* to *K*). The block graft may be reentered in 4 to 6 months, implants inserted, and restored 4 months later (see Figure 39-24, *L* to *S*; Figure 39-25). A hemostatic dressing (collagen, gelatin sponge, oxidized regenerated cellulose) may be placed into the donor area, and closure of the site may be completed after fixation of the graft to the receptor site.

Graft Fixation

After the donor bone harvest, the graft may be stored in sterile saline or immediately fixated to the recipient site. Minimal time should elapse before placement of the block on the host bone.[128,129] The trabecular surface of the graft (when present) should be in contact with the underlying cortex of the host bone, which has been decorticated.[82,130,131] The graft may be recontoured to better adapt to the recipient site; however, it should not be particulated or milled into finer pieces.[132,133] The host site should be contoured to fit the donor graft as often as the donor graft is contoured to fit the host site. After the donor graft adequately rests on the recipient site, without mobility or rocking under firm pressure, two or more fixation screw sites may be prepared for each bone block.

The holes in the donor block graft should be slightly larger than the outer diameter of the fixation screws,

WWW.HIGHDENT.IR

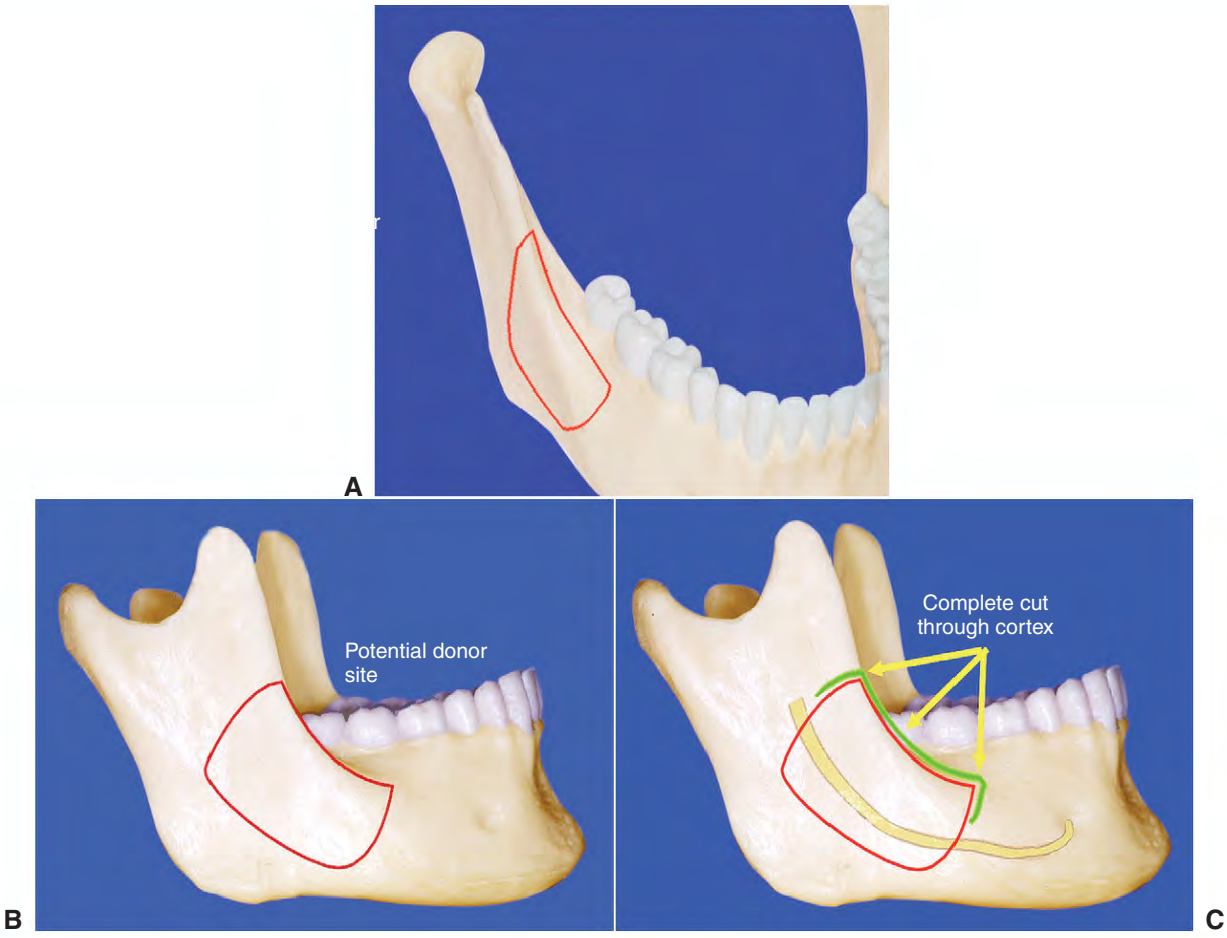

Figure 39-23 **A,** The ramus donor site is lateral to the molars (buccal shelf region) and extends up the ascending ramus. **B,** The ramus donor site uses the outer cortical bone of the ramus and posterior body of the mandible. **C,** The top portion of the ramus donor block *(green line)* is usually above and lateral to the position of the inferior alveolar nerve complex.

but smaller in diameter than the head of the screw. This allows the fixation screw to slip through the block graft and thread into the host bone. The large head diameter of the screw compresses the block graft against the host bone while it threads into the host site for adequate immobilization (Figure 39-26).

The outer thread of the fixation screw is usually 1.4 to 2.0 mm in diameter with a V-shaped thread design. This allows the screw to thread into the host bone during the procedure, and as important, unthread from the host and donor bone after graft maturity. Unlike fracture fixation screws, these devices must be designed to be removed at graft maturity, because endosteal implants will be placed through their pathway. The head of the fixation screw should be 2.2 mm or more in diameter and flat so that it can compress the donor block graft against the host bone.

A lag fixation screw design should not be used. A lag screw design has smooth metal for 5 to 10 mm below the head, and the apical half of the screw has threads. When this device is placed through the block and fixates into the host bone, the concept works well (Figure 39-27). However, when the screw is removed before implant placement, the bone has grown around the smooth neck of the screw and the apical threads must tap the block while it is pulled out to remove the screw. This may pull the block off the host bone, because the interface is still weak between the host and donor.

The end of the screw should be pointed so that it may be self-tapping in softer bone types. A flat end on the screw is of benefit to minimize soft tissue inflammation if it penetrates the opposing cortical plate, but cannot advance in a fixation site that is under prepared in depth.

The surgeon should have two screw diameters available to fixate the block (i.e., 1.4 and 2.0 mm). The smaller diameter is usually first inserted. On occasion, the host bone is too soft or has been stripped when attempting to fixate the block with a small-diameter

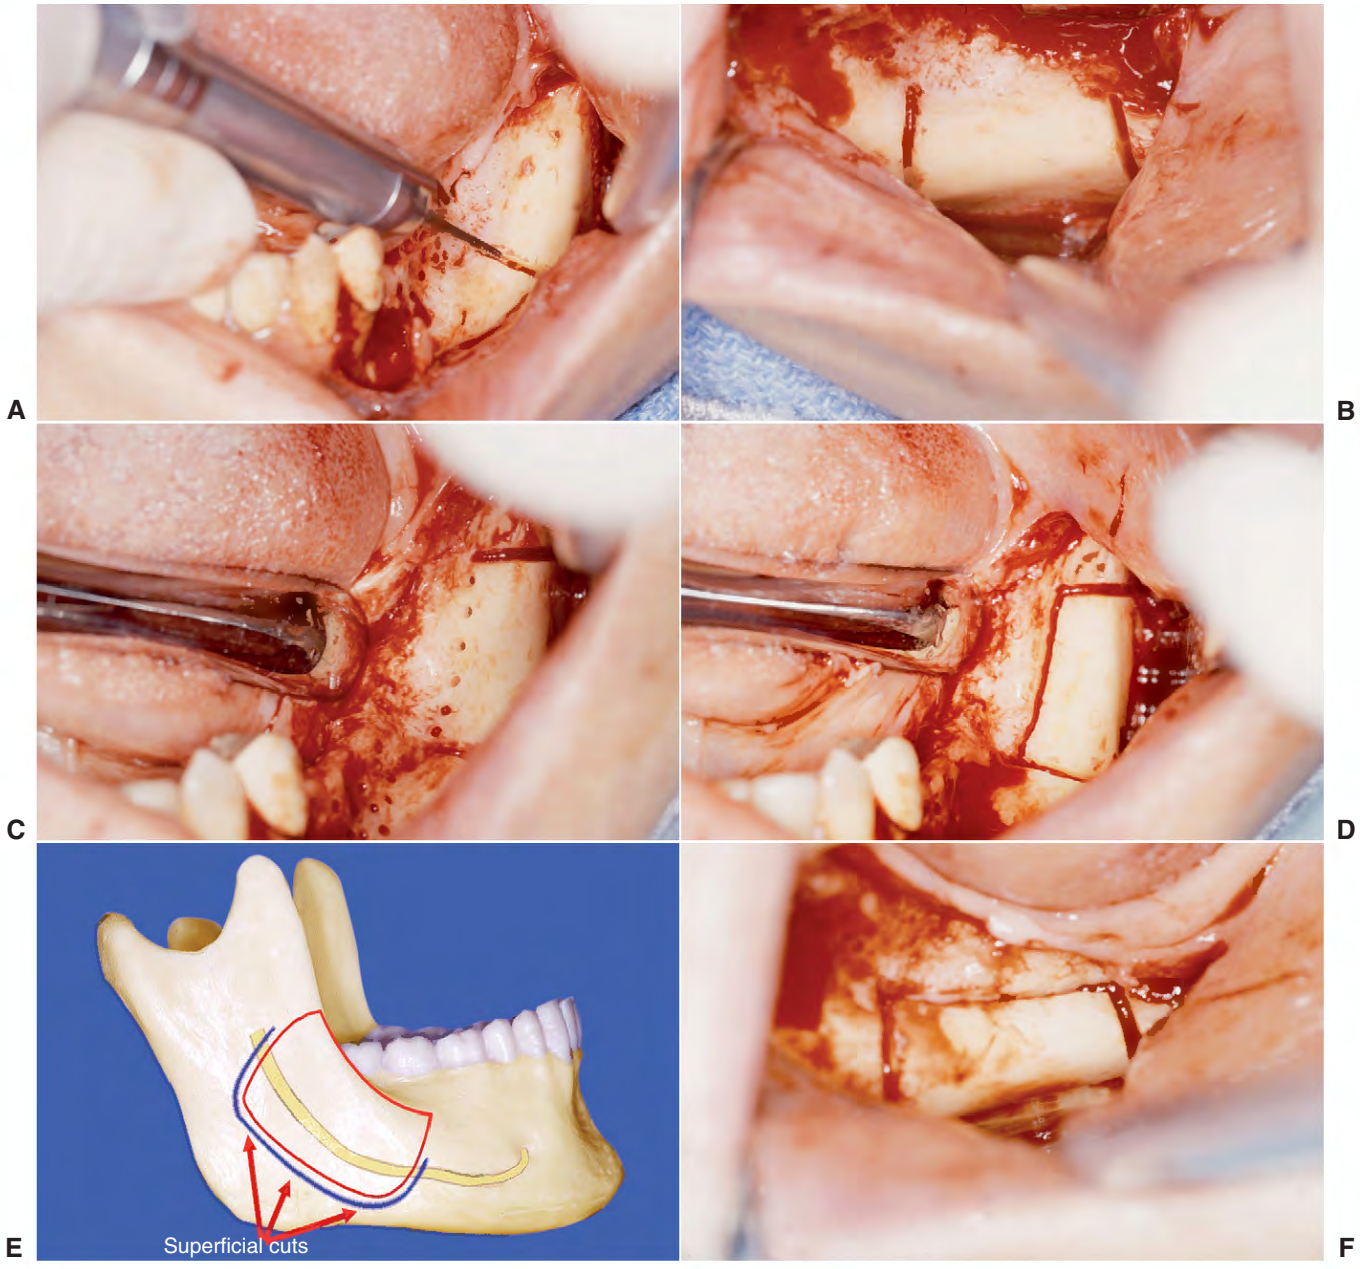

Figure 39-24 **A,** The anterior vertical cut is made with a straight hand piece and a fissure bur or oscillating saw. The position is often at the mid first molar region. The cuts 5 mm above the inferior alveolar nerve (IAN) complex are full thickness. **B,** The posterior vertical cut is often above and lateral to the lingual and IAN and therefore may be made full thickness along the lateral ramus to the superior block margin. The width of the bone block on the superior margin is designed with a small round bur and ranges from 3 to 6 mm in width from the lateral border. **C,** The superior osteotomy is made through the cortical bone and may extend to within 5 mm of the posterior IAN. The horizontal dimension of the ramus block determines the width of the donor site and is related to the amount of bone needed and the anatomy of the donor site. **D,** A fissure bur connects the pilot holes of the horizontal cut. This cut is through the cortical plate and may proceed to 2 mm above the IAN. **E,** The inferior portion of the ramus block is lateral to the IAN. These bone cuts are only thought the cortical bone and do not extend into the trabecular spaces. **F,** The ramus retractor creates a pouch under the masseter muscle and the round bur scratches the bone at the desired depth of the bone block. *Continued*

screw. A larger-diameter screw permits the first to be removed and the same site used to secure the block. Another advantage of two different diameters at surgery is the larger-diameter drill prepares screw sites in the block graft. As a result, the smaller-diameter screws pass through the holes for the lag effect. The smaller-diameter drills prepare the host bone for the RAP and the holes to receive the smaller-diameter screw.

After the graft is mortised to the host bone, two screws or more secure the block. When only one screw fixture is used, the block may rotate or become mobile during initial healing. A high-speed Lindemann bur or

carbides are then used to recontour the bone block after it is fixated in place. It is faster and easier to recontour the block after it is fixated than to attempt to do this in your hand. Any sharp corners or edges are smoothed with the burs.

When an augmentation for height is required, the entire graft should be composed of block graft. Particulate grafts are most predictable for increase of width and when walls of bone are present around the material. A bone graft for height is more prone to incision line opening. Therefore soft tissue–borne provisional restorations should not be used the first month after the graft and then sparingly, only for esthetics.

Trabecular bone harvested from the donor site can be used to fill small discrepancies around block grafts. A mixture of platelet-rich plasma (PRP) and fine particle autograft, allograft, or alloplast may also be used as a filler to provide an additional source of platelet-derived growth factor and transforming growth factor beta.[133-140] Although transforming growth factor beta and platelet-derived growth factor are not osteoinductive, they are capable of promoting bone regeneration in the presence

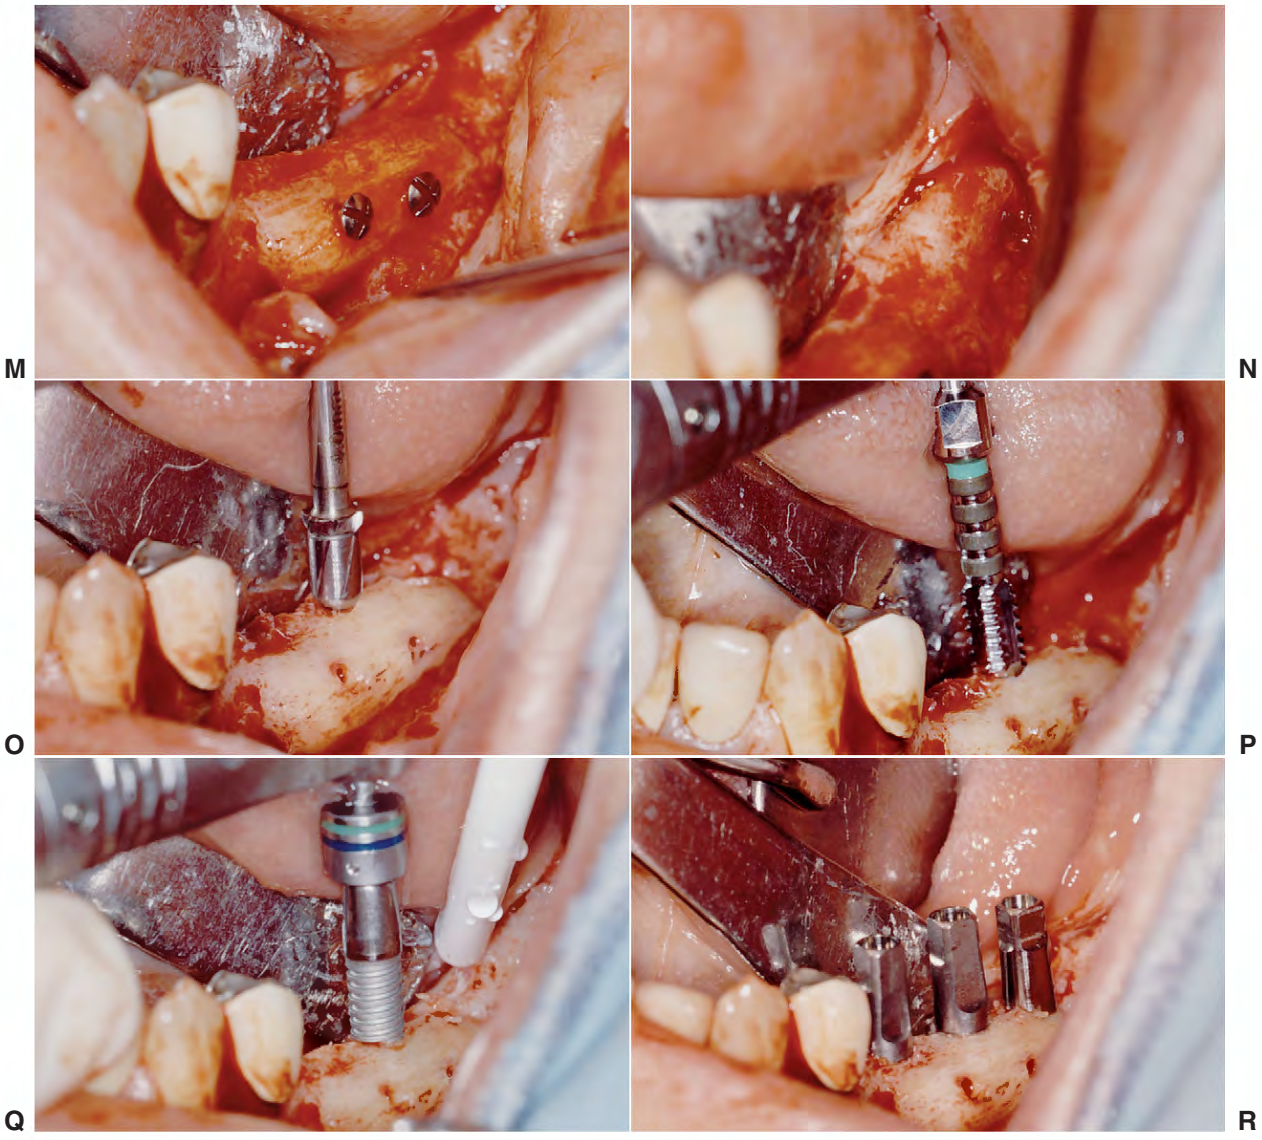

Figure 39-24, cont'd **M,** Reentry into the graft site demonstrates minimal resorption of the graft. **N,** The ramus region has filled with bone, although the external oblique is not as distinct. **O,** The implant osteotomy includes a crest module bur to prepare the bone, which is cortical in nature. **P,** The implant site is tapped to reduce the risk of block fracture from the host site. **Q,** Threaded implants (BioHorizons) are placed into the graft site. **R,** Three endosteal implants are inserted to replace the second premolar and two molars.

of graft materials. In addition to the biological advantages of growth factor amplification, the PRP acts as a fibrin glue to provide adherence of the graft particles for ease of placement around the graft site.[138]

Although it appears that barrier membranes may help minimize autograft resorption,[53,88,141,142] they are not routinely necessary with cortical block bone grafts, which completely fill the graft site and already show minimal volume loss. Not only is the routine use of a barrier membrane questionable, but it also adds additional costs and may lead to complications if early exposure occurs. It also adds unnecessary volume to the graft site, which may increase tension on the overlying soft tissue and increase the risk of incision line opening.

However, if the size of the block graft is inadequate to fill the entire space of the graft site or the harvest is more particulate or trabecular in nature, a barrier membrane should be used. When the host site is larger than two teeth and the block bone graft is inadequate in length, the block should be divided into two pieces. Two pieces are often easier to recontour and fit into position. As important, they may be separated by 5 to 8 mm. In this way, the space between the blocks acts as walls of host bone for the particulate graft. In other words, the particular graft has block graft walls on the

mesial and distal and host bone on the lateral and apical region. Whenever particulate bone is used as a portion of the graft, a resorbable barrier membrane such as acellular dermal matrix should be used over the particulate graft (Figure 39-28).

Studies on the size of particulate autologous bone grafts have shown that smaller particles resorb more quickly and completely than larger graft particles.[132,133] Therefore the autologous particles are usually 3 × 5 mm. When inadequate autologous particles are available, a layered approach is indicated. The autograft is layered over the host bone, the next layer is a mixture of 30% demineralized freeze-dried bone (DFDB) fibers (Grafton), 70% mineralized HA (e.g., FDB, xenograft), and PRP. The top layer is a collagen barrier membrane. A barrier membrane may be used to help contain and stabilize the particulate graft, allow bony regeneration of any remaining space, and minimize the overall volume loss.

Although it is imperative that the soft tissue flap margins be well approximated, the sutures must not be pulled too tightly or tissue ischemia may result. Because the early strength of the healing wound is not achieved for several days, the sutures must be capable of maintaining closure for 2 weeks. If the bone augmentation is large and advancement was more difficult, it is best to use nonabsorbable sutures such as Gore-Tex or Prolene, which maintain their tensile strength for several weeks, and allow them to stay in place 3 weeks. Mucosal dehiscence and premature exposure of the autologous bone transplant are the most common causes of graft failure.* Therefore great care should be taken to properly close the surgical site. Usually horizontal or vertical mattress sutures combined with continuous sutures can achieve proper closure with minimal tension.

Postoperative Instructions

An increase in incision line opening risk has been associated with postoperative smoking and diabetes.[26,145] Patients should stop smoking at least 3 days before surgery and until the incision has healed. It is imperative that the graft be immobilized during healing. Removable soft tissue–borne prostheses should not be worn or should be adjusted to prevent graft loading. The flange area of a removable prosthesis is completely removed, and the edentulous ridge area is generously relieved, which requires the patient to use denture adhesive for prosthesis retention. The patient is instructed to use the provisional removable prosthesis for cosmetic appearance rather than function.

Careful postoperative follow-up is necessary to inspect the bone graft region and eliminate pressure areas from an overlying prosthesis. More favorable provisional solutions are tooth-borne fixed or removable partial dentures, resin-bonded bridges, or denture teeth bonded to the adjacent dentition.[146] The use of transitional implants to support a fixed-interim prosthesis during the healing phase may be considered for patients less tolerant of removable provisional restorations.[147,148]

A comparison of intraoral donor sites for onlay grafting before implant placement was reported by Misch.[44] The volume of the symphyseal donor grafts was almost twice as great as ramus sites (1.74 cm^3 versus 0.9 cm^3). The ramus was primarily a cortical graft, whereas the symphysis block was cortical/trabecular. Dehiscence of the donor site occurred in 10.7% of anterior mandibles, and no incision line opening was found in the posterior mandible or ramus. Temporary nerve paresthesia was reported to be 9.6% in symphyseal graft patients, whereas no sensory complications were observed in ramus graft patients. Altered feeling of the lower anterior teeth affected 29% of anterior mandibles, and no ramus donor block patients reported changes in their posterior teeth. Bone quality was most often D1 for the ramus (11 of 19 cases) and D2 for symphyseal block patients (19/31). There was no difference in the amount of resorption on reentry, no difference in success rates, and no difference in implant survival. Therefore when possible, the ramus site is the first option, because the local consequences of the graft harvest are less (Table 39-1).

Complications: Symphysis Donor Site

The most common concern of patients is the postoperative appearance of their chin. No complications were found on young cleft palate patients treated with augmentation of the symphyseal donor site.[36,37] Ptosis of the chin has not occurred and can be prevented by avoiding degloving of the facial and inferior aspects of the mandible and exposing the lingual aspect.[149] When this approach is used to harvest the symphysis, use of pressure bandages for 3 days is in order.

Although radiographic evidence of incomplete bony regeneration has been reported in elderly patients, it did not result in any discernible profile changes.[39] No alteration in chin contour has been observed clinically or radiographically when grafting the donor area.[38,41,111,150] Although reentry to the symphysis after 4 to 6 months for additional bone harvest has been successful, it is recommended that extraoral donor sites be selected for larger graft requirements rather than making the patient undergo repeated surgeries and extended healing periods between each bone graft.

Although a 5-mm border below the apices of the anterior tooth roots is recommended,[38,41,151] the contents of the incisive canal that innervate the teeth may still be disturbed. Altered sensation of the lower anterior teeth is a relatively common postoperative symptom of the symphysis graft patients.[44,62,150-156] They describe a dullness in sensation of the incisors, which usually resolves within 6 months. Studies showed a significant

همیار دندانسازان

loss of sensitivity that could last well into 12 months. A prospective study showed 20% reduced nerve sensation and 40% superficial impairment.[153,154]

Hoppenreijs et al.[151] examined the lower anterior teeth in children treated with mandibular symphyseal bone grafts and found a high frequency of pulp canal obliteration (12%) and negative pulpal reaction (16%). Reports on tooth vitality after genioplasty or subapical osteotomy also reveal that a substantial percentage (20% to 25%) of teeth test nonvital.[156-158] However, unless clinical signs of pulpal necrosis become apparent (discoloration, radiographic change), endodontic therapy is not indicated.[159] Even if discoloration of a tooth is discovered, it may be closely followed because return of vitality has been observed.[160] Although the author has not observed the need for endodontic therapy, patients should be aware of the risk of pulpal damage.

Complications: Ramus Donor Site

Compared with the symphysis region, the ramus donor site is associated with fewer postoperative complications.[19,44,150,156] Patients have also shown less concern with bone removal from the ramus area, and augmentation of this donor site has been unnecessary. Although vestibular incision dehiscence has occurred with chin grafts, it has not been found with posterior donor sites. Patients are less able to discern neurosensory disturbances in the posterior buccal soft tissues compared with the lower lip and chin. Although the incision along the external oblique ridge could possibly damage the buccal nerve, reports of postoperative sensory loss in the buccal mucosa are less frequent and will most likely go unnoticed by the patient.[161,162] In contrast to the teeth superior to the symphysis donor site, patients have reported minimal altered sensation in their molar teeth.[44,150]

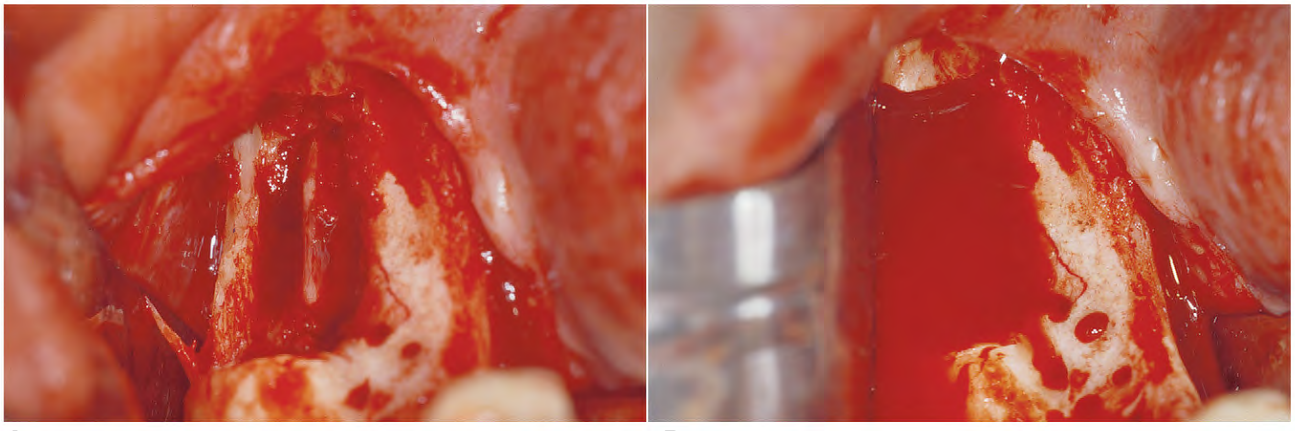
Damage to the neurovascular bundle could also occur during sectioning of the graft. Bone chisels should parallel the lateral surface of the ramus. If the inferior ramus cut is below the level of the inferior alveolar canal, graft separation should not be completed until it can be verified that the neurovascular bundle is not trapped within the graft. Although nerve injury to the inferior alveolar nerve is low, patients should be aware of this risk. On occasion, the IAN is identified and directly observed when the block graft is removed from the ramus (Figure 39-29). When this occurs, Decadron 4 mg, 1 cc, may be placed directly on the nerve for 30 seconds to reduce inflammation and edema. A second dose of 4 mg, 1 cc then is applied for an additional 30 seconds. A collagen sponge may be placed over the site, but HA or graft material is not indicated.

Complication: Host Site

The most common host site complication is graft dehiscence and incision line opening. If graft dehiscence occurs, the wound is allowed to heal by secondary intention after 2 to 4 weeks. The block graft may then be recontoured with a diamond bur to reduce the bulk of exposed bone. The bone above the margins of the tissue is ground off. This procedure is repeated every 2 to 4 weeks until the site is closed (Figure 39-30). No attempt should be made to advance a soft tissue flap to recover the graft for at least 6 to 8 weeks. If the graft becomes mobile, the mobile piece of bone should be removed.

Implant Placement

Sufficient healing time should be allowed for graft incorporation, but implants should be placed early enough to take advantage of their bone-preserving stimulus.[32,39,163] Intraoral block grafts are allowed to heal for a minimum of 4 months for maxillary recipient sites and 5 to 6 months for mandibular sites. Compared with the recommended 6- to 9-month healing period for bone grafts of endochondral origin, a 4-month healing period has been found to be adequate in clinical studies on mandibular bone grafts.[38,58] The



A B

Figure 39-30 **A,** Incision line opening or block dehiscence is a complication of block bone grafts. **B,** The soft tissue should not be resutured over the graft that dehisces during the first few months. Instead, the block is recontoured so the bone above the tissue margins is removed. The area is left to heal by secondary intention.

shorter healing time was based on the hypothesis that membranous bone grafts revascularize earlier than endochondral grafts.[72,164] The rich vascularity of the maxillary cortex in comparison to the mandible allows a more rapid angiogenesis of the onlay graft. The longer healing period for mandibular sites is also to ensure an adequate union between the graft and denser cortex of the host bone. This is critical because the implant osteotomy and insertion are along the graft-host junction. Particulate onlay grafts should be allowed to consolidate and heal for as long as 6 to 9 months unless autologous growth factors have been added to the graft.

As mandibular donor grafts exhibit minimal resorption, predictable gains in bone volume allow implant placement in most planned sites. A staged treatment plan with implant placement following graft healing is the preferred method of reconstruction. Reports on simultaneous implant insertion during bone graft placement have revealed complications such as block graft fracture, wound dehiscence with exposure of implants and graft, and a higher implant failure rate compared with a staged approach.[38-40,46,55,59] In addition, diminished bone contact has been found around titanium implants placed simultaneously with autologous grafts.[12,30,86,165] A staged surgery permits implant placement for ideal prosthetic alignment without the concern of graft fixation or remodeling. Staging the implant placement also provides an improved vascularity of the transplanted bone as the exposed surface area is increased and unimpeded by an inert biomaterial.[53,166] It also allows for any unanticipated increase in graft resorption and should provide a more stable foundation. The implant-bone interface should be improved, as the implant surface is in close contact with the already incorporated bone graft.

The insertion of implants into healed bone grafts as a secondary procedure is similar to their use in jaws that have not been grafted. Autologous bone grafts offer an improved quality of bone at earlier healing times compared with allogeneic bone grafts or guided bone regeneration techniques.[38,58,88,167-169] The density of healed block mandibular bone grafts has been found to be D1 to D2 regardless of the original quality of the recipient site.[38,44,58] An appropriate drilling sequence for dense bone and tapping may be necessary for atraumatic implant placement. The implant surgery activates bone formation and induces interfacial remodeling with bone maintenance, even in unloaded conditions.[170,171] After integration, a progressive bone loading of the implants is recommended.[172] Additional graft resorption after implant insertion has not been noted radiographically on loaded cases.[173-176]

SUMMARY

Autologous bone grafts continue to be the gold standard for jaw reconstruction. Bone harvested from the maxillofacial region offers several advantages in the reconstruction of the residual ridge for implant placement. Intraoral donor sites only require one operational field, which decreases the surgical and anesthetic time. Larger block-type grafts may be harvested from the mandibular symphysis, body, or ramus area. Particulate autograft may be harvested from the maxillary tuberosity, extraosseous tori, ridge osteoplasty, extraction sites, implant osteotomy, and bone collection devices. These grafts require a short healing period and exhibit minimal resorption while maintaining their dense quality. The morbidity of graft harvest is low, and complications usually result in only temporary

debilitation. The use of these techniques allows the placement of implants in ideal positions for optimal esthetics and functional support.

Chapter 40

Extraoral Autogenous Donor Bone Grafts for Endosteal Implants: Ilium and Tibia

Carl E. Misch, Francine Misch-Dietsh, Miles L. Singer, Mathew Lyman

In ridges with abundant bone, all factors converge to provide an ideal long-term prognosis for the implant-supported prosthesis, including favorable ridge relationships. These conditions allow long and wide endosteal implants in adequate numbers, favorable crown/implant ratio, adequate bone density, and favorable orientation of occlusal forces toward the support system. Patients with these advantages usually have less-demanding needs than when unfavorable factors include advanced bone atrophy, as well as the dire need for prosthetic support and retention. When confronted with cases of extreme alveolar and basal bone resorption or discontinuities, most conventional treatment modalities fall short of the intended result. Instead, autogenous bone grafts from extraoral origin, in conjunction with implants, are often indicated to restore these patients.[1-16] In addition, patients with moderate resorptive conditions and ideal prosthetic goals may also require augmentation.

The usual goal of autogenous bone grafts is to provide sufficient available bone to permit the placement of endosteal implants in compromised maxillae and mandibles or to meet the prosthetic and/or esthetic needs and desires of the patient with moderate resorption. Autogenous grafts permit the placement of endosteal implants of increased surface area, height, width, number, and improved location. The type of final prosthesis can be upgraded to a fixed prosthesis with more natural appearance by enhancement of the soft tissue support and possible correction of ridge relationships. The placement of the implants in ideal locations improves stress distribution patterns, interarch relationships, and esthetics of the final prosthesis. As a result, benefits to the patient include implant longevity and improved prosthetics.

HISTORY

Throughout the evolution of oral implantology, several approaches have been proposed to address the problems of the severely resorbed jaw. The lack of support for traditional endosteal implant designs has led to the development of the subperiosteal implant, resting on the remaining bone of the ramus and symphysis in the mandible.[17-18] The endosteal ramus frame implant design also takes advantage of these areas.[19] In the maxilla, extension to the pterygoid plates, maxillary tuberosity, and lateral aspect of the zygomatic process are attempted with endosteal and subperiosteal implants.[20,21] However, the extremely atrophic conditions and the resultant poor biomechanics of the implant system have led to many complications (Figure 40-1). The violation of fundamental prosthodontic principles in the final restoration, as insufficient implant support

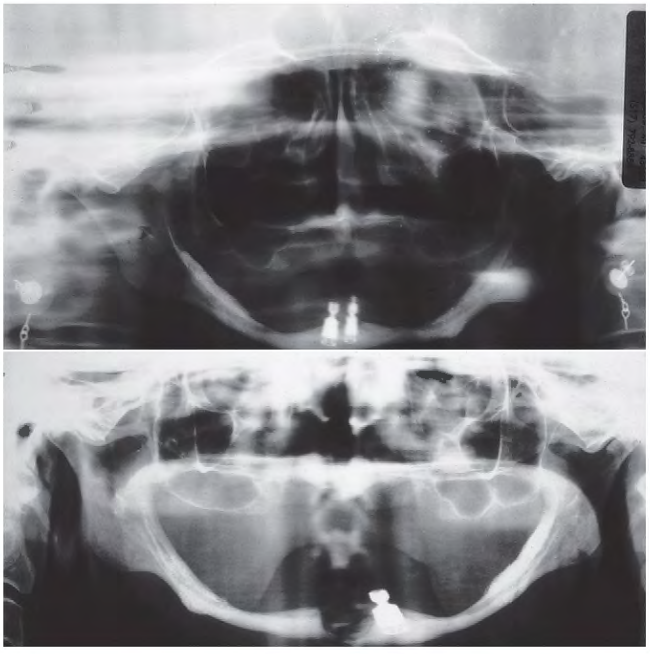

Figure 40-1 **A,** Advanced atrophy of the jaws provides reduced implant surface area, large crown heights, and poor soft tissue support. **B,** Implant failure in patients with advanced atrophy may lead to fracture of the mandible or oral antral and nasal fistulae in the maxilla.

(in size, number, and location) and excessive number of pontics, has encouraged the development of more predictable procedures.

The concept of jaw reconstruction with varied autogenous and alloplastic materials has been used extensively for many years in craniofacial reconstruction.[22-25] However, jaw reconstruction with autogenous bone alone has been characterized by rapid, advanced bone resorption during the 3 to 5 years after the procedure.[26-29] In addition, augmentation of atrophic ridges for conventional complete dentures still does not return a patient to normal mastication and comfort (Figure 40-2). On the other hand, reports of implants in conjunction with autogenous grafts have been reported in the literature, with improved success in relation to prosthetic support and long-term maintenance of the graft. The implants stimulate and maintain the grafted bone and prevent the rapid bone resorption found with autogenous grafts for complete denture support.[1,16,30,31]

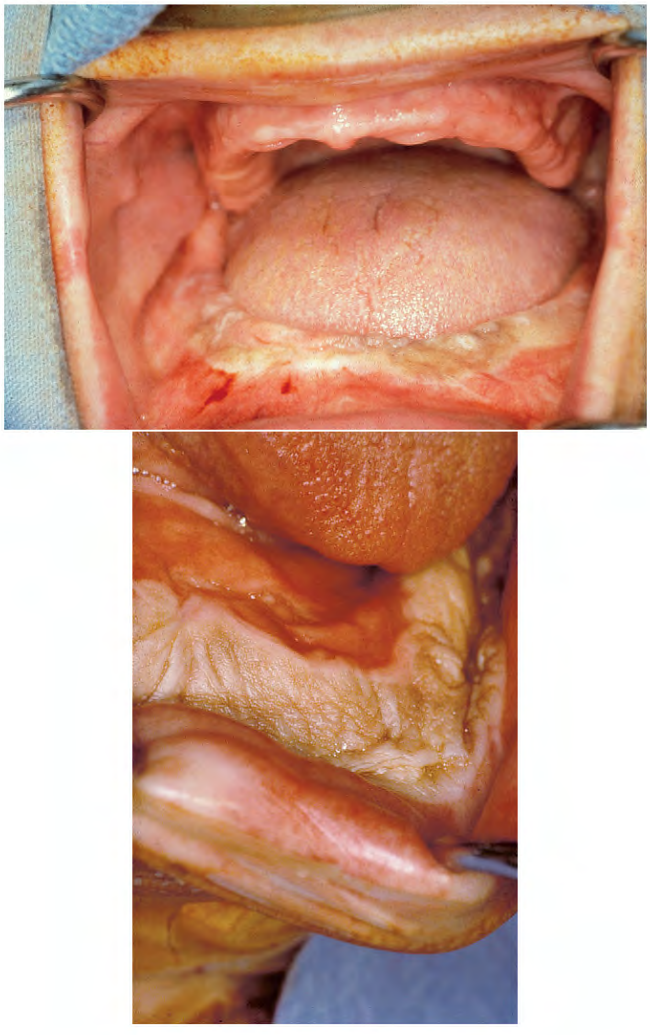

Figure 40-2 **A,** Iliac crest bone grafts with skin grafts to an edentulous mandible initially improve the support for a denture. **B,** The autograft resorbs rapidly over a 3- to 5-year period, leaving loose tissue and poorer denture support than the initial poor condition before the autograft.

When the placement of endosteal implants is desired and advantageous for prosthodontic support, it is beneficial to reconstruct the anatomy of the atrophic jaw with bone or a material that will resorb and be replaced by living bone. The posterior maxilla can be augmented predictably by sinus grafting to permit the placement of endosteal implants, using synthetic bone substitutes, combined with demineralized freeze-dried bone (DFDB) and intraorally harvested autogenous bone.[32,33] No other region of the mouth permits as predictable augmentation for endosteal implants in the severe atrophic state. The subantral (SA) area created for sinus grafts presents many features that are favorable for bone formation. The graft is surrounded by bony walls in a well-vascularized region and protected from loads during healing. Other areas of the mouth that require ridge augmentation more often require onlay autogenous bone grafts to predictably gain bone volume. As a consequence, in most regions of the mouth, the treatment of choice for moderate to severe atrophic conditions is reconstruction with autogenous bone grafting, followed by oral rehabilitation with implant-supported prostheses.

This chapter primarily addresses the iliac crest cortical and trabecular block grafts for onlay augmentation in completely edentulous patients, as well as tibia trabecular bone grafts for barrier membrane procedures. Smaller atrophic regions may be augmented with intraorally harvested bone. An extraoral origin for autogenous bone grafts is necessary for large atrophic regions of the jaws. The preferred extraoral donor sites of autogenous bone include the iliac crest, tibia, cranium, and, to a lesser degree, the rib and fibula.

Treatment Planning

Indications

The prosthetic goal and the patient's needs and desires are the primary determinants for implant-related treatment option selection. Demanding esthetics or functional desires and expectations of the patient may mandate the augmentation of the bony structures, even when other treatment alternatives are available. For example, a patient with moderate atrophy may be a candidate for an implant-supported overdenture. However, when the patient's needs and/or desires require a fixed prosthesis, bone grafting for additional implant number, size, and position may be required. Therefore, when any discrepancy of hard tissues exists that cannot render predictable implant prosthesis treatment, the implant dentist has three options:

1. Select a traditional prosthodontic rehabilitation without implants.
2. Modify the patient's mind by lowering expectations, and plan a prosthesis requiring less implant support.

WWW.HIGHDENT.IR

3. "Improve" the available bone to the amount and form needed to achieve the expected result.

Indications for autogenous grafts for the placement of endosteal implants are presented using the Misch-Judy available bone and Misch prosthetic options classifications.[33a,33b] In addition, bone Division E has been added to the original four divisions to encompass those conditions in which trauma, pathology, surgery, or genetics have resulted in a discontinuity defect of the jaw.

General Considerations

Autogenous bone grafts are osteogenic and able to form bone in the absence of undifferentiated mesenchymal cells. In addition, the autograft may form bone by osteoinduction, osteoconduction, and a barrier membrane approach. In addition, it appears that no age-related change exists in the viability of bone-derived cells.[34] Fresh, autogenous, cancellous bone provides the survival of the maximum number of transplanted bone and pluripotential cells of the marrow.[23] For large grafts, it is usually harvested from the ilium, which presents a high population of pluripotential cells and can deliver the greatest amount of trabecular bone.[35-37] Proponents of the use of solely trabecular bone argue that when harvested from iliac crest, it allows implant placement earlier.[38] Fonseca and Davis[37] recommended the addition of chips from the lateral cortex to increase the bone morphogenetic protein (BMP) concentration. The addition of platelet-rich plasma (PRP)[35,39,40] over the grafted bone attempts to further stimulate the second phase of bone formation and may enhance and stimulate remodeling and incorporation of the graft. However, trabecular grafts are usually maintained in place by the use of cribs.[36] More importantly, the resorption rate is faster than the bone formation rate, and the volume of bone obtained is highly variable. In addition, the quality of bone formed is often poorer compared with other graft options.

An advantage of a trabecular graft is the solid block form, which permits contouring and adaptation of the graft to the recipient bed anatomy.[41] The block graft maintains greater volume of bone compared with particulate onlay grafts, because resorption of the cortical bone is delayed and rigid fixation of the block to the atrophic ridge is possible. The cortical bone on the outside of the graft also acts like a barrier membrane similar to membranes used in guided bone regeneration (GBR).[42] The fibrous tissue is prevented from invading the graft site, and this provides additional time for angiogenesis and new bone formation below the cortical layer. The rigidity and stability of the graft can be achieved by the use of fixation screws to stabilize the graft, eliminating the need for wiring, pins, or the use of a crib.[2,3] The quality of the bone is greater and increases strength, modulus of elasticity, and initial bone-implant contact percent (BIC). A review of the literature of bone grafts and the placement of implants reported similar success rates for block and particulate grafts to the maxilla and mandible,[6] and both procedures are widely reported.

ILIAC CREST CORTICAL AND TRABECULAR BLOCK GRAFTS

According to several publications, autogenous bone harvested from the ilium is the donor site of choice for large-defect bone grafts to the jaws.[1-16,36,43-53] The primary advantage of the iliac crest graft is its large volume. The outer portion of the graft may be primarily cortical, with abundant trabecular bone underneath. The volume of bone harvested permits shaping of two thirds of a mandible or maxilla or filling of larger bony voids.

Relative ease of access and harvesting from the ilium have made it a safe and well-accepted procedure. However, rapid bone resorption of 30% to 90% of the iliac crest bone grafts has been reported when conventional dentures are placed on top of the reconstruction.[29] As a consequence, other treatment options have often been considered, such as zygomatic and pterygoid implants in the maxilla or 7- to 9-mm implants in an anterior mandible. However, the placement of implants into the grafted bone has dramatically modified this resorption rate. Once the implants are placed and in function, the rate of bone resorption is similar to host bone of similar quantity and density in similar conditions.[5,53-55]

In 1972, Kratochvil and Boyne[30] originally reported the iliac crest bone graft procedure with the concomitant use of implants with subperiosteal implants (Figure 40-3). In the past decades, an increasing number of reports have discussed concomitant use of grafted bone from the iliac crest with endosteal root form implants placed simultaneously or in a second step.[1-16,53-75] However, the reported success rates of autogenous bone grafts and dental implants are variable (Table 40-1).

In the early years of reports, implant failure was higher in grafted bone than native host bone. Breine and Brånemark[3] placed implants in 18 atrophic jaws in conjunction with autogenous trabecular bone. Only 25% of the 129 implants remained integrated in 14 atrophic maxillae and four mandibles. Most jaws required additional implants, and 20% of the maxillary jaws never achieved permanent bridge stability. Additional implants placed after graft maturity had 73% survival. In 1987, Keller et al.[58] reported on five patients with 28 implants and bone grafting, with four failing to fixate (85% survival) and four patients with 76% survival (16 of 21 implants) when placed after Le Fort I osteotomy and grafts. They later reported on these patients and 20 additional grafted maxillae after a 2-year evaluation, with an overall implant survival

of 77.4%. Keller and Tolman[59] reported on seven mandibles with iliac crest grafts and 32 simultaneous implant placements, resulting in 87.5% survival rate. In 1988, Listrom and Symington[44] inserted implants in 12 grafted arches, with 85% initial implant survival, as well as a secondary procedure in 10 patients with 43 implants and 77% implant survival. Kahnberg et al.[60] reported on 10 patients in 1989 having received 57 implants simultaneously, with a graft from the iliac crest and eight implants lost (85% survival). Complications included graft exposure in three patients (30%). The use of a splint to protect the graft was reported to significantly decrease this complication.

Results by the same authors were updated in 1995, with 20 arches grafted with simultaneous implant placement and an 88.3% survival rate.[54] In 1997, Schliephake et al.[66] reported on the 5-year follow-up of 137 grafted atrophic maxillae and a cumulative survival rate of 67.8% for implants placed at the time of grafting.

In 1990, Jensen et al.[56] also reported problems with iliac bone grafts and stated the procedure should still be considered in an evaluation stage. Twenty-nine implants were placed in four patients who received iliac crest grafts. Twelve remained fixated and in function, or 41% implant survival. In a study of 23 consecutive grafted maxillae over a 10-year period, Adell et al.[57] reported on 124 fixtures placed simultaneously with the grafts and 16 implants added in a second stage. The survival rate of fixtures placed with the graft was 75.3% at 4 years after grafting. However, 16 implants placed at a secondary procedure resulted in nine implant failures (31% implant survival).

On the other hand, several reports in the literature indicate implant survival in grafted bone is similar to native bone. Hall[53] reported 100% implant success after graft maturity in 10 patients and also reported bone loss similar to nongrafted bone sites where implants were inserted. Tidwell et al.[63] reported on combined sinus and iliac onlay grafts in 48 maxillary patients and found 6.4% implant failure in the sinus and 7.8% implant failure in the anterior region. In 1996, Triplett et al.[64] reported on 129 grafts in 99 patients (including ilium, cranium, and symphyseal grafts). Survival rates for the implants placed at the time of grafting were 83.6% and 90.4% for implants placed in a delayed approach. In 2003, Raghoebar et al.[12] reported on the early loading of 68 implants inserted in a single-stage approach, with iliac crest grafts to 10 maxillae and a 95.6% survival rate after 1 year.

The ideal timing for implant placement in autogenous bone grafts from extraoral origin remains a controversial issue. In 1997, Neyt et al.[65] reported on 17 atrophic maxillae restored with sinus and iliac crest grafts and implants and an overall 92.7% survival rate. All implants were placed in a delayed fashion. In 1999, Umstadt et al.[14] performed 40 iliac crest grafts in a prospective study of 176 implants and reported 87% and 66% survival rate for implants placed in a immediate and delayed fashion, respectively. In 1998, Stellingsma et al.[15] reported 100% success for 40 implants placed in a delayed fashion in 10 augmented mandibles of female patients.

In 2005, Van der Meij et al.[13] also selected an immediate implant placement approach for 17 atrophic mandibles augmented with the iliac crest and restored with two implant overdentures (34 implants). The average length of the study was 4.3 years, with an 88.2% implant success rate. In 2006, Verhoeven et al.[8] reported 100% implant survival rate when placed at the same time as the bone graft in 13 atrophic mandibles, after 10 years. However, 51% of the bone graft had resorbed, mostly during the first year after the bone graft. In 2006, Clayman[9] reported on eight grafted maxillae with delayed placement of 34 implants, with an 83% success rate. Sjostrom et al.[10] elected to place all implants in a delayed fashion. They grafted 25 maxillae that were restored with 192 implants. At the 3-year follow-up, 90% were successful with stable bone levels.

In conclusion, recommendations in the literature range from immediate placement to delays of 4 to 12 months postoperatively. Requirements for the immediate-placement success include the anchorage of immediate implants in native bone, with a minimum of 1.5-mm thickness of graft bone covering the implant. Several other reports underline that implants anchored in graft alone fail.[68-70] Graft maturation is the primary advantage of delayed implant placement, along with the possibility to address eventual postoperative complications and a more precise placement of the implants for the intended prosthesis. Timing of implant placement should, however, attempt to take advantage of the bone-preserving stimulus.[44,71-73] It is also suggested that the implant and graft success may be different whether a maxilla or mandible is the host site.

A retrospective case series study was published in 1994 by Misch and updated in 1999.[55] This report is further updated in this chapter. Patients received iliac crest block grafts for implant-supported prostheses from 1984 to 2005 and were monitored until 2007 (Table 40-2). A total of 182 patients and 221 arches received autogenous bone grafts from the iliac crest to the maxilla (133) and mandible (88). Participants included 146 women and 36 men in the study group. Thirty-three women and six men received grafts in

both the maxilla and the mandible. Six arches in the maxilla were lost to recall and dropped (two patients died before treatment was completed, three patients elected not to continue treatment for economic and personal reasons, and one patient developed an uncontrolled disease and elected not to continue treatment [not reentered]). One arch in the mandible was dropped because the patient elected not to continue treatment for economic reasons (same patient as maxilla). These seven arches were dropped from the study.

A total of four arches failed (all female patients and all maxillae). Therefore a total of 210 arches were restored (123 maxillae, 87 mandibles), with a total success rate of the graft of 95% (92.5% and 98.9% for maxillae and mandibles, respectively) (Table 40-3).

Ninety-one implants were placed to stabilize the block graft, of which 44 were in the mandible and 64 in the maxilla (Table 40-4). Six months later, the implants were evaluated by direct observation for rigid fixation and quantity of bone around the implant. Three implants were mobile, and three other implants exhibited rigid fixation; however, two had poor placement, and one had more than one third of crestal bone loss. Therefore six implants were removed (five of the six were in the maxilla), with 97.7% of mandibular immediate implants placed maintained, whereas 92.2% of maxillary immediate implants were maintained (overall survival 94.4%). After 1993, no implants were placed concomitantly with the grafts to fixate the graft. In some selected cases, however, some were placed in the tuberosity or vomer to support the transitional prosthesis.

Five to 8 months after the autogenous bone graft, 1256 endosteal implants were placed in a delayed fashion. The maxillae received 876 implants, and the mandibles received 380 endosteal implants. Thirty-seven implants did not achieve rigid fixation and were removed at the stage II (uncovery) surgery. Two additional implants were lost after 2 years in function in the posterior maxilla. The survival of the implants placed in a delayed fashion in autogenous bone graft sites was 96.9% in the maxilla and 96.8% in the mandible, with an overall survival rate of 96.9% (see Table 40-2).

In conclusion, a total of 1364 (940 maxillary and 424 mandibular) implants were placed in either an immediate or delayed fashion, with an overall survival rate of 96.7% (96.6% and 96.9% for maxilla and mandible, respectively) and higher survival rates for delayed-placement implants.

The causes of the 45 implant losses included poor implant placement at the time of grafting, parafunction and trauma from the overlying removable prosthesis opposing natural teeth during healing, incision line opening after the autogenous graft (two), and one late failure caused by advanced uncontrolled bone loss. No "sleepers" were counted in this study. Sleepers in the maxilla were used primarily in the tuberosity to help support and retain the denture and protect the bone graft until implant uncovery. The patients in this report have been in function with their final restoration from as long as 238 months (19 years, 9 months) to as little as 12 months, with more than half of the arches in function for more than 12 years. The amount of crestal bone loss observed during the time frame of this study on implants placed after graft maturity after the first year of loading is similar to that for implants placed in full arches that did not receive a graft.

Several authors have advocated the placement of implants after graft bone maturation for 5 to 10 months. A delayed implant placement after graft maturity of 5 to 10 months is also strongly encouraged for several reasons. Incision line opening is a common compli-

WWW.HIGHDENT.IR

cation with larger bone grafts. Implants exposed along with the surrounding graft are more likely to fail or exhibit crestal bone loss. In addition, because the first 5 to 10 months are a primary time of consolidation and/or remodeling of the graft and modeling of new bone, the contours and volumes of the bone block exhibit the greatest changes.[61,74,75] Functional loading of the implants allows this resorption to fall to the value of physiologic involution. The delayed approach permits the placement of implants in optimized bone volume, and it even allows regrafting in regions compromised after initial graft healing. Prosthetic and surgical templates may be used with greater accuracy for delayed implant placement, with precise information on the bony topography for surgical template fabrication. As a result, implants are positioned more ideally for the intended prosthesis.

Procedure

Maxillary Bone Grafts

The iliac crest graft technique to the maxillae has evolved over the last 25 years. Different approaches such as onlay grafting or intrapositional graft with Le Fort I osteotomies have been proposed. Originally, implants were often placed at the same time as the bone graft and positioned anterior to the maxillary sinuses.[3,44,45,56,57] Because the maxilla resorbs to the medial and the mandible resorbs toward the facial as basal bone remains, implants placed at the time of the bone graft are too lingual in the maxilla and too facial in the mandible (Figure 40-4). Poor implant position, increased risk of implants in compromised areas of incision line opening, poor anteroposterior (A-P) implant distance, and less-controlled crestal bone loss during bone revascularization suggested several modifications of the technique.

The maxillary sinus bone graft is one of the most predictable regions of the mouth to form large volumes of bone, even when the graft site is primarily alloplasts and/or allografts. As a result, sinus grafts as part of the iliac crest bone graft approach have been strongly suggested by the authors. This permits the placement of more distal implants of large dimension and surface area for improved biomechanical distribution of stress and strain to the bone. However, one complication of simultaneous sinus and onlay grafts is an increased risk of postoperative infection within the first 2 months after sinus grafting, which occurs in approximately 3% of procedures. The infection compromises the sinus graft and may spread to the onlay portion of the graft. Although relatively low, this risk can be eliminated by performing the sinus graft with primarily alloplasts and allografts 3 to 4 months before the iliac crest graft. In this way, the sinus membrane and ostium complications can be addressed before the iliac crest graft. During the onlay block graft surgery, the inferior one third to one half of the sinus graft may be removed and replaced with autogenous bone. Because the sinus membrane is not manipulated, the risk of infection is minimized.

Another main surgical advantage of early sinus grafting is the opportunity to enhance the soft tissue quality and quantity in the anterior region for primary coverage of the onlay graft. A transitional augmentation may be performed in the premaxilla. A full-thickness incision is made 5 mm to the palatal aspect of the crest from canine to canine. A mucoperiosteal flap exposes the facial region of the ridge. A Vicryl-encapsulated dense hydroxyapatite (HA) (PermaRidge) or AlloDerm acellular tissue graft is placed in the premaxilla region. The mesh of dense HA or acellular tissue acts as a transitional augmentation during soft tissue healing. At the iliac crest graft surgery, the HA "sausage" is removed before positioning the iliac block of bone. The primary

Figure 40-4 **A,** The maxilla resorbs toward the palate in the anterior and posterior region. The mandible becomes wider because the basal bone is lateral to the alveolar bone. Implants secured into basal bone and positioned at the time of iliac crest graft placement are therefore too lingual in the maxilla and too facial in the mandible. **B,** Implants placed at the time of iliac crest augmentation are more facial than the position of the teeth. The overdenture bar is cantilevered to the lingual in the anterior and is in the vestibule of the lip.

WWW.HIGHDENT.IR

همیار دندانسازان

advantage is the improved tissue thickness available to allow primary closure over the graft without tension.

A third reason to perform a sinus graft 4 months before the iliac crest block bone graft is related to fixation. It is sometimes difficult to secure the onlay graft to the thin residual ridge, and primary graft stability is paramount to the success of the procedure. Wires around the nasal spine, piriform rim, and/or zygomatic arches may be required when this occurs. The advantage of sinus grafting several months before the onlay graft is the easier placement of fixation screws and the ability to fixate the graft in the anterior and posterior regions. This reduces the risk of block mobility, especially when opposing mandibular anterior teeth. A fourth reason to perform a sinus graft 4 months or more before the iliac crest graft is that the implant may be inserted at the time of the sinus graft into the maxillary tuberosity and palatal incline of the premaxilla vomer bone. At the iliac crest graft surgery, the implants may be uncovered and used as retentive devices for the transitional prosthesis while the block bone graft matures.

SURGICAL APPROACH: HARVEST OF THE ILIAC CREST TRICORTICAL BLOCK

Anterior Iliac Crest Graft

The iliac crest is widely accepted as the donor site of choice of bone for reconstruction of large defects of the maxillla and mandible. A tricortical bone block provides excellent fixation for implants until the bone graft is fully incorporated. In addition, the ilium provides a generous amount of cancellous bone.

The subcrestal window technique has been described by Behairy and Al-Sebai.[76] This provides a biocortical full-thickness graft while sparing an 8- to 10-mm bridge of iliac crest proximally. However, the harvest of the tricortical bone block is primarily used because of the excellent ridge of cortical bone provided by the crest. The procedure for harvest is described along with the reconstruction technique to prevent cosmetic deformity. This technique also limits hematoma formation caused by exposed cancellous bone. Herniation of abdominal contents is a well-known[77-82] complication of full-thickness iliac crest bone grafting. The technique described may limit this complication.[83] With proper technique, the harvest of tricortical bone graft from the anterior iliac crest can be performed with good results.

Procedure for Harvest of Iliac Crest

Place the patient supine and administer general anesthetic, with placement of a nasotracheal airway to allow free access to the oropharynx. The oral surgery is typically performed after harvest because of space constraints around the patient. If only a one-sided harvest is planned, then the surgeon should place a bump under that side. In selecting the side for harvest, one consideration is the side preferred for sleeping. If bone is to be harvested bilaterally, then no bump is used. Primarily, three different harvest sites of the ilium exist (Figure 40-5). The anterior iliac crest is preferred, because the posterior harvest is usually limited to one or two cortical plates and a tricortical bone harvest is desired. In addition, bone width at the crest of the ilium is often greater in the anterior region compared with the midcrestal anatomy. A 7- to 8-cm transverse incision is made either proximal or distal to the iliac crest. An incision directly over prominence of the iliac crest is avoided[84] because of likely irritation from clothing or seat belts. The incision must remain at least 2 cm lateral to the anterior superior iliac spine (ASIS) to avoid damage to the lateral femoral cutaneous nerve (LFCN), which can rarely course through this area. Electrocautery is used for hemostasis and to dissect through the subcutaneous tissues to the fascia overlying the ilium.

Beginning at least 2 cm lateral to the ASIS, the relatively avascular interval between the abdominal musculature superiorly and the abductor musculature inferiorly is identified and incised with electrocautery directly over the ilium.[85] Subperiosteal dissection by means of electrocautery and a Cobb elevator is used to expose the inner and outer tables of the iliac crest, clearing away the iliacus muscle medially and gluteal muscle at the outer table. It is imperative to remain in a subperiosteal plane during this exposure to avoid damaging neurovascular structures on the inner table. This minimizes muscular bleeding and thus hematoma formation. Staying within this plane also decreases postoperative pain and creates a thick periosteal and facial layer for adequate repair. A self-retaining retractor provides excellent visualization at this point.

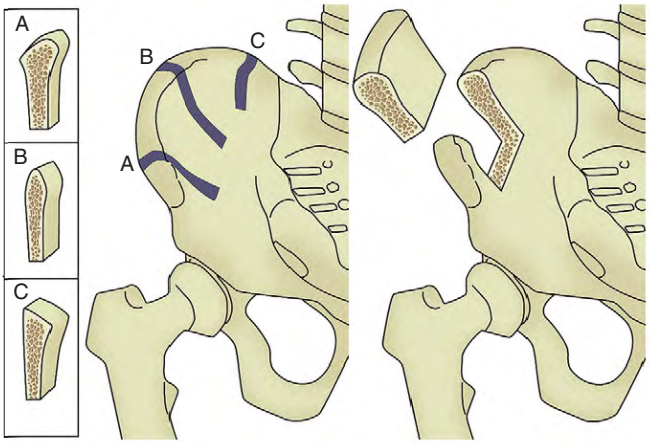

Figure 40-5 The iliac rest may be harvested from the anterior crest *(A)*, the midcrest *(B)*, or the posterior region *(C)*. The anterior site permits a thick tricortical harvest to augment the atrophic jaws.

WWW.HIGHDENT.IR

The ASIS is located and the iliac crest is cut sagittal at least 3 cm lateral, being careful to avoid wandering anteromedially. Attention to these details lessens the likelihood of ASIS avulsion by sartorius and tensor fascia latae muscles. The cut is made using the oscillating saw. The oscillating saw is preferred for sagittal cut as a result of biomechanical studies, which have shown that cutting the iliac crest with the osteotome has the effect of weakening graft strength.[86] A sizing guide is then taken (Figure 40-6), as determined by the oral surgeon preoperatively. It is placed on the inner table, and the size is marked directly onto the ilium. Care is taken to obtain a graft to match the sizing guide, because an inadequate graft lengthens the oral procedure considerably by requiring piecemeal reconstruction. A second sagittal cut is made with the oscillating saw. The area of the ilium where the bone thins considerably is located, and the bone is carefully osteotomized. This bone is then transferred to a basin with sterile saline until the oral surgeon begins contouring.

Technique for Reconstruction of the Iliac Crest

The wound is well irrigated with an antibiotic solution and suctioned dry. The pelvis is then inspected for fracture. A 0.062-inch unthreaded Kirschner wire is driven into one of the cut edges of the cancellous bone left exposed at the donor site. The Kirschner wire is measured, and a 3.5-mm cannulated cancellous screw is chosen so that about one third to half of the screw's length is left exposed, at least 1.0 to 1.5 cm (Figures 40-7 and 40-8). This cannulated screw is then driven over the Kirschner wire in usual fashion, and the Kirschner wire removed. Methylmethacrylate cement is mixed. Using the exact same procedure, a second screw is placed opposite the first (Figure 40-9). These screws are placed to act as rebar to stay the cement once it is placed.

Malleable retractors are now placed at the inner and outer tables, flush with the bone, to provide containment for the cement. Once the cement reaches the

Figure 40-6 A sizing guide is placed at the inner table to ensure adequate harvest for reconstruction. The ability to reconstruct the jaws is affected considerably, because inadequate bone harvest results in inadequate jaw augmentation or piecemeal reconstruction.

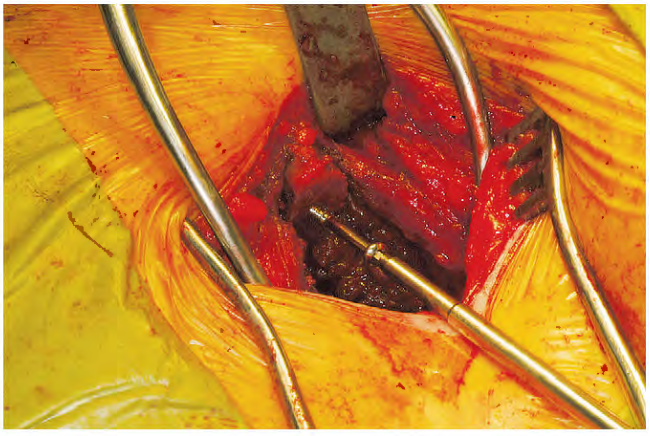

Figure 40-8 A cannulated screw is placed over a Kirschner wire and driven to a depth such that approximately one third of the screw is left exposed.

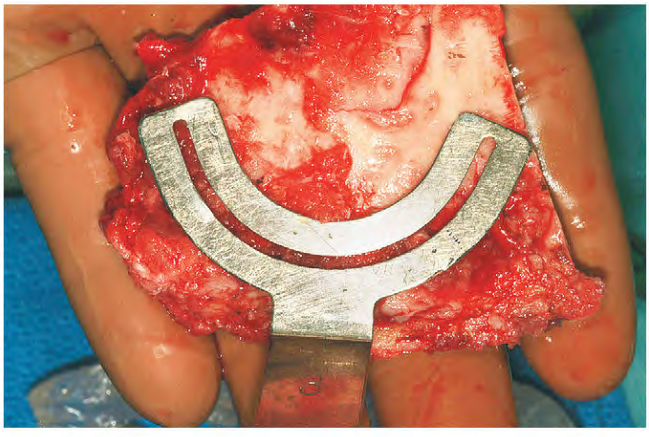

Figure 40-7 A measuring guide is used to determine and verify sufficient volume of the harvested block.

Figure 40-9 Screws are in place, and the site is prepared for bone cement reconstruction.

WWW.HIGHDENT.IR

همیار دندانسازان

consistency of putty, an appropriate amount is placed at the reconstruction site so that it mimics the bone block harvested. Great care is taken with the use of the malleable retractors and large osteotomes, if necessary, to contain the cement (Figure 40-10). As the cement hardens, the retractors are moved slightly to prevent adherence of the cement. The superior aspect of the cement is smoothed with the fingers so that the bone-cement interface is smooth and contoured to the normal anatomy. More cement is added if necessary (Figure 40-11). The wound is irrigated during hardening to prevent thermal damage. Once the cement is hardened, retractors are removed and the reconstruction is inspected for loose cement. Sharp edges are trimmed with a rongeur (Figure 40-12).

The wound is again irrigated. A Marcaine pain pump is placed below the fascia exiting away from the wound. The abdominal and abductor fascia is repaired carefully with No. 1 Vicryl. For subcuticular closure, 2-0 Vicryl is used; the skin is closed with 4-0 Monocryl. Benzoin tincture and Steri-Strips are applied liberally, and a sterile dressing is applied. Scrub is broken, and care is taken by the first team not to contaminate the back table, which will continue to be used during the oral reconstruction.

Figure 40-10 Malleable retractors are used to contain the bone cement.

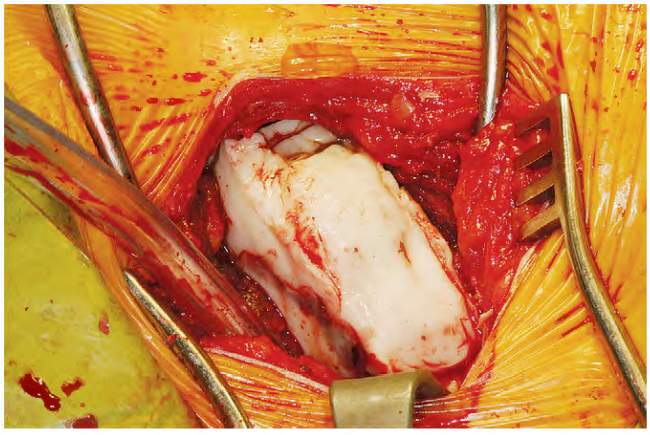

Figure 40-11 Reconstructed iliac crest.

Neurovascular Structures

In this approach the deep circumflex iliac artery is at risk as it courses approximately 2.5 cm inferior to the iliac crest on its internal margin in a tunnel along the transversus abdominis and iliac fasciae. The fourth lumbar and the iliolumbar arteries are also potentially at risk in this approach, because they parallel the crest as they transverse the iliacus and abdominal wall muscles. Subperiosteal dissection and careful retraction at the inner table will prevent damage and subsequent hematoma formation.

The LFCN typically crosses the anterior surface of the iliacus muscle before passing into the thigh, near the ASIS. Normally the nerve passes beneath the inguinal ligament and sartorius muscle; however, in as many as 10% of cases, it may pass over the iliac crest at a point as much as 2 cm lateral to the ASIS.[87,88] The technique, as described, prevents damage to the LFCM.

At the level of the anterior iliac crest, the ilioinguinal nerve passes over the transversus abdominis and internal oblique muscles. It then courses under the external oblique muscle, entering the inguinal canal to pass distally, supplying sensation to the genitalia and nearby skin. Great care should be taken to approach the inner table in the subperiosteal fashion and careful attention given when retracting or using the oscillating saw.[89]

The iliohypogastric nerve, at the level of the anterior iliac crest, passes lateral to the transversus abdominis (passing between that muscle and the obliquus internus abdominis). At this level, the nerve is located slightly more proximal than the ilioinguinal. Neuralgia of the iliohypogastric nerve can result as described previously for the ilioinguinal nerve.

The femoral nerve is also at risk when harvesting bone from the inner table. Located more distally than the ilioinguinal nerve, it is found in the iliac fossa as it

Figure 40-12 A rongeur is used to trim sharp edges.

WWW.HIGHDENT.IR

courses over the iliacus muscle, entering the thigh below the inguinal ligament.

Recipient Site Surgery

Division C–w

An incision is placed on the crest of the C–w ridge, and a full-thickness periosteal reflection exposes the moderately resorbed residual ridge. The posterior ilium has been shown to contain twice as much trabecular bone as the anterior ilium and also to result in less blood loss, morbidity, and no long-term gait disturbances. Therefore both approaches can be selected.[90] A block of one cortical plate and trabecular bone may be harvested from the ilium, or a tricortical harvest from the anterior ilium is made, which is then divided into two cortical and trabecular blocks. In either case, usually four blocks are made. Each bone block is contoured to the desired shape, and the trabecular component is compressed to increase the number of cells. The overlaying cortical plate of host bone is perforated with a small-diameter drill scored to enhance revascularization and to establish the regional acceleratory phenomenon (RAP).[91] The block bone graft is fixated with titanium screws to the lateral aspect of the recipient bone to restore the final ridge form in a more ideal position for future implant placement. The most usual placement is on the facial aspect of the C–w ridge. However, an Angle's Class III mandible may indicate lingual fixation of the bony block. The block graft may also be extended above the crest of the atrophic ridge to increase bone height, when the block graft is greater than 6 mm wide.

Once the block is fixed into position, bone marrow aspirant from the ilium harvest and additional trabecular bone harvested from the ilium are placed around the blocks and fill in any defects. This blend may also be placed under the block before fixation if any irregularity in the host bone exists. The tissues are approximated without tension with horizontal mattress sutures (Figure 40-13). Autogenous grafts of extraoral origin are often not necessary where only one or two segment of the maxilla necessitate bone grafting for width, because intraoral block grafts are often effective with multiple harvest sites.

Division C–h

The patient with a Division C–h ridge has moderate bone in height for endosteal implants and implant prosthetic treatment. In selected cases, shorter endosteal implants or a transosteal implant system can be used for a stable, removable restoration that may be an RP-5 or, with greater implant number, an RP-4 prosthesis. Patients with moderate desires can still be treated adequately by these implant modalities, provided the crown height and factors of stress are compatible with the planned prosthesis. However, for the more-demanding patient expecting a fixed restoration, the addition of autogenous bone is often necessary to obtain sufficient height and width of bone (especially in the maxilla). Most patients with C–h ridges requiring grafts are being treated for improved prosthodontic conditions in the maxillary arch.

The greater available bone after ridge augmentation permits the placement of ideal length and wider implants, improves the surface area of support, improves the stress distribution, recreates a more favorable crown/implant ratio, and returns the soft tissue contours to a more natural appearance. Most often, intraoral block grafts, even with multiple donor sites, are inadequate to augment a C–h edentulous ridge. Many C–h premaxilla treatment plans for a fixed restoration mandate augmentation with autogenous bone grafts before the placement of implants.

The initial incision for C–h available bone is in keratinized tissue and on the palatal aspect of the crest in the maxilla and the midcrest of the mandible, from second premolar to second premolar region. A mucoperiosteal reflection exposes the anterior section of the C–h host bone. A tunnel procedure is used to expose the lateral posterior maxilla or posterior mandible when onlay augmentation is desired.

The soft tissue is prepared for primary closure, without tension, before positioning the block of bone. An incision is made through the periosteum 3 to 5 mm above the height of the mucogingival junction and above the height of the vestibule. Soft tissue scissors are then introduced through the periosteum, and a blunt dissection creates a submucosal tunnel, which extends 10 to 15 mm toward the vermillion border of the lip. On soft tissue closure, the vestibule is reduced, but this is usually of no consequence because implants are used to support the restoration, rather than relying on the valve seal of a removable prosthesis.

The bone harvested from the donor site is often a full-thickness, tricortical block from the anterior ilium. One side of the cortex is thinned and contoured to fit the C–h host bone and perforated to allow revascularization of the trabecular component of the block. Surgical templates designed before surgery are used to help contour the block of bone.

Before the sinus graft, computed tomography (CT) reformatted images are indicated to evaluate the ridge topography. This CT process should also have a CT model fabricated of the resorbed maxilla or mandible. The harvested block may then use the CT model as a template to contour the arch and mating surface of the iliac crest block. When possible, rather than remove bone during the recontouring process, it is compressed to increase the cellular component of the graft.[92] Any bone removed from the block is stored in sterile saline to fill any voids or irregularities between the bone block and the recipient bone.[93]

The C–h edentulous available bone is usually augmented with a block graft on the crest of the atrophic

bone. It often extends to the facial aspect of the ridge several millimeters in the maxilla, whereas it is positioned more lingually in the mandible. Cephalometric analysis may be required to predetermine ideal graft placement. Four to six titanium screws that are 2 mm in diameter and 12 to 18 mm long usually are used to fixate the block graft of autogenous bone. Intimate adaptation of the graft to the recipient bed and rigid fixation are paramount to graft success. An attempt is made to place the screws flush with the block graft.

Additional cortical and trabecular bone harvested from the recontouring of the block and stored in sterile saline[93] is made into particulate bone 3 × 5 × 5 mm in size and then compressed in a 5- to 10-mL

modified syringe.[92] It may be added ("injected") into the posterior regions (sinus graft and/or onlay tunnel technique) and on the labial regions above the block of autogenous bone. This creates further soft tissue support in the anterior and greater bone volume for future implant placement. The bone marrow aspirant (20 to 30 mL) is placed over the grafted site, especially on the mixed cortical and trabecular bone. The tissues are approximated with a nonresorbable suture (e.g., nylon or expanded polytetrafluoroethylene [e-PTFE]) to ensure adequate suture strength for the initial 3 weeks before the sutures are removed. Silk is not suggested because of its potential to wick bacteria under the soft tissue (Figure 40-14).

The endosteal implants are placed 5 to 10 months after the iliac crest graft, using a surgical template designed after the final graft is determined to optimize anterior implant placement. A staged implant placement

reduces the risks associated with incision line opening, which may especially occur in maxillary patients when the opposing arch has only anterior natural teeth (Figure 40-15).

Division D

The completely edentulous Type I, Division D patient has a flat maxilla or pencil-thin mandible with dehiscent mandibular canals, occasionally accompanied by paresthesia of the lower lip. These patients require special considerations because of unfavorable biomechanical, surgical, prosthetic, and esthetic factors. Although these patients have greater requirements to satisfy their oral condition, the severe bone loss creates an unfavorable crown height (four times normal), lack of soft tissue support, poor bone quality from decreased blood supply, complexity of surgical procedure, poor tongue position, unfavorable ridge relationship, increased moment

forces, and unfavorable stress distribution patterns for predictable endosteal implant support (Figures 40-16 and 40-17).

Autogenous grafts represent the treatment of choice before nearly any implant restoration in the Division D maxilla or mandible. The risks associated with the aggressive placement of implants of any type in the severely atrophic mandible have been previously reported.[94,95] Regardless of past training in any surgical or prosthetic discipline, the clinician must remember that these patients require many unique surgical and prosthodontic treatment modifications. The patient's condition may worsen rather than improve if treatment plans are not specific and well coordinated. Implant survival of 90% in Division D conditions is more dangerous for these patients, because the 10% failure may result in atrophic mandibular fractures, oroantral fistulae, and more extensive complications, requiring many surgeries to restore them to their original poor Division D condition. Therefore augmentation is indicated for most patients before implant placement (Figure 40-18).

Exposure of the mandible should include the crest of the atrophic ridge between the mental foramen, the

mandibular symphysis, mental foramina, and superior genial tubercles. A subperiosteal tunnel is created along the lingual aspect of the mandible, along the mylohyoid ridge and extending to the retromolar pad region. Even in severely atrophic mandibles with mandibular nerve dehiscence, bone covers the mandibular canal under the retromolar pad. As a result, a periosteal elevator within the retromolar lingual tunnel may be used to elevate the pad and then proceed forward, separating the overlying tissues off the mandibular neurovascular complex. The tunnel may then be expanded, exposing the external oblique (which is greatly reduced in height), lateral body, and ascending ramus lateral to the retromolar pad. Care is taken not to reflect muscle attachments of the mylohyoid, genioglossus, masseter, temporalis, and digastric muscles, because these provide the primary blood supply to the mandible and soft tissues that will revascularize the bone graft.

Division D mandibles often result in square-shaped arches, and anterior implants are more likely to be placed in a straight line. Mandibular nerve repositioning may be indicated when patients desire a fixed prosthesis,

WWW.HIGHDENT.IR

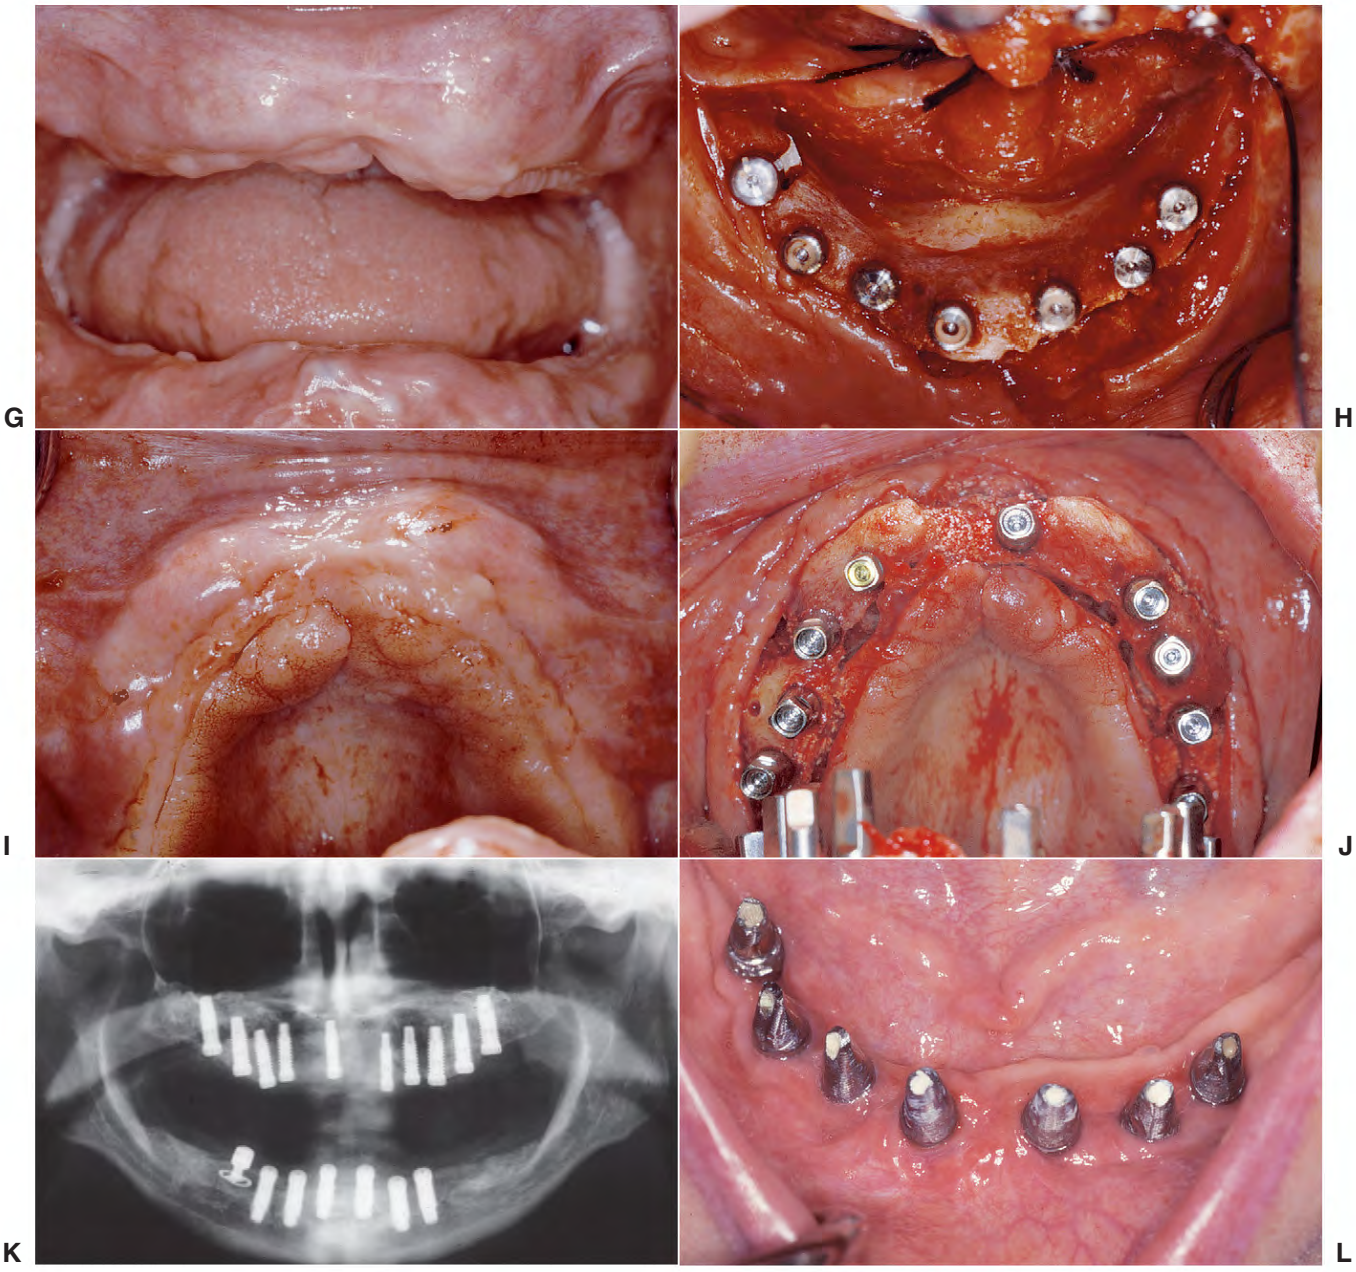

Figure 40-14, cont'd **G,** A 6-month postoperative intraoral view of the maxillary and mandibular arch after iliac crest grafts. **H,** Seven implants are inserted into the mandibular arch, 6 months after the iliac crest graft. **I,** Occlusal view of the maxillary arch 6 months after iliac crest graft. **J,** Ten maxillary implants are inserted into the maxillary arch, 6 months after the iliac crest graft. **K,** A postoperative radiograph of 10 implants in the maxillary arch and seven implants in the mandible arch. **L,** After 6 months, abutments are inserted into the mandibular implants. *Continued*

because additional implants and shorter cantilevered restorations result. Nerve repositioning is much less difficult in the Division D bone when the canal is dehiscent. In addition, many of these patients already have paresthesia of the mandibular nerve complex. Ease of surgery and previous history of paresthesia result in complications less often affecting the overall treatment. This improves the A-P distance for implant placement, because it places the most distal implant in the second premolar or first molar region. This dramatically decreases the length of the cantilever and modifies the arch form to an overall more favorable condition for long-term survival of the prosthesis.

As in the C–h patient, the crest of the ilium is sectioned so that the crest and bicortical inner and outer table are harvested. In this manner, the cortical bone may be shaped to augment the anterior segment of the atrophic arch width and height and extend at least to the first to second premolar region. A surgical template is selected that corresponds to the arch form. Once the block is contoured using hand rongeurs, the interior cortical bone of the block is thinned, decorticated with

round drills, and compressed to fit the atrophic ridge. The trabecular portion of the block is compressed to increase the density of cells per area. The graft is placed and contoured with awareness of the final form for the proposed restoration.

Four to six fixation screws are placed through the block of bone and fixated into the atrophic recipient bone. A screw may be placed in the mandibular midline, which maintains width and density from the genial tubercles and muscle attachments. Additional screws may also be placed in the anterior region as required.

The host bone in the mandible is often D1 density, and care is taken to direct the fixation osteotomy to the center of the atrophic ridge. When possible, the inferior border is not completely penetrated to maintain cortical integrity for additional strength during the initial healing process. The grafted bone block is contoured for smooth borders, and any remaining bone harvested is ground in a bone mill or with hand rongeurs to a dimension of $3 \times 5 \times 5$ mm, compressed in a 5- to 10-mL syringe to increase the cells per volume, and placed into the distal periosteal tunnel. If additional volume is required, then 10 to 50 mL of bone marrow aspirant from the ilium and resorbable calcium phosphate ($CaPO_4$) may be added to the cortical and trabecular particulate mixture.

After 5 to 10 months, five to seven implants may be placed between the foramina in the mandible. Those endosteal implants may support a final fixed prosthesis, and no soft tissue support is required over the distal aspects of the autogenous graft. When adequate bone height is present above the mandibular canal, implants may also be inserted (Figure 40-19).

Maxillary Division D bone graft approaches have evolved over the years. Sinus grafts are usually performed before the iliac crest graft procedure (Figure 40-20). A full-thickness primary incision is carried from the anterior aspect of the arch to the distal aspect of the canines (similar to the C–h patient). Care is taken to avoid incision through the nasal mucosa, which may increase the risk of infection. A mucoperiosteal reflection exposes the posterior maxilla zygomatic processes, infra-orbital foramina, lateral and inferior piriform rims, nasal spine, incisive foramen, and anterior one third of the hard palate. A small rotary drill is used to perforate the crest of the maxilla (or slightly score it when the atrophic ridge is less than 5 mm in height) to enhance revascular-

In the Division D premaxilla, subnasal elevation to gain approximately 2 to 4 mm in height may be indicated in the lateral piriform rim for canine implants or the inferior piriform rim for lateral or central incisor implants. Once this procedure is accomplished bilaterally, a template is selected to contour the premaxillary block graft. The harvested full-thickness block graft, which corresponds in size to the template, is shaped for proper contour with hand rongeurs. As for the C–h maxilla, a CT model can assist in contouring the corticotrabecular block to the recipient bone anatomy.

The block usually needs to be fixated 5 to 8 mm anterior to the residual ridge to improve the facial contour of the maxillary hard and soft tissues. The inferior

cortical surface of the block is thinned, perforated, and compressed to increase the cellular component per area. A template of the denture is used to identify the canine to first premolar region in the block graft. A fixation screw is inserted in this region. Additional screws are added as needed to ensure absolute stability of the graft.

After block fixation, a rotary drill is used to smooth the contours of the corticotrabecular block graft, which is then covered with particulate bone and PRP. These materials are also used to fill the voids above the block positioned anteriorly. The soft tissues are approximated with interrupted horizontal mattress nylon or e-PTFE sutures without tension. After 5 to 10 months, a total of 7 to 10 implants may be placed in the anterior and posterior regions for an RP-4 or fixed (FP-3) prosthesis (Figures 40-21 and 40-22).

Iliac Crest Postoperative Analgesia

The postoperative pain and gait disturbances from harvesting bone from the iliac crest are significant surgical considerations. The use of an epidural catheter for infusion of local anesthetic into the iliac donor site has shown a dramatic decrease in postoperative pain and much earlier ambulation.[96] Bupivacaine is administered through a catheter every 6 to 12 hours as needed for pain relief. The catheter is usually removed on the second or third postoperative day.

Complications: Iliac Crest

A variety of complications have been associated with harvest of full-thickness iliac crest bone graft, including pain, herniation of abdominal contents, fracture, neuralgia, hematoma, seroma, infection, and cosmetic deformity.[79-83,97-103] Cosmesis is more often troublesome to the thin patient, who often exhibits proud contour of the pelvis.

Donor site pain is likely the most common complication after the iliac bone graft harvesting. A variety

of authors[98-100] have indicated donor site pain to occur in 15% to 29% of patients. Use of the avascular plane may limit such donor site pain.

Hematomas are more common for anterior structural harvests than for posterior harvests and can occur in as many as 10% of cases.[101] The presently described harvesting technique allows for closure without suction drainage, with no increased risk of hematoma because the methyl methacrylate reconstruction provides local tamponade, in the author's experience.

Herniation of abdominal contents can occur after full-thickness iliac crest bone harvest.[102] This is an extremely rare complication, however. During the subperiosteal exposure of the inner table, the abdominal and iliacus fascial and muscular attachments are detached. This weakens the ability of these structures to retain abdominal contents. The reconstruction technique described closes the defect left after harvest. Meticulous technique should be used in closing the fascia.

An improper incision at the harvesting site may cause neurologic problems, with injury to the LFCN. This complication can be avoided by making the incision medial or lateral to the crest and ensuring proper exposure of all structures. The lateral incision is preferred.

Tibial Bone Grafts

The proximal tibial metaphysis provides an excellent source of trabecular bone for grafting.[103,104] This donor site offers a small cortical segment approximately 5 to 10 mm in diameter, 2 mm thick, and 10 to 40 mL of trabecular bone with low reported morbidity.[104-107] However, this area is contraindicated in children and adolescents because possible disruption of the epiphyseal growth center may occur.[104] In addition, the fat content of the marrow is sometimes greater than that found in the ilium.[108,109]

The tibial bone graft harvest is primarily trabecular bone and is therefore primarily used with a barrier membrane and GBR procedure. The layered approach

to GBR is addressed in Chapter 37. When ramus and/or symphysis donor sites do not provide sufficient volume, the tibia graft is an excellent source of trabecular bone.

The preparation of the recipient bed is similar to other grafting procedures, with proper aseptic preparation and skin disinfection with a chlorhexidine scrub. The surgeon gains access to the tibial plateau by a 2- to 3-cm oblique incision through the skin on the anterolateral aspect of the leg directly over Gerdy's tubercle, which is lateral to the tuberosity. Catone et al.[104] describe the incision as angled, with its cephalic limit superior and medial to the tibialis anterior muscle origin (below the articular surface of the tibial plateau) and extending lateral to the patellar ligament. Bleeding is controlled by electrocautery or preoperative placement of a tourniquet. After incising through the subcutaneous and fascial layers of the iliotibial tract, the periosteum is reflected to expose the cortex of the tibial metaphysis. The outer cortical bone and core of cancellous bone may be removed with a large 8- to 10-mm trephine bur

under copious sterile saline. On removal of the block, additional cancellous bone can be harvested with orthopedic curettes. An alternative approach is the use of a hollow, cylindrical, hand-driven Wagner instrument to procure rods of cancellous bone.[107] In most cases the cortical window is used in the oral reconstruction and is not replaced in the donor site. No drain is usually needed, and no fill of the donor site is necessary. Sometimes a hemostatic such as collagen may be inserted to assist in hemostasis.

The tibial wound is approximated in layers, with a resorbable suture and closed using a continuous subcuticular suture or staples. Antibiotic ointment is applied, and a pressure dressing is maintained for 48 hours. Patients may begin ambulation on the donor leg after the procedure but are advised to avoid full load bearing for several days. Possible complications reported are hematoma, postoperative pain, infections, and dehiscence, with incidence ranging from 1% to 4%[105] (Figures 40-23 and 40-24).

Division E

Discontinuity defects of the jaw (Division E) often require use of autogenous bone grafts to restore a patient to normal contour and function. Mandibular reconstruction with various types of materials has been attempted since the early 1800s, including allogenic, alloplastic, and autogenous materials.[110]

The cause of the discontinuity may be from trauma, disease, surgery, or genetics. Pathologic causes for discontinuity may include many conditions, of which carcinomas are the most common. The most common site for intraoral carcinomas is the lateral aspect of the tongue (20%); this affects mainly male patients. Carcinomas of the floor of the mouth account for 10% to 15% of all intraoral malignancies. Alcohol and tobacco

abuse are the main causative factors. The prognosis depends greatly on the size of the tumor, location, extent, and differentiation. Treatment is accomplished by surgical removal of the lesion, radiation therapy, and/or combined chemotherapy. The surgical excision of the lesion often requires extensive resection of the floor of the mouth, variable portions of the mandible, and regional lymph nodes. Preoperative radiation therapy increases postoperative complications, with infection being the most common. Nerve damage with eventual shoulder drop, hemorrhage, and necrosis of the flaps are also possible complications. The patient is left with severe physiologic, cosmetic, and psychological deficits. The remaining mandibular segment is retruded, then deviated medially and upward. The deviation is often increased during opening by as much as 1 or 2 cm. The loss of mandibular continuity impairs mastication, deglutition, phonation, and respiration. The patient presents a concave facial asymmetry because of the loss of tissues and the adherence of the skin to the deep tissues of the neck. The deviation and partial loss of innervation around the commissures result in drooling of saliva.[37] Optimum treatment of mandibulectomy patients is achieved with coordinated surgical, prosthodontic, and speech therapies. The decision to reconstruct the mandible immediately or in a second phase depends on the amount and character of the remaining tissues (more than 5000 cGy of irradiation reduces the healing capacity of hard and soft tissue), the prognosis of the treatment, the age and general health of the patient, and whether any residual tumor remains.[111-115]

The risk of osteoradionecrosis (ORN) is higher in the presence of a soft tissue bed of poor quality (i.e., hypoxic, hypovascular, hypocellular).[113-115] Surgical reconstruction of the mandible with large defects may also require replacement of soft and hard tissue. Additional soft tissue to cover the defect may use myocutaneous flaps combined with hyperbaric oxygen and may be indicated in patients to induce angiogenesis and fibroblastic activity.[115]

Vascular Bone Grafts

Facial deformities caused by ablative surgical techniques have long been a challenge for the reconstructive surgeon and prosthodontist. Advances in microvascular surgical techniques using composite vascularized grafts have dramatically increased the predictability of jaw discontinuity reconstruction. Vascularized bone grafts are more often indicated when blood supply is severely compromised to the graft site or when the recipient bed is scarred. The most common conditions are the patient with cancer who has undergone radiation therapy or the Division E bone anatomy. Vascularized iliac crest grafts have been used with increasing frequency for mandibular reconstruction, because this area provides a large quantity of corticocancellous bone with favorable contours.[116-120] An ilium microvascular graft consists of

a portion of the iliacus and gluteus medius muscles, the anterior and medial aspect of the iliac crest, and the deep circumflex iliac artery and variable veins. More recently, the fibula has emerged as the free-tissue transfer of choice in many reconstructive centers for restoring composite mandibular defects. Its proponents report a greater total thickness of cortical bone and high implant survival rates.[121,122] The application of osseointegrated implants in these grafts has significantly improved the outcome of prosthetic rehabilitation.[112,120,122-128]

In contrast to nonvascularized free bone grafts, bone successfully transferred by microvascular surgery remains viable without cortical or trabecular bone necrosis.[129,130] Therefore the advantage of the vascularized bone graft

is that it maintains normal physiologic function. The improved potential for incorporation of a vascularized bone graft indicates its use in compromised regions, such as postirradiation sites. The success of implants placed in healed vascularized grafts for mandibular reconstruction appears similar to their success in non-grafted bone sites.[131-136] The simultaneous placement of implants with microvascular bone flap reconstruction has shown an approximately 80% success rate using Ti implants with a short follow-up. Often difficulty exists in attaining primary implant stability because the quality of iliac free vascular grafts is often very

spongeous with a thin cortical layer.[136] It is more advantageous to allow the graft to mature before implant placement, because for these patients, it is more difficult to determine the prosthetic support needs at the time of bone grafting.

Although free microvascular grafts from the fibula and ilium are popular among many reconstructive surgeons, Marx and Morales[137] pointed out that these grafts have several limitations from a dental perspective. The fibula is straight and limited in height, which

Continued

compromises arch form. Marx has shown impressive results in the treatment of discontinuity defects, with the use of cancellous marrow grafts from the ilium supported with growth factor additions.[138]

The scapula is also a source of bone in microvascular grafts for jaw reconstruction. Teot et al.[139] and Swartz et al.[140] reported on the potential of the lateral scapular border with blood supply by branches of the circumflex scapular artery.[124,141] The scapula allows the design of multiple cutaneous panels on separate vascular pedicles to facilitate three-dimensional (3D) reconstruction. Complications are those common to the microvascular grafts and restricted elevation for the arm if scarring occurs. Once the vascularized grafts are healed, the soft tissue and bone may be receptive for endosteal implants after the usual protocol based on prosthesis type, amount of available bone, and density of bone.

Distraction Osteogenesis

Distraction osteogenesis refers to the formation of new bone between vascular bone surfaces created by an osteotomy and separated by gradual distraction.[142] Ilizarov[143] developed the technique for the management of musculoskeletal conditions, such as posttraumatic defects and deformed limbs that demonstrated induction of bone formation between osseous segments as they were pulled apart. Distraction osteogenesis has also been applied to the craniofacial skeleton. It has been used in the repair of continuity defects, mandibular lengthening, and maxillary advancement. Recently research has focused on the use of distraction osteogenesis for alveolar ridge augmentation and implant placement.[144-150]

The concurrent soft tissue neogenesis and stretching of mucosa that accompany the osseous distraction are unique characteristics that may allow augmentation in more challenging clinical situations.[151] For instance, soft tissue integrity is often a limiting factor in bone grafting for implant placement, especially in areas such as the posterior mandible.

Complications: Receptor Site

The general causes of failure for autogenous grafts or of the donor site are variable and well documented. The primary cause of failure of bone grafts in conjunction with endosteal implants include improper diagnosis, treatment planning, and/or sequencing; poor soft tissue management; too many implants placed at surgery in grafted bone only; improper implant position at surgery; and esthetic requirements ignored during augmentation. Improper diagnoses include sinus pathologic condition before sinus grafting, periapical pathologic condition, or advanced periodontal disease, which may compromise the graft as a result of infection, as well as systemic or local disease, which compromises hard and soft tissue healing.

Improper treatment planning includes an attempt to restore a patient to an FP-1 prosthesis when the intraoral condition is Division D. These patients may receive a fixed restoration after the autogenous graft, if adequate amounts of bone, soft tissue coverage at surgery, and bone modeling occur, but a natural-appearing prosthesis cannot be promised. Patients requesting this specific result are prone to unrealistic expectations. Poor treatment plans also include too few and too short implants to support the final prosthesis. For example, a maxillary fixed prosthesis almost always opposes a fixed restoration or natural teeth. The moment forces are greater, the esthetic demands are greater, the bone density is poorer, and the SA augmentations are more critical to success. To obtain more than 95% implant and prosthetic survival in the grafted maxilla, eight to 10 implants may be required, with limited posterior cantilever of the prosthesis.

Poor treatment sequencing may include attempting to place all the implants at the time of the autogenous graft. Division C–h and most Division D mandibles are best treated and have fewer complications with only screws for fixation of the block graft. Division C–w atrophic conditions usually have fixation of a block of bone with a lateral screw or a particulate graft and barrier membrane with a tunnel approach and no implant placement. Only implants that can be positioned without compromise to the position, angulation, contour, hygiene considerations, and direction of load for ideal conditions should be placed at the graft surgery. The more implants placed at the time of the graft, the greater the risk for incorrect placement of implants, mandibular fracture, and splitting of the graft block. The loss of one implant may spread to two or three, and the risk of prosthetic compromise dramatically increases. In addition, the progressive bone-loading concepts used during prosthetic reconstruction are very important in patients with autogenous augmentation.

The primary postoperative complication is wound dehiscence that is directly related to implant failure, thus the decision by the authors to delay implant placement. The treatment is similar to procedures in the intraoral donor graft chapter (see Chapter 39).

Careful closure without tension is paramount to avoid incision line opening. It usually necessitates periosteal release to ensure that the soft tissue passively drapes over the graft. In addition, the fabrication of a transitional prosthesis without pressure is a mandatory step in the prevention of wound dehiscence. The patient should be thoroughly educated to wear the transitional prosthesis as little as necessary. A maxillary denture with no lingual flange and/or the lingual acrylic cut out completely (leaving only a row of teeth) over the grafted area and with contact only on the hard palate and tuberosities may be worn only when necessary. A modified night guard appliance adjusted to lower anterior teeth and with bite blocks in the tuberosities may also be used when lower anterior teeth are present.

Other postoperative complications similar to other implant procedures include postoperative infection, loss of a portion of the graft, dehiscence, pain, and sinusitis. Poor soft tissue management has the most devastating effect during the immediate postoperative phase of the autogenous graft and is reported most often. Improper flap design may result in compromised blood supply to the underlying graft. Trauma from the opposing teeth, or excessive tension on the incision line, results in the incision line opening and graft exposure with loss of significant height and/or width of bone. Soft tissue management also includes stage II uncovery of the implants. Adequate width of attached gingiva of minimum thickness is the soft tissue interface of choice around the implants. Autogenous tissue grafts and gingivoplasty techniques are commonly required for graft patients.

A Division D mandible is often less than 7 mm in width. An implant placed through the block graft and into the underlying host bone may not go through the center of this atrophic ridge. Instead, the osteotomy may be off center and have removed all the lateral cortical plate and one half the inferior plate at the implant site. When the implant is threaded into position, or shortly thereafter, the mandible may fracture.[73,74] This compromises the rigidity of the implant graft and the mandibular bony healing. This complication may be reduced by using 2-mm fixation screws, rather than implants, to stabilize the graft.

The primary reason to place screws in conjunction with the graft is to ensure the stability of the grafted bone. Wires may stretch and allow graft movement during healing. In addition, they may erode the graft on the surface regions where they are tied with pressure. Most wires are stainless steel, and fibrous tissue often forms at the interface. As a result, a fibrous tissue trail may form through the bone and result in soft tissue next to the implant placed in the site. Fixation screws rigidly position and maintain the block. In addition,

WWW.HIGHDENT.IR

they may be inserted at any angle or location, which allows more flexibility at the time of surgery to secure the bone block.

When implants are placed to stabilize the graft, they should be thoroughly evaluated when the additional implants are placed 6 months later. If an implant-bone defect exists, then the area may be repaired with autogenous bone. Another option is to remove the implant and reinsert another one deeper into position, or the implant can be removed and another one placed in a different site.

The patient requiring autogenous grafts is usually compromised from the lack of soft tissue support. The maxilla resorbs toward the medial aspect in the posterior and anterior regions. The mandible resorbs toward the lateral in the Division C–h and D conditions. As a consequence, the autogenous grafts should be placed in position for the required esthetic result, not the current position of the atrophic bone. This requires maxillary grafts to be cantilevered to the facial plane, or the surgeon performs a Le Fort osteotomy in conjunction with the interpositional graft placement. Mandibular grafts should be placed with a lingual inclination but with implants at a more vertical trajectory.

SUMMARY

The use of autogenous grafts for or in conjunction with implants has been reported for more than 20 years. During this period, predictable techniques and refinements have occurred. The grafting procedures may be indicated for the moderately resorbed jaw with demanding prosthetic requirements. The autogenous grafts are usually indicated for severe resorption, to improve anatomical conditions for long-term survival of implants and the related prosthesis. The Misch-Judy bone classification may be used as a diagnostic guide for surgical approach and prosthetic concerns.[33a] An additional Division E is provided for discontinuity defects of the jaws. This chapter addresses these indications, survival rates, and failures of autogenous grafts in conjunction with endosteal implants.

Chapter 41

An Implant Is Not a Tooth: A Comparison of Periodontal Indices

Carl E. Misch

The primary function of a dental implant is to act as an abutment for a prosthetic device, similar to a natural tooth root and crown. The restoring dentist designs and fabricates a prosthesis similar to one supported by a tooth and, as such, also evaluates and treats the dental implant similarly to a natural tooth. Yet fundamental differences in the support system have to be recognized. The purpose of this chapter is to compare the periodontal indices for a natural tooth and an osteointegrated implant.

LITERATURE REVIEW

Several dental health criteria have been adapted for implants.[1-12] The clinical criterion most commonly reported is the survival rate, or whether the implant is still physically in the mouth or has been removed.[2] Proponents of this method say it provides the clearest presentation of the data; critics argue implants that should be removed because of pain, disease, or the inability to be restored still may be maintained yet wrongfully reported as successful. Reports of natural teeth used to support a prosthesis follow a similar criterion: whether the restoration is still in the mouth. Therefore survival rates rather than success rates are the most common method to report the "success" of the prosthesis, whether the prosthesis is supported by implants or natural teeth. A majority of reports that include clinical criteria include mobility, radiographic assessment, and gingival and plaque indices. Subjective criteria of discomfort and patient satisfaction also are mentioned.

The American Dental Association Council on dental materials, instruments, and equipment states that consideration for an endosteal implant should be given to the evaluation of (1) durability; (2) bone loss; (3) gingival health; (4) pocket depth; (5) effect on adjacent teeth; (6) function; (7) esthetics; (8) presence of infection, discomfort, paresthesia, or anesthesia; (9) intrusion on the mandibular canal; and (10) the patient's emotional and psychological attitude and satisfaction.[3,4] Smith and Zarb[5] suggested that patient comfort, sulcus depth, gingival status, damage to adjacent teeth, and violation of the maxillary sinus, mandibular canal, or floor of the nasal cavity are not attributable to the material or design of an implant. As a result, they suggest these should be considered separately and should not be computed in the percentage of implant successes. One may reasonably state that factors controlled primarily by the dentist and the psychological attitude of the patient are not conditions influenced by the implant. However, the sulcus depth and gingival status next to the implant indeed may be related to implant design or surface condition. For example, a smooth, polished collar contributes to crestal bone loss, which affects sulcus depth. The implant surface condition may allow bacteria to form readily on the surface after crestal bone loss and may affect the gingival status of the implant.

This chapter compares the following criteria for implants and natural teeth: (1) longevity, (2) pain, (3) mobility versus rigid fixation, (4) percussion, (5) crestal bone loss, (6) radiographic evaluation, (7) keratinized tissue, (8) probing depths, (9) bleeding index, (10) peri-implant disease, and (11) implant failure.

Periodontal indices are often used for evaluation of dental implants. However, implants are fundamentally different than natural teeth in that they do not decay, have no dental pulps to function as early indicators of disease, and have no periodontal membrane. A comparison of natural teeth and implants for each criterion provides insight into their differences in the health-disease continuum. Once one understands the basis for evaluation, these criteria may then be used to establish a health-disease implant quality scale related to patient treatment.

LONGEVITY

Success criteria for endosteal implants have been proposed previously by several authors, including Schnitman and Shulman,[6] Cranin et al.,[7] McKinney et al.,[8] Albrektsson et al.,[9,11] and Albrektsson and Zarb.[10] As Box 41-1 shows, the report by Albrektsson et al.[9] was specific for implants with rigid fixation and is used widely today. However, the amount of crestal bone lost during the first year may affect the sulcus depth and environment for the longevity of the implant. Yet this criterion is not mentioned in Albrektsson and Zarb's classification of health. In addition, survival rates suggested in this guideline are low compared with present-day reports and do not consider the prosthesis survival rather than implant longevity.

The consideration of a minimum implant survival rate should be in the context of the final prosthesis' survival. For example, many early reports indicated that a fixed prosthesis in a completely edentulous arch may be supported by four implants. More recently, the suggestion has been made to fabricate a fixed prosthesis with immediate loading on as few as three or four implants. In a study of 25 patients with 25 prostheses supported by only four implants, there would be 100 implants. A 75% implant success rate would result in 0% prosthesis success, if each patient lost only one implant. An 85% implant 5-year survival rate still would affect almost half the implant restorations. Of course, this survival rate is not acceptable. Implant survival by itself is not an acceptable criterion to evaluate an implant system, and studies must include the restoration. Albrektsson et al.[9] have stated that the required implant success rate is a minimum of 85% for 5 years and 80% for 10 years. These success rates are similar to prosthesis success on natural teeth.[13] However, the initial proposed criteria do not evaluate the prosthesis and may be unacceptable to the patients undergoing restoration. Implant survival and the associated prosthesis survival rates need to be evaluated together, because the restoration is the most important aspect to the patient.

Dental implant success rates reported in the literature typically do not address prosthesis failure. Instead, as long as the prosthesis may be refabricated, the reported implant success is not affected. More relevant information is gained when longevity criteria include information on the prosthesis. The clinical criteria established by Misch for optimum to satisfactory health for implants also evaluates prosthesis survival, not only implant survival, and suggests a minimum of 90% prosthesis survival for 10 years[1] (Box 41-2).

Of course, these rates require even greater implant survival, and overengineering the support system often is required to obtain this goal. If eight rather than four implants support a fixed prosthesis, possibly one or two implants may be lost and the same prosthesis still may be used without additional implants and only slight modification of the restoration.

As a result, for 25 patients each restored with eight implants to support a full-arch restoration, and if each patient lost one implant, the survival of the prosthesis still may be 100% and the implant survival 87%.

For the patient and doctors involved in treatment, to lose 10% of the implants before fabrication of the prosthesis is far better than to have 5% implant failure after delivery of the restoration.[14] The average implant restoration in a partially edentulous patient has three implants as support. A 5% difference in implant survival may affect 15% of the prostheses. In addition, computed data of dental implant survival/success should include all implants inserted, not just the implants restored or those successfully loaded after 1 year.

Box 41-1 Criteria for Implant Success

- An individual unattached implant is immobile when tested clinically.
- The radiograph does not demonstrate any evidence of periimplant radiolucency.
- Vertical bone loss is less than 0.2 mm annually after the first year of service of the implant.
- Individual implant performance is characterized by an absence of persistent or irreversible signs and symptoms such as pain, infections, neuropathies, paresthesia, or violation of the mandibular canal.
- In the context of the foregoing, success rates of 85% at the end of a 5-year observation period and 80% at the end of a 10-year period are minimum criteria for success.

From Albrektsson T, Zarb GA, Worthington P et al: The long-term efficacy of currently used dental implants: a review and proposed criteria of success, *Int J Oral Maxillofac Implants* 1:1, 1986.

PAIN

Subjective findings of pain, tenderness, and sensitivity are common dental conditions that the dentist treats as part of a general practice. Pain and tenderness are

Box 41-2 Suggested Criteria for Implant Success

- Implant quality scale* of 1, 2, or 3 with a survival rate better than 90% at 10 years
- Prosthesis survival rate better than 90% at 10 years
- Implants that are supporting a prosthesis

WWW.HIGHDENT.IR

subjective criteria and depend on the patient's interpretation of the degree of discomfort. *Pain* is defined as an unpleasant sensation ranging from mild discomfort to excruciating agony. Tenderness is more an unpleasant awareness of the region. A natural tooth often becomes hyperemic and sensitive to cold as the first indicator of a problem. A tooth with a more serious condition becomes sensitive to heat and painful to percussion, indicating pulpitis. Dental emergencies usually are associated with pain, and the dentist is adept at its diagnosis and treatment planning. An implant rarely is troubled by the subjective criteria of pain or sensitivity. The implant does not become hyperemic and is not temperature sensitive, and the early warning signs and symptoms of a problem may not be present. In addition, pain rarely is associated with the implant after healing. This criterion is less contributory to implant health determination.

Once the implant has achieved primary healing, absence of pain under vertical or horizontal forces is a primary subjective criterion. Percussion and forces up to 500 g (1.2 psi) are used clinically to evaluate tooth or implant pain or discomfort. Usually (but not always), pain does not occur unless the implant is mobile and surrounded by inflamed tissue or has rigid fixation but impinges on a nerve. The most common condition that causes discomfort is when a loose implant abutment is entrapping some of the soft tissue in the abutment-implant connection. Once the soft tissue in the region is eliminated and the abutment is secured, the discomfort subsides. When the abutment-implant connection is secure and pain is present, consideration is given to an implant body fracture.

On rare occasions an implant may cause discomfort during function, although a clinical examination is unable to identify a cause. The persistent presence of pain during percussion or function on properly inserted implants and components often requires removal of the implant, even in the absence of mobility. Because pain is a subjective criterion, the dentist asks the patient to relate the pain from the implant site on a scale of 1 to 10, with 1 being a slight aggravation and 10 being the most intense pain the patient can perceive. When the patient reports a pain level greater than 5, the dentist should strongly consider removal of the implant. Pain from rigidly fixated implants is rare and is observed as an early problem, whereas pain from a mobile implant may occur early or late in treatment. In either case, the condition rarely improves. Pain on loading has been observed more often on immediately loaded implants compared with those healing unloaded for an extended period.

Implant sensitivity or mild tenderness rather than pain in a rigid implant is most unusual and signals a more significant complication for an implant than for a tooth. Tenderness during function or percussion usually implies healing in the proximity of a nerve or, on rare occasions, bone stress beyond physiologic limits.

If the implant tenderness immediately after surgery occurs in the proximity of the mandibular canal, the implant may be unthreaded 1 mm and reevaluated for a decrease in symptoms after 3 or more weeks. If the tenderness is after stage I healing and is not due to surgical encroachment on an anatomical landmark, stress may be the causative element. Attention is first brought to the soft tissue and prosthetic components. Treatment then consists of the elimination of as much stress on the implant or prosthesis as is possible for 3 or more weeks. The dentist especially should address occlusion and parafunctional habits in the presence of implant sensitivity. Most often the prosthesis should be modified, or additional implants may be placed to dissipate the forces. The tenderness may be decreased with these procedures but rarely is eliminated. Instead, the dentist notifies the patient of the poor prognosis and asks whether the tenderness is significant enough to warrant the removal of the implant. It should be emphasized this condition is rare and has been observed only a few times by the author in more than 30 years.

MOBILITY

Tooth Movement

The tooth exhibits normal physiologic movements in vertical, horizontal, and rotational directions. The amount of movement of a natural tooth is related to its surface area and root design. Therefore the number and length of the roots; their diameter, shape, and position; and the health of the periodontal ligament primarily influence a tooth's mobility. A healthy tooth exhibits zero clinical mobility in a vertical direction. Actual initial vertical tooth movement is about 28 µm and is the same for anterior and posterior teeth.[15] The vertical movement of a rigid implant has been measured as 2 to 3 µm under a 10-lb force and is due mostly to the viscoelastic properties of the underlying bone.[16]

Horizontal tooth mobility is greater than vertical movement. A very light force (500 g) moves the tooth horizontally 56 to 108 µm. The initial horizontal mobility of a healthy, "nonmobile" posterior tooth is less than that of an anterior tooth and ranges from 56 to 75 µm, which is two to nine times the vertical movement of the tooth. Initial horizontal mobility is even greater in anterior teeth and ranges from 90 to 108 µm in health.[15,17]

Muhlemann found that tooth movement may be divided into initial mobility and secondary movement.[18] The initial mobility is observed with a light force, occurs immediately, and is a consequence of the periodontal ligament. If an additional force is applied to the tooth, a secondary movement is observed, which is related directly to the amount of force. The secondary tooth movement is related to the viscoelasticity of the bone and measures as much as 40 µm under considerably greater force.

WWW.HIGHDENT.IR

Implant Movement

Rigid fixation is a clinical term that means the absence of observed clinical mobility. *Osseointegration* is a histologic term defined as bone in direct contact with an implant surface at the magnification of a light microscope.[19] Over the years, these two terms have been used interchangeably, and implant abutment support is most predictable with rigid fixation. Rigid fixation indicates the absence of clinical mobility of an implant tested with vertical or horizontal forces less than 500 g, similar to evaluating teeth. Lack of clinically observable movement does not mean the true absence of any movement. A "nonmobile" posterior natural tooth actually moves horizontally 56 to 73 µm. The human eye does not perceive this movement.

The anterior teeth, which often have slight clinically observable movement, actually move approximately 0.1 mm. A healthy implant moves less than 73 µm; thus it appears as zero clinical mobility.[16] Lack of implant mobility (IM) does not always coincide with a direct bone-implant interface.[8] However, when observed clinically, rigid fixation usually means that at least a portion of the implant is in direct contact with bone, although the percentage of bone contact cannot be specified.[20] A mobile implant indicates the presence of connective tissue between the implant and bone.

The implant-bone interface also exhibits lateral movement. Sekine et al.[16] evaluated the movement of endosteal implants with rigid fixation and found a range of 12 to 66 µm of movement in the labiolingual direction. Komiyama[21] reported 40 to 115 µm of implant movement in the mesiodistal direction under a force of 2000 g (about 4.5 psi) and a labiolingual range of 11 to 66 µm.

Rangert et al.[22] suggested that part of this movement may be due to component flexure. However, the greater implant movement in the mesiodistal dimension corresponds to the lack of cortical bone between the implants in this direction compared with the thicker lateral cortical plates present in the labiolingual dimension. The mobility of implants varies in direct proportion to the load applied and the bone density and reflects the elastic deformation of bone tissue. These mobility characteristics corroborate the findings of Fenton et al.,[23] who applied a 500-g load for 4 seconds to maxillary anterior teeth and osseointegrated implants. The implants were displaced a mean of 10 µm with a rapid elastic return (less than 1 millisecond), whereas the teeth showed a mean displacement of 57 µm with a prolonged viscoelastic return.

Increased tooth mobility may be caused by occlusal trauma or bone loss. However, increased tooth mobility alone is not a criterion of periodontal health or pathology. Unlike a tooth, for which mobility is not a primary factor for longevity, mobility is a primary determining factor for implant health.[24,25] Rigid fixation is also an excellent indicator of the health status because it is an easy, objective test. As such, rigid fixation is usually the first clinical criterion evaluated for a dental implant. The techniques to assess rigid fixation are similar to those used for natural tooth mobility. Two rigid instruments apply a labiolingual force of approximately 500 g.[26] The amplitude of tooth mobility may be rated from 0 to 4, where 0 is normal mobility from physiologic movement, 1 is detectable increased mobility, 2 is visible mobility up to 0.5 mm, 3 is severe mobility up to 1 mm, and 4 is extreme mobility including vertical movement. This same gradient may be used for oral implants with slight modification. As Box 41-3 depicts, IM-0 corresponds to the absence of clinical mobility, IM-1 demonstrates detectable increased movement, IM-2 is visible mobility movement up to 0.5 mm, IM-3 is severe horizontal mobility greater than 0.5 mm, and IM-4 is visible horizontal and vertical movement. The implant mobility scale was used frequently for plate form implants because a clinical goal was for slight mobility when joining the device to natural teeth. However, the goal for root form implants always should be rigid fixation and IM-0 status.

A natural tooth with primary occlusal trauma exhibits an increase in clinical mobility and radiographic periodontal ligament space. Once the cause of trauma is eliminated, the tooth may return to zero clinical mobility and a normal radiographic appearance. This scenario is not predictable around an implant. Implants with slight detectable mobility of approximately 0.1 mm of horizontal movement (IM-1), similar to the mobility of a healthy central incisor, on occasion may return to rigid fixation and zero mobility. However, to reachieve rigid fixation, the implant should be taken completely out of occlusion for several months.

Chances improve to return rigid fixation to an implant if no mobility is noted before the implant is placed into function. An implant with horizontal movement greater than 0.5 mm (IM-3) is at much greater risk than a tooth. The dentist should not restore an implant with any clinical mobility, because the risk of failure is great. However, once the prosthesis is completed and IM-1 develops, the risk is small to decrease almost all stress and evaluate implant mobility after several months. An osseointegrated implant with greater than 0.5 mm

Box 41-3 Clinical Implant Mobility Scale

Scale	Description
0	Absence of clinical mobility with 500 g in any direction
1	Slight detectable horizontal movement
2	Moderate visible horizontal mobility up to 0.5 mm
3	Severe horizontal movement greater than 0.5 mm
4	Visible moderate to severe horizontal and any visible vertical movement

WWW.HIGHDENT.IR

horizontal mobility (IM-3) or any vertical mobility (IM-4) should be removed to avoid continued bone loss and future compromise of the implant site.

On occasion, an implant that was rigid may spin in the bone at stage II uncovery, when the implant abutment is threaded into position.[27,28] The weak bone-implant interface is broken when the shear forces of adding an abutment are placed on the implant body. If this occurs, the implant cover screw should be reinserted and the implant allowed to "reintegrate" with the bone. The chances are good that 3 additional months of healing will allow the implant to reestablish a bone-implant interface. At the reinsertion of the abutment, a lesser torque is used initially, so the interface does not strip again. After an additional time of progressive loading, the abutment screw may be tightened as usual, although a countertorque method on the abutment is suggested.

The Periotest (Gulden-Medizinteknik, Bensheim an der Bergstrasse, Germany) is a computer-mechanical device, developed by Schulte, that measures the dampening effect or attenuation degree against objects by developing a force of 12 to 18 N against a pistonlike device, which then measures the distance the piston recoils into the chamber after striking an object.[29] A soft surface or mobile object gives higher recordings than a hard or rigid object. The recordings range from negative (8) to positive (50) numbers. Teeth with zero clinical mobility have typical ranges from 5 to 9. The degree or absence of clinical movement around an implant corresponds to values ranging from −8 to +9, or 17 degrees. This greatly aids the dentist's tactile senses. The bone density around the implant may be correlated with these numbers. This device has been used as a clinical tool to evaluate slight changes in implant rigid fixation or to identify prostheses that become partially unretained[30-32] (Figure 41-1). More recently, a nondestructive resonance frequency analysis technique to measure implant stability and osteointegration has been introduced and provides similar valuable information as to the clinical movement and bone density around implants.[33,34]

PERCUSSION

Percussion often is used on teeth to determine which tooth is sensitive to function or is beginning to abscess. In the past, percussion was used to evaluate the presence of rigid fixation. However, percussion is an indicator neither of clinical health nor of rigid fixation. The ringing sound that occurs on percussion only corresponds to the presence of some bone at the interface because 2 mm of bone and 16 mm of bone-implant interface sound almost identical. Percussion may be used to diagnose pain or tenderness with an implant but is misleading if used to determine the status of rigid fixation.

CRESTAL BONE LOSS

Periodontal probing is used to assess attachment levels to the tooth and is a prime indicator of health. Radiographic bone loss around a tooth does not indicate the presence of a disease state but is a reflection of past or present periodontal disease. Occlusal trauma may cause an increase in tooth mobility but does not cause marginal bone loss in the absence of periodontal disease.

The marginal bone around the implant crestal region is usually a significant indicator of implant health. Most often the surgical trauma causes little bone loss, but on occasion bone loss may reach several millimeters. The dentist may assess the presence of surgical bone loss before fabrication of the prosthesis. Crestal bone loss after prosthesis delivery is a primary indicator of the need for initial preventive therapy. Early loss of crestal bone beyond 1 mm from the microgap of the abutment after prosthesis delivery usually results from excess stress at the permucosal site or implant crest module design.[24,25,35]

The level of the crestal bone is measured from the crestal position of the implant at the stage II uncovery surgery. When the abutment is attached to the implant body, approximately 0.5 to 1 mm of connective tissue forms apical to this connection.[36] An implant originally placed 2 mm above the bone and another countersunk 2 mm below the bone have a different initial bone loss history after the abutment is attached to the implant. Whenever possible, the implant should be inserted at or above the bone crest to avoid an increase in the sulcus depth around the implant related to the crestal bone loss after abutment placement. Initial bone loss during

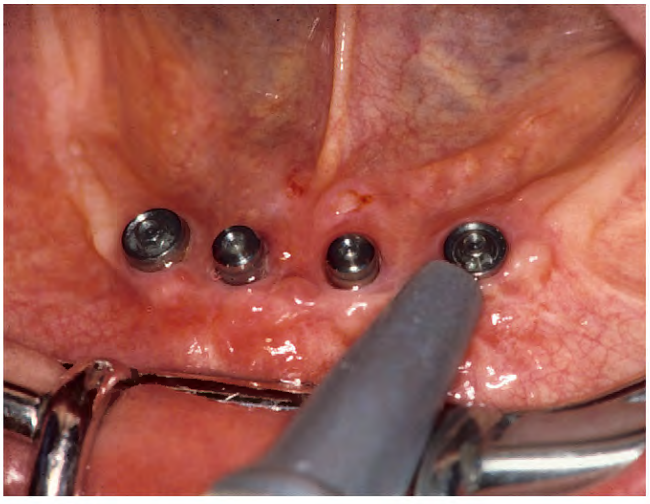

Figure 41-1 The Periotest (Gulden-Medizinteknik) may be used to evaluate implant rigid fixation or prostheses that become partially unretained. A clinical evaluation of zero mobility may correspond to a −8 to +9 Periotest value. These numbers may indicate changes in bone density around the implant or failure of a retention mechanism for the prosthesis.

WWW.HIGHDENT.IR

the surgical healing phase also may vary for submerged and unsubmerged healing protocols.[37-43]

Once the implant is connected to a permucosal element, the marginal bone may be lost during the first month from (1) the position of the abutment-implant connection or (2) the crest module design of the implant. The abutment-implant connection will cause 0.5 to 1.0 mm of bone loss when it is at or below the bone. In addition, when smooth metal is below the abutment-implant connection and extends onto the neck of the implant, additional bone loss will occur in direct relation to the smooth metal region. The bone levels will most often reside at the first thread or at a roughened surface after the first month a permucosal element or abutment extends through the soft tissue.

The initial bone loss beyond the abutment connection and smooth neck region of the implant after function is often a result of excessive stress at the crestal implant-bone interface.[24,25,35] The dentist should evaluate and reduce stress factors, such as occlusal forces, cantilever length, and especially parafunction, on observation of initial bone loss after loading. Secondary bone loss around an implant is usually a compound condition created by bacteria and increased stress (a result of parafunction or increasing crown height from crestal bone loss and anaerobic bacteria forming once the sulcus is greater than 5 to 6 mm).[44]

Several studies report marginal bone loss after the first year of function in the range of 0 to 0.2 mm.[19,43,45-48] Adell et al.[19] determined that successful implants after the first year of loading had an average 0.1 mm of bone loss for each following year. Cox and Zarb[45] observed a similar amount of mean bone loss of 0.1 to 0.13 mm per year after the first year of prosthesis function. Kline et al. reported these numbers represented an average of bone loss measurements. The majority of implants do not lose bone each year.[43] However, if one implant in 10 loses 1 mm of bone, the average bone loss is 0.1 mm. One should be careful when an implant is losing bone as shown radiographically. One should suspect occlusal overload, including parafunctional habits. Occlusal overload is especially notable when only one or two implants have lost bone and the other implants in the restoration are not affected.

Clinical observations obtained by probing or radiographic measurements of 0.1 mm per year for bone loss are more operator sensitive and not reliable. Probing changes of 0.5 mm or more are also more realistic to monitor. Therefore a yearly clinical assessment of bone loss in increments of 0.5 mm or more is suggested to monitor incremental marginal bone loss.

Slight changes in interproximal bone loss can be determined by radiographs. The threaded implant pitch (distance between the threads) is a known distance for each system (e.g., 0.6 mm for a classic Brånemark design) and can be used as a radiographic marker.

Under ideal conditions a tooth or implant should lose minimum bone. However, it is not possible to quantify how much bone loss indicates success or failure. In general, if more than half the implant height has lost crestal bony contact, the implant is at significant risk and is considered a failure, regardless of the original amount of implant-bone contact. In addition, the probing depth of the soft tissue should be considered related to the bone loss. If an implant has lost 5 mm of bone and has a probing depth of 10 mm, the situation is much worse than an implant with 6 mm of bone loss and a 3-mm probing depth.

RADIOGRAPHIC EVALUATION

The radiographic assessment of natural teeth assists in determining the presence of decay, lesions of endodontic origin, and periodontal bone loss. Radiographs may be used to evaluate the result of periodontal diseases on the supporting bone but cannot indicate the presence or absence of the disease process. Assessments of bone loss for natural teeth may include: (1) the presence or absence of intact lamina dura; (2) the width of the periodontal ligament space; (3) the bone crest morphology (even or angular); and (4) the distance from the cement-enamel junction (CEJ) and the coronal level to periodontal ligament (PDL) (normal or abnormal width). Normal radiographic bone levels next to natural teeth are typically between 1 to 3 mm from the CEJ.

Implants do not decay and do not develop endodontic-related conditions. However, the crestal bone region is often the most diagnostic for the ranges of optimum, satisfactory, and compromised health conditions. Radiographic interpretation is one of the easiest clinical tools to use to assess implant crestal bone loss but has many limitations. A radiograph only illustrates clearly the mesial and distal crestal levels of bone. However, early bone loss often occurs on the facial aspect of the implant. An absence of radiolucency around an implant does not mean bone is present at the interface, especially in the anterior mandible. As much as 40% decrease in density is necessary to produce a traditional radiographic difference in this region because of the dense cortical bone.[49] When the bone is wide, the V-shaped crestal defect may be surrounded by cortical bone and, as a result, the radiograph is less diagnostic.

Parallel periapical radiographs are more difficult to obtain for implants than for teeth. The implant is often apical to the apex of the preexisting natural tooth. As a result, the apex of the implant often is located beyond muscle attachments or in regions almost impossible to capture with a parallel radiographic method. A foreshortened image to accommodate the apical portion of the implant defeats the purpose of radiographic interpretation of the crestal bone. Crestal bone loss is evaluated

WWW.HIGHDENT.IR

best with vertical bitewing films or periapical radiographs that do not include the apical portion of the implant.

The clear depiction of the threads on the radiograph indicates use of a proper angulation. If the threads are clear on one side but fuzzy on the other, the angulation was incorrect by approximately 10%[50] (Figure 41-2). Ideally, the abutment-implant connection should appear as a clear line between the two components. When the top of the implant is placed at the crest of the regional bone, the amount of crestal bone loss is most easy to evaluate. If both sides of a threaded implant are unclear, the radiograph is not diagnostic for crestal bone loss assessment.

A peri-implant radiolucency indicates the presence of surrounding soft tissue and is a sign of implant failure. The cause may be from infection (bacterial), iatrogenic (heat-induced bone loss), nonrigid fixation (iatrogenic or patient-induced), or local bone-healing disorders.

On rare occasions an apical radiolucency has been observed on a nonmobile implant. This is most likely a perforation of one of the lateral cortical plates of bone but also may be from contamination of the drill, overheating, or infection.[51,52]

If the apical radiolucent region expands or is accompanied by a fistula, reentry surgery and correction are warranted. If the implant is mobile, it must be removed. If the implant has rigid fixation and the crestal half is in good order, the apical cause of the radiolucency must be removed and aggressively curetted, which may include sectioning and removal of the apical portion of the implant.

The implant quality of health evaluation protocol depends on clinical observations. A baseline radiograph is obtained at the initial delivery of the prosthesis. By this time the biological width and influence of the implant crest module design have already contributed to its influence on crestal bone loss. Because crestal bone changes often occur during the first year of loading, preventive maintenance appointments are scheduled every 3 to 4 months and a periapical/vertical bitewing radiograph at 6 to 8 months is compared with the baseline. Another vertical bitewing radiograph is taken at 1 year and compared with the previous two images. If no changes are apparent, subsequent radiographic examinations may be scheduled for every 3 years, unless other clinical signs warrant more frequent examinations.

If crestal changes are evident by probing or radiographs, stress reduction and hygiene are modified accordingly. Radiographs are taken and reviewed every 6 to 8 months until the bone is stable for two consecutive periods. If bone loss greater than 2 mm is observed from the bone levels noted at the prosthesis delivery, the dentist should strongly suspect parafunction. Night guards and stress reduction on the affected implants are indicated.

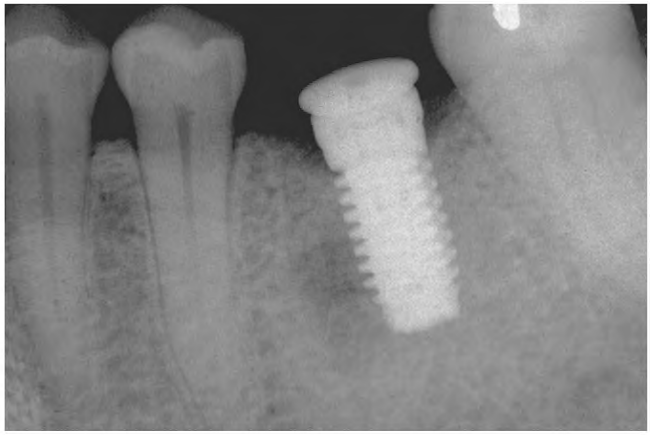

Figure 41-2 On this periapical radiograph the threads are clear on one side only. The central ray was not directed completely perpendicular to the implant body, but was within 10 degrees. This film is not ideal but is clinically acceptable in most situations.

KERATINIZED TISSUE CONCERNS

The absence or presence of a zone of keratinized gingiva around teeth and oral implants remains a controversial issue.[53-71] No direct evidence confirms or denies the need for nonmobile keratinized tissue next to natural teeth. Lang and Loe[53] advocate a minimum 2 mm of keratinized gingiva and 1 mm of attached gingiva to maintain gingival health. In longitudinal studies, however, Wennstrom[54] and Kennedy et al.[55] demonstrated that the lack of adequate keratinized and attached tissue does not compromise the long-term health of soft and hard tissue as long as patients maintain good oral hygiene. Moreover, Stetler and Bissada[57] addressed mucogingival considerations in restorative dentistry in 1987. They concluded that if subgingival restorations were to be placed in areas of minimally keratinized gingiva and less than optimal plaque control, augmentation to widen the zone of keratinized tissue may be warranted. They also noted that in unrestored teeth, the difference in the inflammatory status of sites with or without a wide zone of keratinized tissue was not significant. Valderhaug and Birkeland demonstrated that subgingival placement of a restoration was associated with a significantly higher rate of gingival inflammation, attachment loss, and gingival recession over 10 years.[58] The tooth with the least amount of keratinized tissue is often the mandibular first premolar. Yet this tooth is rarely the first tooth lost from periodontal disease. If all other periodontal indices are normal, the amount or absence of keratinized gingiva has little to do with the expected longevity of the tooth.

The need for keratinized tissue around dental implants seems more controversial than that around teeth.[59-71] In theory, structural differences in implants compared with teeth make them more susceptible to the development of inflammation and bone loss when exposed to plaque accumulation or microbial invasion

WWW.HIGHDENT.IR

(e.g., less vascular supply, less fibroblasts, lack of connection tissue attachment to cementation).[36] Several reports demonstrate the long-term implant survival in the absence of keratinized tissue[19,60,61] (Figure 41-3). Although reports are more cautious with mobile mucosa next to an implant, nonmobile tissue appears to be the primary criterion relative to tissue type.

Although keratinized tissue around a tooth may not be mandatory for long-term health, a number of benefits are present with keratinized mucosa. The color, contour, and texture of the soft tissue drape should be similar around implants and teeth. The interdental papillae should ideally fill the interproximal spaces. A high smile line often exposes the free gingival margin and interdental papillae zones. The keratinized tissue is more resistant to abrasion. Hygiene aids are more comfortable to use. The degree of gingival recession appears related to the absence of keratinized gingiva. Root sensitivity and esthetic concerns may be associated with gingival recession. From a restorative dental aspect, keratinized mucosa is more manageable during the retraction and impression-making process. Subgingival margin placement is more precise, as is long-term stability, in the presence of keratinized tissue.

The presence of keratinized tissue next to an oral implant presents greater benefits than with natural teeth (Figure 41-4). Some reports indicate the lack of keratinized tissue may contribute to implant failure. Kirsch and Ackermann[68] reported that the most important criterion for implant health in the posterior mandible was related to the absence or presence of keratinized gingiva. Mobile, nonkeratinized mucosa exhibits greater probing depths, which has been confirmed histologically. A study by Warrer et al.[67] in monkeys found that an absence of keratinized mucosa increases the susceptibility of periimplant regions to plaque-induced destruction (Figure 41-5).

Keratinized gingiva has more hemidesmosomes; thus the junctional epithelial attachment zone may be of benefit when in keratinized tissue. The orientation of collagen fibers in the connective tissue zone of an implant often appears perpendicular to the implant surface, whereas these fibers in mobile, nonkeratinized tissue run parallel to the surface of the implant. Schroeder et al.,[59] James and Schultz,[69] McKinney et al.,[8] and Listgarten et al.[70] have suggested that mobile mucosa may disrupt the implant-epithelial attachment zone and contribute to an increased risk of inflammation from plaque.

In addition to the general advantages, keratinized tissue around implants may be beneficial in several

Figure 41-3 Attached keratinized tissue in the mandible is often less in the first premolar region. Likewise, a first premolar implant site often has little keratinized tissue. Yet no current study indicates that the first premolar tooth or implant is the least predictable location for health or survival. This suggests that although ideal for long-term maintenance and health, the presence of keratinized tissue may not be mandatory.

Figure 41-4 The ideal soft tissue situation around teeth or implants is keratinized, nonmobile tissue.

Figure 41-5 Mobile, nonkeratinized tissue around a threaded or rough implant often is associated with plaque retention and increased risk of complications.

WWW.HIGHDENT.IR

other ways. In a two-stage protocol, the implant is less likely to become exposed during the healing process. The formation of an interdental/implant papillae is completely unpredictable with mobile unkeratinized tissues. However, no clinical or histologic benefits are reported with unkeratinized nonmobile mucosa. When the unkeratinized tissue is mobile, several reports state that this is unsatisfactory. Ono et al.[72] have proposed a classification of attached gingiva and surgical alternatives to improve soft tissue types in edentulous sites for implant placement. Meffert et al.[73] prefer to obtain keratinized tissue before implant placement, especially in the posterior regions. Interestingly, the studies that have advocated the need for keratinized mucosa around dental implants have investigated implants with rough surfaces.[67,68,74,75] On the other hand, the studies that have questioned the need of keratinized mucosa around dental implants have also examined implants with smooth surfaces.[61,64,76]

Failure of rough surface implants (e.g., hydroxyapatite [HA]-coated and plasma-sprayed implants) have been related to a lack of keratinized mucosa.[74,77] A study by Chung et al. evaluated the significance of keratinized mucosa in the maintenance of dental implants with different surface conditions.[78] All 69 patients and 339 implants in the study had implant restorations for at least 3 years and as long as 24 years with an average of 8.1 years. Bleeding index, modified plaque index, gingival index, probing depth, width of attached keratinized mucosa, and amount of attached mucosa were recorded. In addition, average annual bone loss was calculated using past and present radiographs. Gingival inflammation and plaque accumulation was significantly higher in patients with less than 2 mm of keratinized mucosa or 1 mm of attached mucosa. The surface condition of the implant was not statistically significant in this study, although the smooth implants with less than 2 mm of keratinized mucosa were less stable than other groups relative to the soft tissue profile.

This study found the average annual bone loss was not influenced by the amount of keratinized or attached mucosa or the type of implant surface configuration (smooth versus rough). The greatest amount of bone loss was observed with rough implants in keratinized mucosa of less than 1 mm, but the difference was not statically relevant. This compares to a metaanalysis by Esposito et al. who reported 20% less peri-implantitis in smooth-surface implants as compared with rough-surface implants.[79] The presence of keratinized mucosa was most significantly advantageous in the soft tissue health of posterior implants, as indicated by the gingival index. Posterior implants, even in the presence of keratinized tissue, had a 3.5-fold higher annual bone loss than anterior implants (0.14 versus 0.04 mm).[78] Therefore implant location appears more important than the presence of keratinized mucosa.

The question relative to the need for keratinized tissue around implants should be modified to "Which would you prefer?" No one has stated that the unkeratinized tissue is better than keratinized tissue for any reason; therefore the controversy has abated. Some authors prefer keratinized mucosa more intensely than others. If one side of controversy demonstrates benefits while the other side states that keratinized tissue is not mandatory, both sides may be correct.

In specific clinical instances, attached, keratinized gingiva is more often desirable. For example, a fixed prosthesis type 1 (FP-1) restoration in the esthetic zone requires keratinized mucosa to develop the soft tissue drape around the implant crowns. A second prime example is a mandibular overdenture, which benefits from a vestibule and zone of nonmobile tissue around the implant abutments.

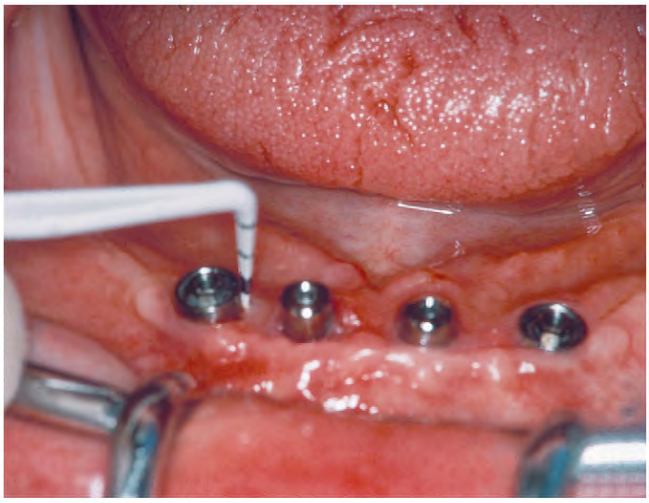

Figure 41-6 Peri-implant probing may be used to evaluate soft tissue depth, bleeding index, the presence of exudate, tissue mobility thickness, and the amount of crestal bone loss.

PROBING DEPTHS

Probing depths around teeth are an excellent proven means to assess the past and present health of natural teeth. The increasing sulcus depth around natural teeth is related to disease and bone loss. Likewise, probing depth indices often are used to evaluate dental implants (Figure 41-6). However, relating implant sulcus depth to health is controversial.

When probing next to an implant or a tooth, the probe not only measures the sulcus depth, but also penetrates the junctional epithelial attachment. A primary reason is found in the different makeup of the biological width[36,38-42,80,81] (Tables 41-1, 41-2). Therefore the probe next to a natural tooth measures the sulcus depth and the depth of the junctional epithelial attachment. The connective tissue attachment zone in a natural tooth has 13 different fiber groups of which six physically

Table 41-1 Comparison of Tooth and Implant Support Structures

STRUCTURE	TOOTH	IMPLANT
Connection	Cementum, bone, periodontium	Osseointegration, bone functional ankylosis ligament
Junctional epithelium	Hemidesmosomes and basal lamina (lamina lucida and lucida, lamina densa zones)	Hemidesmosomes and basal lamina (lamina, lamina densa, and sublamina lucida zones)
Connective tissue	Thirteen groups: perpendicular to tooth surfaces ↓ collagen, ↑ fibroblasts	Only two groups: parallel and circular fibers No attachment to the implant surface and bone ↑ collagen, ↓ fibroblasts
Biological width	2.04 to 2.91 mm	3.08 mm
Vascularity	Greater; supraperiosteal and periodontal ligament	Less, periostal
Probing depth	3 mm in health	2.5 to 5.0 mm (depending on soft tissue depth)
Bleeding on probing	More reliable	Less reliable

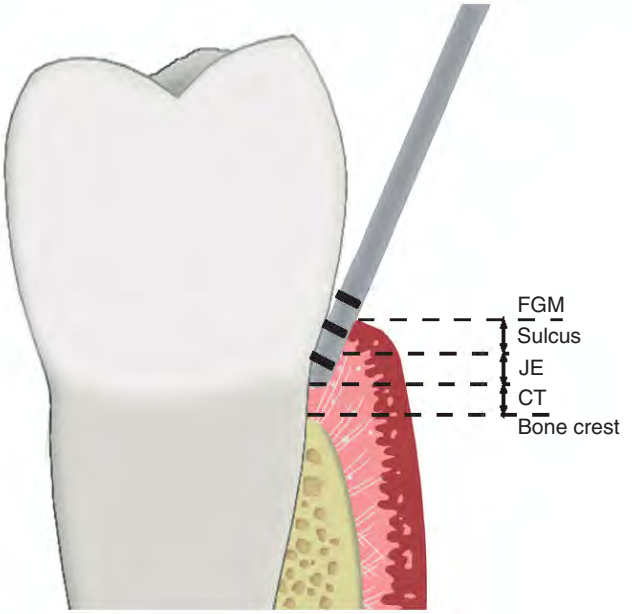

Figure 41-7 The biological width of a natural tooth has a connective tissue zone that inserts into the cementum of the tooth. A periodontal probe will penetrate the sulcus and the junctional epithelial attachment. *FGM,* Free gingival margin; *JE,* junctional epithelium; *CT,* connective tissue.

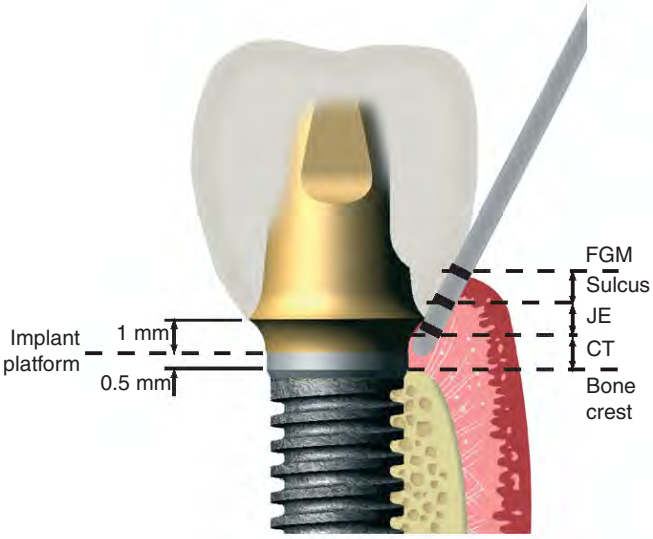

Figure 41-8 An implant has no connective fibers in the connective tissue zone that insert into the implant. The peri-implant probe penetrates the sulcus, junctional epithelial attachment, and most of the connective tissue zone. *FGM,* Free gingival margin; *JE,* junctional epithelium; *CT,* connective tissue.

insert into the cementation of a tooth. This zone stops the further probe penetration and acts as a barrier for the ingress of bacteria. The connective tissue attachment zone with ideal health is approximately 1 mm in height above the alveolar bone crest. An implant has a sulcus, a junctional epithelial attachment, and a zone of connective tissue (Figure 41-7). However, the structures are not similar to a tooth. The junctional epithelial attachment zone has a hemidesmosome attachment with a lucida and a lamina densa layer, as well as a sublaminal zone and glycoaminoglucine layer. Thus the zone has less attachment strength to the implant and probe, and bacteria can go through this region easier than with a tooth. In addition, the connective tissue zone has only two fiber groups and neither of those insert into the implant. As a result, with an implant, the probe goes beyond the sulcus, through the junctional epithelial attachment, through the type III collagen connective tissues, and reaches closer to the bone.[82] The tissue above the bone before implant insertion may also be 4 mm thick or more. As a result of greater tissue thickness before surgery and a 1-mm greater probing depth, the probing depth next to a healthy implant is typically greater than that of a healthy natural tooth (Figure 41-8).

Because the probe penetrates deeper next to an implant compared with a tooth, one should take care not to contaminate the implant sulcus with bacteria from a

diseased periodontal site. The location of the probe tip subgingivally for a tooth depends on the pressure used, the presence of inflammation, and the angle at which the probe is introduced in the sulcus depth between the junctional epithelium and the root surface. In addition, reports in the literature suggest that the reproducibility of attachment level measurements may be questionable independently from the instrument used to perform the measurements.[83,84] These variables are similar for a dental implant. In addition, fixed prostheses with subgingival margins of crowns with wider emergence profiles often make probe positioning difficult around the 4 mm diameter of most implant bodies.

The benefit of probing the implant sulcus has been challenged in the literature because sound scientific criteria are lacking. The potential for damage to the fragile attachment or marring of the implant surface exists during probing. The correct pressure recommended for probing is 20 g, yet conventional probing often exerts a force more than five times this level and varies greatly. Pressure-sensitive probes have been made available to address these issues but are rarely used in a clinical practice.[85-87] Lekholm et al.[65] found that the presence of deep pockets was not accompanied by accelerated marginal bone loss. Stable, rigid, fixed implants were reported with pocket depths ranging from 2 to 6 mm. Healthy, partially edentulous implant patients consistently exhibit greater probing depths around implants than around teeth.

The implant sulcus depth may be a reflection of the original soft tissue thickness of the area before implant placement. The posterior maxillary tissue can be thicker than 4 mm after tooth extraction and subsequent bone volume loss before implant placement. Gingivoplasty to reduce the flap thickness and pocket depth can be performed at the initial surgery. The advantage of the reduction in tissue thickness at this time is the tissue heals and matures as the bone-implant interface develops. However, thinning the flap at the initial surgery may cause greater loading of the implant body during healing from an overlying soft tissue-borne temporary prosthesis. After initial bone healing, the stage II uncovery surgery also may correct tissue thickness; however, when an overlying soft tissue prosthesis is worn during healing it may prematurely load the developing implant interface and cause bone loss or failure.

An increasing probing depth is a more significant sign than a probing depth unrelated to a time interval because it usually signifies bone loss, except in cases of gingival hyperplasia or hypertrophy. Probing using fixed reference points on the abutment or crown margin allows evaluation of crestal bone loss versus tissue hypertrophy (Figures 41-9 and 41-10).

Despite the limitations, charting the attachment level in implant permucosal areas does aid the dentist in monitoring these regions. As the sulcus depth increases, the oxygen tension decreases. The bacteria in an implant sulcus are similar to those of a natural tooth.[88,89] A toothbrush and daily hygiene procedures cannot clean a sulcus greater than 2 mm.[90] Sulcus depths greater than 5 to 6 mm have a greater incidence of anaerobic bacteria[60,87] and often require gingivectomy or bone revision surgery. Therefore as a general rule, to enable the patient to perform effective daily hygiene, the ideal implant sulcus should be maintained at less than 5 mm.

The monitoring of early crestal bone loss is most important during the first critical year of stress accommodation of the bone. Minor bone changes are clinically easier to observe with a periodontal probe than with radiographs. Early bone loss may occur on the facial aspect of the implant; radiographs only demonstrate clearly the mesial and distal regions.

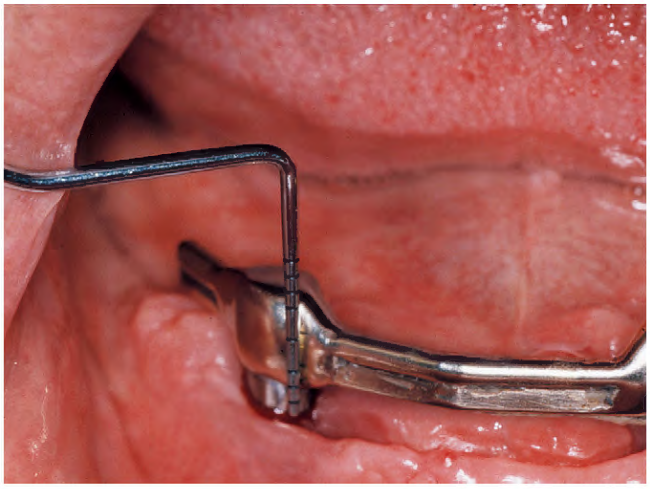

Figure 41-9 Because the soft tissue may shrink or hypertrophy, a long-term record of bone changes can be monitored from the restoration margin. This implant has a bleeding index of 2.

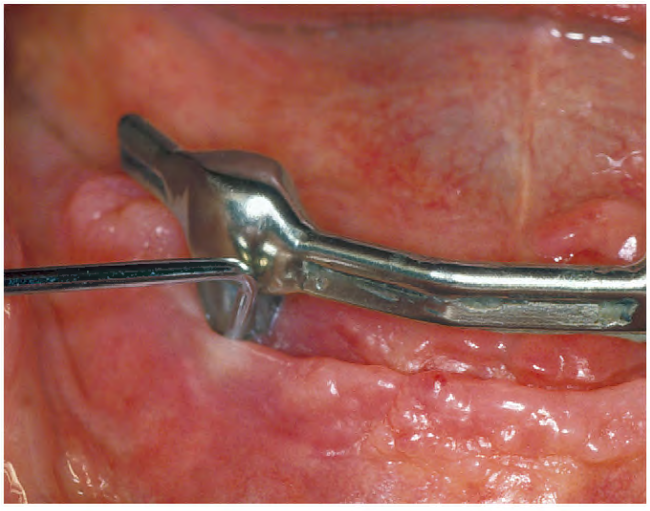

Figure 41-10 On the facial aspect of the implant, the probing depth is greater than 12 mm. A radiograph cannot assess the bone levels on the facial or lingual aspects of an implant.

WWW.HIGHDENT.IR

Changes in crestal bone levels warrant close monitoring and early intervention. Patient education to reduce parafunctional stress on the implant system, the use of parafunctional appliances, and other stress-reducing methods are required when early crestal bone loss beyond the first thread is detected. Despite the uncertain meaning of pocket depth increase, probing is an appropriate method to assess potential deleterious changes in the peri-implant environment and should be performed every 3 to 4 months for 1 year after prosthesis delivery. After this time, if crestal bone levels are stable, probing is still relevant. Probing also reveals tissue consistency, bleeding, and exudate. Therefore probing is important not only to measure increasing sulcus depths but also to allow the dentist to evaluate several peri-implant parameters at the same time and at the same sites.

Controversy exists as to the material from which the probe should be fabricated. In theory, different metal types (e.g., stainless steel, titanium) should not come into contact because of a risk of contamination of the two metals and the resulting galvanic corrosion that may develop and cause crestal bone loss. As a result of this fear, the suggestion has been made that only titanium surgical instruments be used to contact the implant and that only titanium or plastic instruments be used to probe or scale the implant.

Touching the surface of the abutment subgingivally with a stainless steel instrument is not of clinical concern. However, scratching the surface may contribute to plaque migration following the direction of the scratch. Plaque follows the direction of scratches on a titanium plate, even though right angles and a maze pattern may be scratched onto the surface. Therefore, when probing almost to the bone level around the implant, one should take care not to scratch the surface because plaque that forms at the surface may follow the scratch subgingival to the bone level. This is particularly important during scaling procedures or during the removal of cement below a crown margin. One should use semicircular strokes, parallel to the sulcus or crown margin, to scale the implant above the bone. If a scratch occurs, plaque will not have a direct "highway" below the tissue.

BLEEDING INDEX

Gingival bleeding when probing correlates with inflammation and the plaque index. A bleeding index is an indicator of sulcus health. Easily ulcerated sulcular epithelium representing inflammation from plaque is the primary cause of bleeding when probing. Bleeding also can be provoked by undue pressure on the probe.

Controversy surrounds the issue of using bleeding and gingival health as an implant health indicator.[70] Unlike a natural tooth, implant success in the first few years is related more often to biomechanical equilibrium than to gingival health. Compared with a natural tooth, the soft tissue inflammation from bacteria may be more restricted to above the crestal bone because of the lack of a periodontal membrane or fibrous tissue between the implant and the bone interface. As a result, the bleeding index may not be as important a factor when evaluating the early implant quality of health. Adell et al.[64] found no evidence that gingivitis was a precursor of progressive bone loss. Lekholm et al.[65] also found that gingivitis and deep sulcular pockets were not accompanied by accelerated bone loss.

Both of these reports apply to a machined-surface titanium screw design (e.g., Nobel Biocare). In contrast Kirsch and Mentag[77] found a correlation between the gingival sulcus depth and implant failure. The implant design studied in this report had an intramobile element with a larger implant body abutment crevice and a titanium plasma spray body (e.g., IMZ).

A similar correlation between implant failure and gingival health status was observed when a porous titanium alloy microball surface was exposed above the bone (e.g., Endopore).[92] Jepsen et al. identified the elevated levels of proteolytic enzymes in the implant sulcus with inflammation and bleeding on probing as predictors of implant disease.[93] The correlation between gingival health and implant success appears in part to be related to the cervical surface condition of the implant.

Lekholm et al.[64] and Quirynem et al.[91] found that plaque and gingivitis around implants were correlated. Steflik et al.[20] found that the gingival bleeding index correlated highly with the plaque index and the crevicular fluid index. The dentist already is encouraged to probe the sulcular region to evaluate bone loss. Periodontal probing is less demanding than the determination of a gingival sulcular fluid volume index. One may observe the bleeding index while probing for sulcus depth and therefore may record it easily to help establish gingival health.

Regardless of whether gingival health is relative to success, all dentists agree that the ideal soft tissue condition around an implant is an absence of inflammation. Radiographic bone loss and increased pocket depth have been correlated with sulcular bleeding.[20] Therefore the gingival status around an implant should be recorded and used to monitor the patient's daily oral hygiene. However, surrounding soft tissues around implants have fewer blood vessels than teeth; therefore inflammation is typically less around implants than around teeth.[36,94,95]

The most common bleeding gingival index used for implants is the Loe and Silness gingival index.[26] When used on teeth, this index scores gingival inflammation from 0 to 3 on the facial, lingual, and mesial surfaces of all teeth. The symptom of bleeding comprises a score of at least 2.[96]

WWW.HIGHDENT.IR

The gingival index scores also may be used to record the gingival inflammation on the facial, lingual, and mesial surfaces of all implants. A simplified gingival index has been suggested for use with teeth in a clinical practice setting because the differences in scoring levels of gingival indexes are too gross.[26] Because the bleeding index evaluates this inflammation, the Loe and Silness index is adequate for implants, and because fewer implants typically are used to restore a region compared with the presence of natural teeth, one also may evaluate the distal surface because the implants are more than 2 mm apart and access often is unobstructed. When the sulcus depth is less than 5 mm and the bleeding index increases, use of chlorhexidine often is indicated, along with other professional and home care methods. Sulcus depths in excess of 5 to 6 mm have a greater incidence of bleeding and usually require gingivectomy or revision surgery.

During the first year of clinical examinations for the peri-implant tissues, the dentist should record color, form, and consistency along with bleeding on probing and should probe depths for all sites. After 1 year of stable probing depths, the examination may be restricted to facial and lingual checks at maintenance appointments and may be correlated with radiographic observation for the mesial and distal surfaces. Removal of the prosthesis for evaluation is not indicated unless warrented by changing conditions. Repeated removal of a screw-retained fixed prosthesis causes wear of the screw attachment system and causes more frequent partially unretained restorations over the long term.

PERI-IMPLANT DISEASE

Gingivitis is a bacteria-induced inflammation involving the region of the marginal gingiva above the crest of bone and next to a natural tooth. It is always associated with plaque and may be classified as (1) acute necrotizing, (2) ulcerative, (3) hormonal, (4) drug induced, or (5) spontaneously occurring.[27] These categories also can relate to the gingival tissues around an implant because the mode of attachment of the gingiva to a tooth and implant has been reported to be similar.[69]

The bacteria in gingivitis around a tooth may affect the epithelial attachment but without loss of connective tissue attachment. Because the connective tissue attachment of a tooth extends an average of 1.07 mm above the crestal bone, at least 1 mm of protective barrier above the bone is left. In contrast, no connective tissue attachment zone exists around an implant because no connective fibers extend into the implant. Therefore no connective tissue barrier exists to protect the crestal bone around an implant.[69,97]

Periodontitis around teeth is characterized by apical proliferation and ulceration of the junctional epithelium, progressive loss of the connective tissue attachment, and loss of alveolar bone. Bacteria also cause periodontitis. The disease has been classified as adult, rapidly progressive, localized juvenile, and prepubertal periodontitis.

After prosthesis delivery, early crestal bone loss around an implant usually is not caused by bacteria. Most often the bone loss results from stress factors too great for the immature, incompletely mineralized bone-implant interface or an extension of the biological width into a smooth metal crest module.[24] Therefore an implant may exhibit early crestal bone loss with a different mechanism or cause compared with natural teeth. However, on occasion, bacteria may be the primary factor. Anaerobic bacteria have been observed growing in the microgap between the implant and the abutment or in the sulcus of implants, especially when sulcus depths are greater than 5 mm (Table 41-3; Box 41-4).

The term *peri-implantitis* describes the bone loss around an implant. The loss may be induced by stress, bacteria, or a combination of both. Stress-induced bone loss occurs without bacteria as the primary causative agent. However, once the bone loss from stress or bacteria deepens the sulcular crevice and decreases the oxygen tension, anaerobic bacteria may become the primary promoters of the continued bone loss.

An exudate or abscess indicates exacerbation of the peri-implant disease and possible accelerated bone loss (Figures 41-11 and 41-12). Short-term antibiotic treatment and aggressive topical application of chlorhexi-

Figure 41-11 Peri-implant probing measures pocket depths and may indicate the presence of exudate. Symptoms of exudate should be addressed with aggressive therapy.

Figure 41-12 Surgical reentry into the implant site from Figure 41-13 demonstrates advanced bone loss around the facial aspect of the implant.

dine or local antibiotics, with thorough, extensive professional and patient care of the soft tissue, are indicated. An exudate persisting for more than 1 to 2 weeks usually warrants surgical revision of the peri-implant area to eliminate causative elements.

Once the exudate is eliminated, the bacterial smear layer remaining on the implant surface must be eliminated before bone can grow in close contact with the implant. The reduced bone height, after the exudate episode, makes the implant more prone to secondary occlusal trauma. Therefore the dentist must reevaluate stress factors for the new bony condition and often must reduce them to improve long-term performance.

SUMMARY

An unhealthy implant most often is treated similarly to a natural tooth presenting the same conditions. Implementation of aggressive implant maintenance treatment is warranted with any detectable horizontal mobility, exudate, a pocket depth of 5 mm and increasing, a bleeding index of 2 or above, and slight tenderness to percussion and function. An implant may need less treatment than a natural tooth when sulcus depths are compared. However, based on mobility, an implant needs more treatment than a tooth.

The ultimate decision of implant success lies with the practicing dentist rendering continued dental therapy for the patient. A single-tooth implant with 0.5 mm of mobility is less at risk than a 12-unit fixed prosthesis implant abutment with 0.2 mm of mobility. A gray scale of decision making exists, and absolute rules make for easy decisions, but rules are not necessarily the correct ones for all patients.

Chapter 42

Maintenance of Dental Implants: Implant Quality of Health Scale

Jon B. Suzuki, Carl E. Misch, Diana Bronstein, Lynn D. Terracciano-Mortilla

Implant dentistry has evolved into a well-understood clinical science with expansive documented research to validate what, years ago, many believed to be experimental. There has been an incredible amount of focus on the biology and biomechanics of implant dentistry, and results have helped to develop and refine techniques based on proven data rather than unsubstantiated trial-and-error procedures. The evolution of research and understanding of biological concepts in implant dentistry has caused many areas of conflict and controversy. Theories and techniques have developed and changed, and the types of materials used in implant dentistry have changed dramatically.

The tremendous growth in this field created new ideas and terminology that are either undefined or being redefined based on new knowledge.[1] What one study proves in certain cases, another may completely disprove. It can become confusing for a clinician to know the correct protocols, procedures, tools, and techniques to use. As materials and techniques are researched and developed, previous theories may undergo criticism and controversy. It does not necessarily negate the findings of the past; however, we must modify techniques and tools to keep current with the changes in technology and research. One area of expansion of knowledge and conflict of views relates to the maintenance of dental implants. Early research explored techniques and instruments that were current for the methods and materials of that time. Although many of those implants still exist and are functional in patients, research and advances in technology have given us newer materials and advances in implant design and structure that do not necessarily possess the same challenges from a maintenance perspective.

A thorough review of mucoepithelial attachment is essential before commencing any maintenance procedures. Controversies and parameters for probing and radiograph exposure essential to clinicians are also discussed here. Thorough reviews of the tooth versus implant differences, as well as identification of the bacterial similarities and differences, also are discussed. The literature review explores the success or failure of implants and discusses in length the parameters that need to be adhered to when evaluating implants and the peri-implant tissue.

Once the clinician understands the parameters of implants and teeth, a specific plan can be created for the patient and the clinician can advise what is expected during each phase of treatment and demonstrate various oral hygiene options to suit the patient's needs during each stage of therapy. Patients must be thoroughly educated and retrained before deciding to commence implant therapy.[2] The ability of the patient to understand financial, time, and maintenance obligations is crucial and must be made clear to the patient initially and during subsequent appointments. In addition to educating patients, clinicians will need to assess compliance with a home care routine[3] and must possess the clinical competencies to perform maintenance procedures. As the number of dental implants placed in patients continues to increase, there is a need to understand the importance of maintenance as it relates to long-term implant success.[4] The role of the dental hygienist in implant maintenance and care is increasing and becoming more defined[5] (Box 42-1).

Implants and their prosthetic devices are different from natural teeth and may require different procedures and instruments for both professional and patient care.[6] Instruments must be effective at removing biofilms and accretions, and procedures performed by patients and/or clinicians should avoid damage to all portions of the implant, abutment, restoration, and tissues.[7] Establishment and maintenance of a soft tissue seal around the transmucosal portion of the implant can enhance the success of an implant. This barrier is fundamentally a result of wound healing. The maintenance of healthy peri-implant tissues may contribute to implant success factors. Tissues and an implant sulcus

Box 42-1 Role of the Dental Hygienist in Implant Maintenance

- Identification of potential implant patients
- Education and motivation throughout treatment
- Development, continual assessment, and modification of patient-specific oral hygiene procedures
- Evaluation of prosthesis (components, attachments, mobility, and retention)
- Evaluation of peri-implant tissue
- Probing
- Exposure of clinically acceptable radiographs
- Removal of biofilms, soft and hard accretions
- Recommendation of oral hygiene implements
- Determination of a patient specific recall interval
- Cotherapist to identify potential problems or complications
- Documentation of implant status

Box 42-2 Plaque Biofilm Development and Colonization

Identify potential implant patients

Bacterial adhesion
↓↓
Supragingival plaque
Gram+, streptococci, Actinomyces
↓↓↓
Plaque maturation (gram-, rods, and filaments)
↓↓↓↓
Well-differentiated subgingival plaque
(Gram-, anaerobes)

free of inflammation and infection, as well as an absence of virulent bacteria, can enhance a patient's general and oral health.

PLAQUE BIOFILM AND DENTAL IMPLANTS

The differences between tooth and implant biologies make dental implants more susceptible to inflammation and bone loss in the presence of bacterial plaque accumulation.[8] Biofilms are the primary causative factor of periodontal disease processes. Sticky masses of bacteria with a polysaccharide matrix, water, and bacteria accumulate on hard and soft surfaces in the oral cavity and can be disturbed and removed with mechanical or chemical obliteration. If undisturbed, mature plaque will form. Current chemotherapeutics cannot penetrate thick biofilm, and rough surfaces have been found to hold more biofilm[9] than smooth surfaces. Bacteria will migrate from teeth to implants and from implant to implant.[10] Similar to teeth, clinical findings of failing implants include inflammation, pockets, and progressive bone loss.[11] Another similarity lies in the bacteria responsible for periodontitis and peri-implantitis.

When evaluating the peri-implant microbiota, Lee et al.[12] compared microbial changes between patients with a history of periodontal or peri-implant infections and implants that have been in function for a length of time. This study found a history of periodontitis had a greater impact on the peri-implant microbiota than implant-loading time. The major influence on the peri-implant microbiota was, however, the microbiota on remaining teeth. *Porphyromonas gingivalis* and *Bacteroides forsythus*, red complex periodontal pathogens, colonized several implants, although all implants were successfully osteointegrated. Thus it is important to educate patients about their responsibility to decrease plaque effectively, especially if they have a history of periodontal disease.

Plaque biofilm development and maturation have similarities for natural teeth and dental implants. The gingival sulcus in periodontal health and the perimucosal attachment of a successful dental implant are essentially similar.[13] In a study by Mombelli and Mericske-Stern of the plaque from 18 edentulous patients with successful dental implants, facultative anaerobic cocci (52.8%) and facultative anaerobic rods (17.4%) were reported. However, the pathogens *P. gingivalis* and spirochetes were absent, and minimal (7.3%) gram-negative rods were present.[13]

Generally, pellicle—a naturally occurring glycoprotein in the saliva—first adheres to the intraoral structure, whether it be a tooth or an implant. Gram-positive cocci bacteria are the first "early colonizers," beginning with single cocci and progressing to streptococci forms (Box 42-2).

Without appropriate oral hygiene measures (e.g., brushing, flossing, interdental cleaning), additional bacteria colonies including gram-negative rod-shaped bacteria synergistically grow with the established gram-positive bacteria. The gram-negative bacteria are frequently facultative or strict anaerobic bacteria and are considered "late colonizers." Many, if not the majority, of these gram-negative bacteria are black pigmented and are classified under a number of genera (e.g., *Bacteroides, Prevotella, Porphyromonas, Fusobacterium*).

Plaque biofilm reported to be associated with failing dental implants also consists largely of gram-negative rods.[14] Clinically, failing dental implants are characterized by soft tissue inflammation, increased probing depths, increased mobility, and peri-implant radiolucency. Specific pathogens in implant pockets greater than 6 mm include *Actinobacillus actinomycetemcomitans*, *Prevotella intermedia*, and *P. gingivalis*, in more than one third of the sites, as confirmed by DNA analysis.[15]

More specific studies on plaque biofilm around dental implants suggest similarities[16] between periodontal

WWW.HIGHDENT.IR

diseases and failing implants, but differences have also been reported.[17,18] Mombelli[18] did not detect spirochetes in plaque samples from well-maintained and clinically healthy implants. Rams et al. noted higher proportions of staphylococci (15.1%)[19] than usually found in gingivitis (0.06%) and periodontitis (1.2%) sites.[19] This finding suggests that staphylococci may be more significant in developing peri-implantitis lesions than previously recognized.

Changes involve both the hard and soft tissues surrounding an implant. The implant may exhibit all the signs of peri-implant mucositis, as well as exudate, increase of pocket depth, and bone loss. If left untreated, significant bone loss, infection, and mobility could result, leading to the failure of an initially integrated implant.

Comparisons of plaque biofilms have been reported in a limited study of Brånemark and ITI (Straumann Institute) implants and are remarkably similar in controlled studies. Mombelli et al.[20] compared 10 patients with Brånemark implants and 10 patients with ITI implants and sampled the deepest pockets around the implants. After 3 and 6 months, several periodontal pathogens were cultured and isolated, including *P. gingivalis*, *P. intermedia*, *Fusobacterium nucleatum*, and various spirochetes. None of the implants was colonized by *A. actinomycetemcomitans*. Longer investigations by Leonhardt et al.[21] extended these microflora reports on dental implants in 19 patients. At 3 years, the osteointegrated implants were colonized predominantly by *P. gingivalis*, *P. intermedia*, and *A. actinomycetemcomitans*.

Natural dentitions with dental implants appear to increase the risk for implant infections, compared with completely edentulous patients. This suggests that natural teeth may serve as a reservoir for periodontal pathogens that may extend their growth to contiguous implants in the same oral cavity.[22] Quirynen and Listgarten[23] reported that proportions of coccoid forms (65.8%), motile rods (2.3%), and spirochetes (2.1%) in implant pocket areas were similar to the microorganisms in natural teeth (55.6%, 4.9%, and 3.6%, respectively).

Fully edentulous patients exhibited more coccoid forms (71.3%), fewer motile rods (0.4%), and no spirochetes. Quirynen and Listgarten[23] concluded that microflora in partially edentulous implant patients were potentially more pathogenic than fully edentulous patients. Implants with longevity of more than 3 or 4 years appear to have greater numbers of bacteria than implants in place for 1 or 2 years.[24]

Peri-implant mucositis is an inflammatory change of the soft tissue surrounding an implant. Peri-implant mucositis around an implant is similar to gingivitis around a tooth. There is no loss of attachment apparatus for teeth with gingivitis nor loss of bone for implants with peri-implant mucositis. The primary etiology is plaque biofilm. Like gingivitis, peri-implant mucositis is reversible once the etiologic agent, plaque biofilm, is removed. If allowed to progress, peri-implantitis may result, which includes loss of osteointegration, similar to loss of attachment and bone with periodontitis.

SOFT TISSUE INTERFACE

Patient Oral Hygiene

Removal of supragingival plaque with use of toothbrushes can significantly reduce the amount and composition of the subgingival microbiota. This reduction should translate to decreased risk of periodontal disease initiation or recurrence. Furthermore, the decreased prevalence of periodontal pathogens in supragingival plaque lowers potential reservoirs of these species.[25]

The absence of adequate keratinized mucosa in endosseous dental implants, especially in posterior implants, was associated with higher plaque accumulation and gingival inflammation, but not with more annual bone loss, regardless of their surface configurations.[26] The implant type, with the presence or absence of keratinized tissue, may be a challenge for oral hygiene procedures for many patients. The clinician should stress the importance of adequately performing plaque control and select products and procedures well suited to the needs and ability of the patient.

Patients rely on clinicians to suggest or recommend products for oral hygiene procedures. As with most patients, the "tell-show-do" method of home care instruction is important. Documentation in the patient record regarding recommendations and instructions, as well as the patient's compliance and effectiveness, will be important to evaluate long-term success for each patient.[27,28] When choosing and recommending implements for oral hygiene, the clinician should take into consideration the location, length, and angulations of abutments, superstructure design, anatomical limitations, patient habits, motivation, and manual dexterity of each patient.[29]

Contributing factors that may influence product selection are plaque and calculus accumulation, as well as the general health of the patient (including diseases and medications). To avoid patients becoming discouraged and poorly motivated, it is wise to keep oral hygiene instructions simple.[30,31] Partially edentulous patients exhibit higher pathogenic bacterial counts than edentulous patients, which may cause seeding of pathogenic bacteria from one site to another.[32]

The final prosthesis should allow for access by the patient and clinician to keep the areas plaque free.[33] The clinician should instruct the patient in the use of toothbrushes (manual or automatic); floss (with threading devices, if necessary); tufted brushes; interdental brushes (with coated wires); toothpicks; and oral irrigators. Patient instructions may include the use of antimicrobials, such as cetylpyridium chloride (Crest Pro-Health, Proctor and Gamble, Cincinnati,

WWW.HIGHDENT.IR

Ohio) or chlorhexidine gluconate (Peridex, OMNII-3M, West Palm Beach, Fla.; Perioguard, Colgate, New York, N.Y.) due to substantivity and ability to inactivate oral bacteria.[34] Chlorhexidine gluconate can be used as a rinse or applied specifically to the site with brushes or cotton swabs.

If oral irrigation is used, the patient should be instructed to use the lowest setting and direct the irrigation flow through the contacts to avoid excessive pressure to the implant tissue cuff. Incorrect use could alter tissue adaptation and induce bacteremia around the implant.[35] Additionally, clinicians should recommend that the patient be gentle, yet thorough, postsurgically to avoid complications of healing from aggressive hygiene procedures.

INSTRUMENT SELECTION

Maintaining a smooth surface of titanium without pits and scratches can prevent plaque accumulation.[36] Instrument selection should depend on tip designs that are not bulky (to avoid unnecessary tissue manipulation), and the design should facilitate manipulation by the clinician. A clinician may also evaluate the prosthesis design, location of deposits, and tenacity of calculus to help select appropriate instruments.

Metallic ultrasonic and sonic scalers have been reported to gouge titanium.[37] A plastic or rubber sleeve over an ultrasonic scaler appears not to alter titanium.[38] Conventional ultrasonic scalers with a nonmetal tip also are suitable for implant maintenance.[39] Air polishers are effective and safe for maintenance procedures around implants.[40,41]

Stainless steel–tipped instruments have been found to be detrimental to a smooth titanium surface.[42] This is important to consider when sharpening implant hygiene instruments to ensure a sharpening stone free of steel scrapings. A variety of nonmetallic, plastic, graphite, nylon, or Teflon-coated instruments are available and have been proven to be safe to use on titanium implant surfaces.[37-49] Improved gingival and soft tissue architecture result from scaling with these instruments. A titanium curette and a rubber cup with flour of pumice are suitable for cleaning implant surfaces.[43,44]

After the removal of calculus, polishing with a rubber cap and toothpaste, fine prophy paste, commercial implant polishing pastes, and tin oxide have been shown to be safe for titanium surfaces.[45,46] A rubber point or soft untufted rotary brush can also be used.[47]

The primary purpose of instruments used is to thoroughly remove plaque and calculus. Ramaglia et al. demonstrated that a plastic curette and air-powder-water spray did not alter the implant surface, but these instruments may leave deposits. These deposits should be removed by irrigation to avoid any adverse tissue healing.[50]

IMPLANT MAINTENANCE PROCEDURES

As dental implants become more widely used as replacements for missing teeth, clinicians will certainly see increases in clinical problems in complex cases.[14] Frequent recall visits after implant placement and restorations are necessary for evaluation and establishment of good oral hygiene after treatment. Healthy tissue should have no inflammation with a primary etiology of plaque and calculus formation. The recall visit also is a time to detect potential problems to encourage early intervention should a problem arise. An appropriate periodontal probe should be used for pocket measurements.

Unlike the attachment to the porosities of teeth, the adherence and tenacity of calculus around implants are usually less binding. This can decrease the chance of traumatizing the tissue and perimucosal seal during procedures to remove deposits. With adequate oral hygiene, subgingival calculus should be minimal, if present at all. Because titanium usually does not have calculus embedded into it, adequate oral hygiene should prevent the accumulation of heavy accretions. If crestal bone loss has occurred, the type of implant surface or coating exposed may encourage plaque or calculus adherence.

Healthy implant tissues may have a tight seal and can create challenges while scaling. Because the perimucosal seal is more fragile than a normal tooth sulcus, it is important to use short, exploratory working strokes with light pressure. Depending on the location of the calculus, a horizontal, vertical, or oblique stroke may need to be used while avoiding tissue trauma.[51] When an instrument must be used subgingivally to remove calculus or excess cement, insertion and instrumentation should be gentle and light strokes should be in a semicircular pattern. Attention to placing the blade carefully under the deposit and drying calculus or cement with compressed air may make detection and removal easier and more comfortable for the patient.

Poor tissue tone (i.e. flaccid, friable tissue) around an implant abutment can harbor food, plaque, and calculus and increase the occurrence of inflammation and infection. If maintenance and hygiene procedures cannot adequately improve tissue tone, surgical correction may be necessary to reduce chronic inflammation and infection.

Hygiene procedures performed by the clinician and patient can be limited by prosthetic designs that have bulky restorations and inadequate embrasures, preventing ready access to the implant–gingival margin interface area.[52] Because loss of osseous support is a factor in implant failure, problems that may arise from a prosthesis may prove difficult to maintain in the treatment planning phase.[53] Periodic occlusion monitoring may detect discrepancies to indicate occlusal changes needed.[54]

WWW.HIGHDENT.IR

CHEMOTHERAPEUTIC AGENTS

Chlorhexidine gluconate has been shown to reduce plaque in the oral cavity and around dental implants.[55] Long-term use of antimicrobials such as chlorhexidine gluconate, cetylpyridium chloride, or phenolic compounds may be used along with brushes and floss to minimize staining.[20] It is significant to note that the alcohol in newer generations of chlorhexidines serves to preserve and stabilize the solution.[56] Studies have shown a decrease of antimicrobial benefits in preparations that are alcohol free.[56] If the clinician uses subgingival irrigation, the cannula should be inserted carefully in the peri-implant tissue to avoid gouging the surface. Care should be taken to avoid inserting the cannula to the base of the implant sulcus to prevent fluid distention into surrounding tissues.[57] Chlorhexidine gluconate has proved to be a useful irrigant.[58] It is also wise to use a neutral sodium fluoride in a patient with dental implants because certain acidic fluorides can alter titanium.[59,60]

A study on nonsurgical mechanical treatment on sites with peri-implantitis lesions with microencapsulated minocycline (Arestin, Orapharma, Johnson and Johnson, Warminster, Pa.) and 0.12% chlorhexidine gel found reductions of pocket depths and bleeding on probing for as long as 12 months.[61] Local antibiotic therapies also have proved successful in the treatment of peri-implantitis.[62]

The effect of mechanical treatment alone or combined with antiseptic therapy on peri-implant tissues translated into less inflammation, as evaluated histomorphometrically, when compared with nontreated controls. The proportion of inflammation found in the mucosal tissues of the control implants was greater than the proportion found for both treatment groups. More importantly, both treatment groups showed similar low proportions of inflammation after 2 months of treatment. Thus it can be concluded that mechanical treatment alone or combined with chlorhexidine, sustained by plaque control, results in inflammation compatible with health.[63]

Systemic antibiotics also may be useful to treat infection. Assessing the problem, complication, or condition to be treated is as important as knowing the cause.[64]

IMPLANT QUALITY OF HEALTH SCALE: A CLINICAL ASSESSMENT OF THE HEALTH-DISEASE CONTINUUM

The criteria for success in implant dentistry remain complex. The vast majority of clinical studies reporting success and failure do not qualify the type of success achieved. Instead, the term *success* primarily has been used interchangeably with survival of the implant. The term *failure* has been used to indicate the implant is no longer present in the mouth. Nearly all reports in the prosthetic literature also report success as survival. What is success for a natural tooth? In the periodontal literature, a quality of health is presented, and well-established guidelines based on clinical criteria describe the ideal health of natural teeth. The general term *success in implant dentistry* should be replaced with the concept of *quality of health,* with a health-disease continuum describing the status of implants.

Periodontal indices often are used to evaluate dental implants; however, the latter are fundamentally different because they do not decay, have no dental pulps to function as early indicators of disease, and have no periodontal membrane. In addition, the terms used to describe periodontal disease conditions are often inappropriate when applied to implants. As the mechanisms, causative factors, pathogenesis, and host factors are better understood, the descriptions of implant-related diseases have evolved. Success criteria for endosteal implants have been proposed previously by other authors, including Schnitman and Shulman,[65] Cranin et al.,[66] McKinney et al.,[67] Albrektsson et al.,[68] and Smith and Zarb.[69] As Box 42-3 shows, the report by Albrektsson et al.[68] was specific for implants with rigid fixation and is used widely today. An implant quality of health scale with five levels has been established by James and modified by Misch.[70,71] The James-Misch scale also proposes management modalities corresponding to these five levels. In 2007, a consensus conference in Pisa, Italy (sponsored by the International Congress of Oral Implantologists) modified the James-Misch scale to four conditions that describe success, survival and failure.[71a]

Ideal clinical conditions for natural teeth include absence of pain, less than 0.1 mm of initial horizontal mobility under lateral forces of less than 100 g, less than 0.15 mm secondary mobility with lateral forces

Box 42-3 Criteria for Implant Success

- An individual, unattached implant is immobile when tested clinically.
- A radiograph does not demonstrate any evidence of peri-implant radiolucency.
- Vertical bone loss is less that 0.2 mm annually after the first year of service of the implant.
- Individual implant performance is characterized by an absence of persistent or irreversible signs and symptoms such as pain, infections, neuropathies, paresthesia, or violation of the mandibular canal.
- In the context of the foregoing, a success rate of 85% at the end of a 5-year observation period and 80% at the end of a 10-year period are minimum criteria for success.

From Albrektsson T, Zarb GA, Worthington P et al: The long-term efficacy of currently used dental implants: a review and proposed criteria of success, *Int J Oral Maxillofac Implants* 1:1, 1986.

WWW.HIGHDENT.IR

of 500 g, absence of observed vertical mobility, periodontal probing depths of less than 2.5 mm, radiographic crestal bone height 1.5 to 2.0 mm below the cement-enamel junction, intact lamina dura, no bleeding on probing, no exudate, and absence of recession or furcation involvement on multirooted teeth (Box 42-4).[72] Many of these same criteria are listed as ideal conditions for dental implants.[65-71]

The American Academy of Periodontology has defined five periodontal types for diagnosis and treatment of natural teeth, shown in Table 42-1.[73] The American Academy of Periodontology categories of disease do not indicate strict success or failure, but rather a range from health to disease. This classification allows a clinical approach to treatment in each category. A similar scale for implants has been established as an aid to diagnosis and treatment that also proposes management approaches according to the signs and symptoms.[70]

Box 42-4 Ideal Clinical Conditions of Teeth

- Absence of pain
- Less than 0.1 mm initial horizontal mobility under lateral forces less than 100 g
- Less than 0.15 mm secondary mobility with lateral forces of 500 g
- Absence of observed vertical mobility
- Periodontal probing depths less than 2.5 mm
- Radiographic crestal bone height 1.5 to 2.0 mm below cement-enamel junction
- Intact lamina dura
- No bleeding on probing
- No exudate
- Absence of recession
- Absence of furcation involvement on multirooted teeth

The scale presented for implant quality of health based on clinical evaluation was agreed upon by the International Congress of Oral Implantologists in 2007[71a] (Table 42-2). This quality of health scale allows the dentist to evaluate an implant using the listed criteria, place it in the appropriate category, and then treat the implant accordingly. The prognosis also is related to the quality scale.

Group I represents implant success with optimum health conditions. No pain is observed with palpation, percussion, or function. No mobility is noted in any direction with loads less than 500 g of implant movement (IM). Less than 2.0 mm of crestal bone has been lost since the placement of the implant. The implant has no history of exudate, and no radiolucency is present around the implant body (Figure 42-1). The probing depth is equal to or less than 5 mm and is stable after the first year. Ideally, the bleeding index is 0 to 1. Group I implants follow a normal maintenance program. Prognosis is very good to excellent.

Table 42-1 Classification of Periodontitis

TYPE	TERMINOLOGY	DESCRIPTION
I	Gingivitis	Inflammation of the gingiva characterized by changes in color, gingival form, position, surface appearance, and appearance and presence of bleeding or exudate
II	Slight periodontitis	Progression of gingival inflammation into deeper periodontal structures and alveolar bone crest with slight bone loss; usual periodontal probing depth of 3 to 4 mm with slight loss of connective tissue attachment and slight loss of alveolar bone
III	Moderate periodontitis	More advanced stage of type II; increased destruction of the periodontal structures, noticeable loss of bone support, possibly accompanied by an increase in tooth mobility; furcation involvement possible in multirooted teeth
IV	Advanced periodontitis	Further progression of periodontitis, with major loss of alveolar bone support, usually accompanied by increased tooth mobility; furcation involvement in multirooted teeth likely
V	Refractory progressive periodontitis	Several unclassified types of periodontitis included that are characterized by rapid bone and attachment loss or by slow but continuous bone and attachment loss; condition resistant to normal therapy and usually associated with gingival inflammation and continued pocket formation

Modified from Council on Dental Care Programs: Reporting periodontal treatment under dental benefit plans, *J Am Dent Assoc* 17:371-373, 1988.

Table 42-2 Implant Quality Scale

GROUP	MANAGEMENT	CLINICAL CONDITIONS
I. Success (optimum health)	Normal maintenance	No pain or tenderness upon function 0 mobility <2 mm radiographic bone loss from initial surgery Probing depth <5 mm No exudate history
II. Survival (satisfactory health)	Reduction of stresses Shorter intervals between hygiene appointments Gingivoplasty Yearly radiographs	No pain 0 mobility 2-4 mm radiographic bone loss Probing depth 5 to 7 mm No exudate history
III. Survival (compromised health)	Reduction of stresses Drug therapy (antibiotics, chlorhexidine) Surgical reentry and revision Change in prosthesis or implants	No pain upon function 0 mobility Radiographic bone loss > 4 mm Probing depth > 7 mm May have exudate history
IV. Failure (clinical or absolute failure)	Removal of implant	Any of the following: Pain upon function Mobility Radiographic bone loss >1/2 length of implant Uncontrolled exudate No longer in mouth

From International Congress of Oral Implantologists, Consensus Conference, Pisa, Italy, 2007.

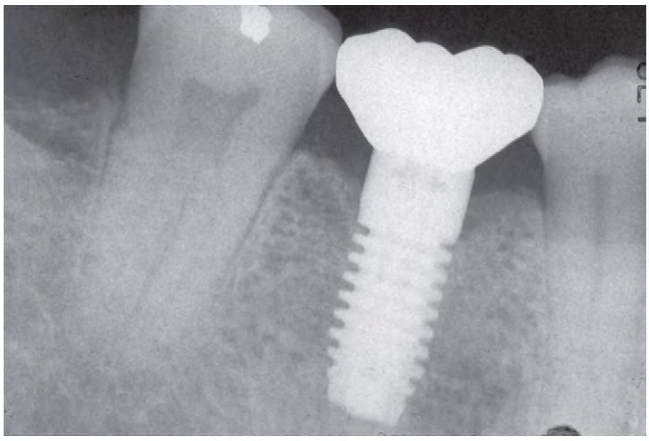

Figure 42-1 Group I represents optimum health conditions around an implant. Less than 1.5 mm of crestal bone loss occurs during the first year of occlusal loading from the time of prosthesis delivery. A periapical radiograph can be obtained to assess mesiodistal bone levels.

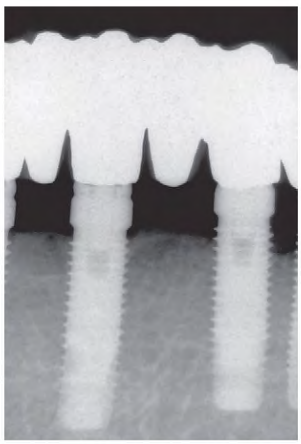

Figure 42-2 Group II represents satisfactory health around an implant. Radiographic bone loss between 1.5 and 3 mm from stage II uncovery is visible on the left implant. The right implant has lost an additional 1 mm of bone since the prosthesis delivery. The probing depths are stable. The tissue was reduced, and the threads above the bone on the right implant were reduced in depth.

Group II implants exhibit satisfactory health and are stable but show a history of or potential for clinical problems. No pain or tenderness is observed on palpation, percussion, or function. No observable mobility exists in the horizontal or vertical direction with loads less than 500 g. Crestal radiographic bone loss is between 2 and 4 mm from implant placement (Figure 42-2). The probing depths may be greater than 5 to 7 mm because of the original tissue thickness and marginal bone loss but are stable. The treatment indicated for group II implants consists of a stress reduction protocol for the implant system, shorter intervals between hygiene appointments, reinforcement of oral hygiene instructions, annual radiographs until the crestal bone has stabilized, and gingivoplasty or sulcus reduction procedures where indicated. The prognosis is good to very good depending on the depth of the implant sulcus.

WWW.HIGHDENT.IR

For pockets 3 to 4 mm in depth, the following can be concluded[63]:

1. Mechanical therapy alone or combined with chlorhexidine results in the clinical resolution of peri-implant mucositis lesions.
2. Histologically, both treatments result in minimal inflammation compatible with health.
3. The mechanical effect alone is sufficient to attain clinical and histologic resolution of mucositis lesions.[63]

Group III implants are also classified as *survival*, but exhibit a slight to moderate peri-implantitis and compromised health status. Peri-implantitis is defined as an inflammatory process affecting the tissue around an implant that results in loss of supporting bone.[75] Group III implants are characterized by radiographically evident vertical bone loss, peri-implant pocket, bleeding on probing (plus suppuration), mucosal swelling and redness, but no pain upon function (Figure 42-3). These implants warrant more aggressive clinical therapy. No pain is apparent in function, but tenderness may be slight on percussion or function. No vertical or initial horizontal mobility (IM-0) is evident. Greater than 4 mm of crestal bone loss has occurred since implant insertion. Greater than 7 mm and increasing probing depths are also present, usually accompanied by bleeding when probing. Bone loss is less than 50% around the implant. Exudate episodes may have lasted more than 1 to 2 weeks and may be accompanied by a slight radiolucency evident around a crestal region of the implant.

Group III implants warrant aggressive surgical and prosthetic intervention. Stress factors are addressed first. The prosthesis may be removed in nonesthetic regions or the bar may be removed under overdentures, especially when IM-2 exists. Modification of the occlusal scheme and methods to decrease the forces in the afflicted regions after hard and soft tissue surgical treatment include decreasing cantilever length, occlusal adjustment, and occlusal splint therapy. In cases of rapid bone changes, the prosthesis design may be modified completely from a fixed to a removable restoration to stress relief and soft tissue support. Additional implants to support the restoration may be indicated, especially if the patient is unwilling to wear a removable prosthesis. When additional implants and a new prosthesis are considered, implants with any detectable movement should be removed.

Systemic and topical antibiotics and local chemical agents such as chlorhexidine are indicated in the presence of exudate. However, this method is usually of short-term benefit if the causative agents of implant failure are not eliminated. Culture and sensitivity tests may be indicated, especially if existing signs and symptoms do not subside within a few weeks. Surgical management most often consists of soft tissue removal or exposure of a portion of the implant (Figure 42-4). Bone grafts may be used along with these approaches around the implant. A three-step approach is implemented for this category in the following order: (1) antimicrobial therapy (local or systemic); (2) stress reduction; and (3) surgical intervention. The prognosis is good to guarded, depending on the ability to reduce and control stress once the surgical corrections have improved the soft and hard tissue health.

Group IV of implant health is clinical or absolute failure (Figure 42-5). The implant should be removed under any of these conditions: (1) pain on palpation, percussion, or function; (2) greater than 0.5 mm of horizontal mobility (IM-3); (3) any vertical mobility (IM-3); (4) uncontrolled progressive bone loss; (5) uncontrolled exudate; (6) more than 50% bone loss around the implant; (7) generalized radiolucency; or (8) implants surgically placed but unable to be restored

Figure 42-3 Group III implants have a comprised health status and warrant a surgical procedure to decrease the risk of further deterioration. Probing on the facial of this implant indicates a 6-mm pocket, and exudate is present.

Figure 42-4 This implant required surgical reentry to decontaminate the surface of the implant and remove the noxious elements. A reduction of thread, depth, and a bone graft or apical-positioned flap was indicated.

WWW.HIGHDENT.IR

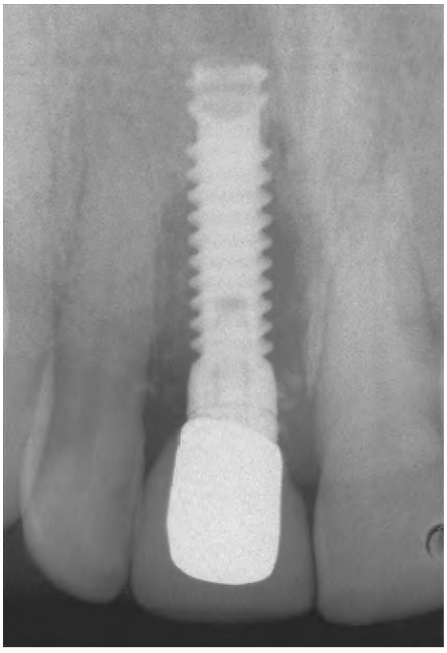

Figure 42-5 The mesial or distal bone height around an implant can be assessed on a periapical radiograph. This radiograph demonstrates bone loss to the apex of the implant. Although the implant exhibits no mobility or discomfort, it should be removed because more than half the implant has crestal bone loss.

(sleepers). Implants that are surgically removed or exfoliated are also in the category of failure. Occasionally, the patient will not permit removal of the implant. Regardless of whether the patient returns for implant removal, the implant is recorded as a failure in all statistical data. The patient should be warned against the irreversible damage to the surrounding bone with implants retained in this condition. Consideration should be given to their removal because future treatment may be compromised.

REPAIR OF THE AILING, FAILING DENTAL IMPLANT

I. If an active infection (purulence, bleeding, swelling) is present with radiographically visible bone loss and the disease process is continuing, the following steps should be implemented:

   A. Reflect the tissue and degranulate the defect (metallic curettes are acceptable).
   B. If the implant is hydroxyapatite (HA) coated and the HA is undergoing resorption and has changed color and texture, remove all the HA until the metallic surface is visible. Use of ultrasonics such as Cavitron (Dentsply) is best; use of hand curettes is too slow, and use of air abrasives is dangerous because of danger of air emboli in marrow spaces.
   C. Detoxify the dental implant with citric acid applied with cotton pledget or camel's hair brush. Thirty seconds per surface is sufficient. The super-saturated citric acid solution (40%, pH 1, crystals mixed with sterile water) will last in the refrigerator for about 1 year.
   D. Graft with freeze-dried bone or alloplast if completely detoxified. Graft with an alloplast such as HA or bioglass if not completely detoxified.
   E. Protect the graft with a membrane for guided bone regeneration if needed. Resorbable membranes (such as Alloderm [Lifecell, Branchburg, N.J.; distributed by BioHorizons, Birmingham, Ala.] and Biomend [Zimmer Dental, Carlsbad, Calif.]) are acceptable. If the defect cannot be closed via primary intention healing with soft tissue, use the dense 3-polytetrafluoroethylene membrane (e.g., TEF-Gen; Lifecore Biomedical, Chaska, Minn.).
   F. Leave the repaired implant out of function and "covered" for 10 to 12 weeks.
      NOTE: If the surface of the implant is metallic (titanium, Ti-6Al-4V, titanium plasma spray), go from Step A to Step C.

II. If no active infection is present and if an HA-coated implant is in place and the HA looks intact without ongoing resorption (bone loss from traumatic occlusion, overloading, off-axis loading, and so on), the following steps should be implemented:

   A. Reflect the tissue and degranulate the defect with metallic curettes.
   B. Detoxify the HA surface with citric acid (40%, pH 1) for 30 seconds per surface. Flush and irrigate with sterile water or sterile saline to stop demineralization process of the citric acid. Thirty seconds of citric acid application will detoxify and "freshen" the surface.
   C. Continue with grafting, guided bone regeneration (GBR) materials, and procedures as noted previously for treatment of the "infected" implant.
      NOTE: The only difference is that removal of the HA is not necessary because the coating is relatively noncontaminated and still capable of biological healing.
      IMPORTANT: Do not use tetracycline on intact HA because it changes the calcium/phosphate ratio of HA. Do not leave citric acid on HA surface for more than 1 minute; it continues to "remove".

Group V, the last category for implant quality, is absolute failure. It consists of implants surgically removed or exfoliated and no longer in the mouth (Figure 42-6). The remaining edentulous area often is treated with autogenous or synthetic bone graft procedures, which are performed to replace the missing bone. Once the favorable bony conditions are restored, implants may be inserted again with good prognosis.

WWW.HIGHDENT.IR

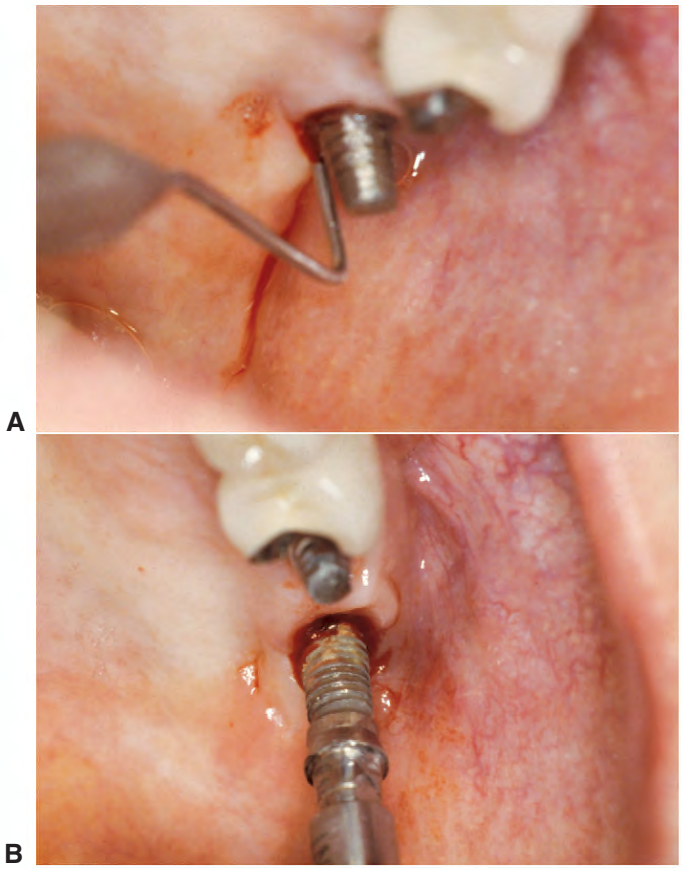

Figure 42-6 **A,** Implants in group V represent absolute failure and implants no longer in the mouth. The implant in this picture is an implant with more than 50% loss: it is in category IV. **B,** The implant should be removed when in group IV; therefore the implant is unthreaded from the site. The implant now is converted into group V.

IMPLANT FAILURE

The terminology for implant failure often is confusing, with different terms describing similar situations and, worse, vice versa. As such, Jividen and Misch[76] have suggested a terminology for implant failure using the time period of failure as a primary criterion. Many implant failures are not described ideally by the time of the complication and are not addressed in this nomenclature.

IMPLANT CROWN ESTHETIC INDEX

An implant crown esthetic index was developed by Henny et al. as an objective tool in rating esthetics of implant-supported single crowns and adjacent soft tissues.[77] The important item of esthetics is rarely included in evaluation studies. Esthetics can be rated in both a subjective and an objective manner. A subjective method is the use of questionnaires, which must be completed by the patient.

An objective method with a rating score, which has to be carried out by a professional observer, has never been described in the field of dental implants. Jemt introduced an index to assess the height of interproximal mucosa adjacent to single-implant restorations, but did not account for entire peri-implant contour and surface structure. An objective rating score, with a division in different items, provides insight into the esthetic result of a specific treatment and also facilitates analysis to improve surgical or prosthetic treatment. It is also possible to compare the esthetic result as a function of time to analyze the stability of a treatment procedure.[78]

1. Implant-supported single-tooth restoration in position 21. Labial convexity of the crown is slightly overcontoured, slight mismatch in color of the crown, slight deviation in position of the labial mucosal margin, and the labial surface of the mucosa is slightly undercontoured. The total score is 4 points on the index, which means moderate esthetics.
2 Implant-supported single-tooth restoration in position 11. The mesiodistal dimension of the crown is slightly overcontoured. The total score is 1 point on the index, which means satisfactory esthetics.
3. Implant-supported single-tooth restoration in position 21. The mesiodistal dimension of the crown is slightly overcontoured, a slight mismatch in color of the crown, slight deviation in position of the labial mucosal margin, and a gross mismatch in color and surface of the mucosa. The total score is 8 points on the index, which means poor esthetics.

The nine selected items were as follows:

Mesiodistal Dimension of the Crown. The mesiodistal dimension must be in harmony with the adjacent and contralateral tooth; a judgment can be given on a 5-point rating scale (grossly undercontoured, slightly undercontoured, no deviation, slightly overcontoured, grossly overcontoured).

Position of the Incisal Edge of the Crown. The position must be in harmony with the adjacent and contralateral tooth; a judgment can be given on a 5-point rating scale (grossly undercontoured, slightly undercontoured, no deviation, slightly overcontoured, grossly overcontoured).

Labial Convexity of the Crown. Convexity of the labial surface of the crown must be in harmony with the adjacent and contralateral tooth; a judgment can be given on a 5-point rating scale (grossly undercontoured, slightly undercontoured, no deviation, slightly overcontoured, grossly overcontoured).

Color and Translucency of the Crown. Color and translucency of the crown must be in harmony with the adjacent and contralateral tooth; a judgment can be given on a 3-point rating scale (gross mismatch, slight mismatch, no mismatch).

Surface of the Crown. Labial surface characteristics of the crown, such as roughness and ridges, must be in harmony with the adjacent and contralateral tooth; a

WWW.HIGHDENT.IR

judgment can be given on a 3-point rating scale (gross mismatch, slight mismatch, no mismatch).

Position of the Labial Margin of the Peri-Implant Mucosa. The labial margin of the peri-implant mucosa must be at the same level as the contralateral tooth and in harmony with the adjacent teeth; a judgment can be given on a 3-point rating scale (deviation of 1.5 mm or more, deviation less than 1.5 mm, no deviation).[78]

Position of Mucosa in the Approximal Embrasures. The interdental papillae must be in their natural position; a judgment can be given on a 3-point rating scale (deviation of 1.5 mm or more, deviation less than 1.5 mm, no deviation).

Contour of the Labial Surface of the Mucosa. The contour of the mucosa at the alveolar bone must be in harmony with the adjacent and contralateral tooth; a judgment can be given on a 5-point rating scale (grossly undercontoured, slightly undercontoured, no deviation, slightly overcontoured, grossly overcontoured).

Color and Surface of the Labial Mucosa Color (redness) and surface characteristics (presence of attached mucosa) must be in harmony with the adjacent and contralateral tooth and must have a natural appearance; a judgment can be given on a 3-point rating scale (gross mismatch, slight mismatch, no mismatch).

It has been decided to use the adjacent and contralateral tooth as a reference, rather than the generally accepted rules for shape and position of teeth.[78] These rules are derived from young female patients and cannot be applied to all patients, as the proportions between the general shape of the face, size, sex, and other teeth have to be maintained. Penalty points were given to each of these items if not matching to the desired situation: 1 penalty point for minor (slight) deviations and 5 penalty points for major (gross) deviations. The total score leads to a judgment about esthetics (Box 42-5).[78]

It should be noted that one major deviation automatically leads to a poor esthetic result and can never be accepted as moderate or satisfactory. The making of the implant crown is the last part of the total implant treatment. Prosthodontists are daily involved with prosthetic restorations and evaluation of the total treatment. This experience could be a reason why prosthodontists are more consistent in their scores than oral-maxillofacial surgeons.

Box 42-5 Esthetic Scale

0 points = Excellent esthetics
1 or 2 points = Satisfactory esthetics
3 or 4 points = Moderate esthetics
5 or more points = Poor esthetics

SUMMARY

Implant success is as difficult to describe as the success criteria required for a tooth. A range from health to disease exists in both conditions. The primary criteria for assessing implant quality are pain and mobility. The presence of either greatly compromises the implant; removal usually is indicated. Probing depths may be related to the presence of local disease or preexisting tissue thickness before the implant was inserted. An increasing probing depth is more diagnostic and signifies bone loss, gingival hyperplasia, or hypertrophy. Bone loss usually is evaluated best with probing rather than with radiographs. The most common cause of bone loss during the first few years of function is related to factors of stress. The bleeding index is observed easily and indicates inflammation of the gingiva. However, implant health status is not as related to sulcular inflammation as would be the case with a natural tooth.

Implant failure is easier to describe and may consist of a variety of factors. Any pain, vertical mobility, uncontrolled progressive bone loss, and generalized peri-implant radiolucency warrant implant removal. Implant quality factors were established by James and modified by Misch into an implant quality scale that not only assesses the implant health-disease continuum but also relates treatment and prognosis to the existing conditions.

Dental Evaluation-Completely Edentulous Arches

Extraoral Evaluation

PHYSICAL CHARACTERISTICS

Cosmetic Index	Poor ❑	Average ❑	Good ❑
Countenance	Tense ❑	Average ❑	Pleasing ❑
Color and Skin Texture	❑ Normal	❑ Other	
Complexion	❑ Fair	❑ Average	❑ Dark
Patient Attitude	❑ Receptive ❑ Exacting ❑ Indifferent		
Neuromuscular Coordination	Poor ❑	Average ❑	Good ❑

SEX ❑ Male ❑ Female
AGE ❑ Young ❑ Middle ❑ Mature
ESTHETIC/AGE POTENTIAL Low ❑ Average ❑ High ❑

PERSONALITY Delicate ❑ Average ❑ Vigorous

LIPS Short ❑ Long ❑

EYES ❑ Brown ❑ Hazel ❑ Blue ❑ Green ❑ Gray

HAIR ❑ Brunette ❑ Brown ❑ Blonde ❑ Red ❑ Gray

FACE ❑ Square ❑ Tapering ❑ Ovoid

PROFILE ❑ Normal ❑ Retrognathic ❑ Straight ❑ Prognathic

PRESENT DENTURE EVALUATION

Type of Denture ❑ Maxillary ❑ Mandibular

Denture History Previous Dentures	Type	Quantity

Denture Experience ❑ Favorable ❑ Unfavorable

❑ Masticatory efficiency	❑ Poor	❑ Average	❑ Good
❑ Stability and retention	❑ Poor	❑ Average	❑ Good
❑ Esthetics	❑ Poor	❑ Average	❑ Good
❑ Phonetics	❑ Poor	❑ Average	❑ Good
❑ Comfort	❑ Poor	❑ Average	❑ Good
❑ Occlusal vertical dim.	❑ Poor	❑ Average	❑ Good

Intraoral Evaluation Completely Edentulous

SIZE OF JAWS	Small	Normal	Large
Maxilla	❑	❑	❑
Mandible	❑	❑	❑

ARCH FORM
Maxilla ❑ Square ❑ Ovoid ❑ Tapered
Mandible ❑ Square ❑ Ovoid ❑ Tapered

RESIDUAL RIDGE
Maxilla ❑ Square ❑ Ovoid ❑ Tapering ❑ Flat
Mandible ❑ Inverted "U" Shape ❑ Parallel Wall ❑ Flat ❑ Inverted "U" Shape ❑ "U" Shape ❑ Thin ❑ Parallel Walled Undercut

RIDGE PARALLELISM
Both ridges parallel ❑
Maxilla divergent anteriorly ❑
Mandible divergent anteriorly ❑
Both divergent anteriorly ❑

RIDGE RELATION ❑ Normal ❑ Prognathic ❑ Retrognathic

INTERARCH DISTANCE Insufficient ❑ Sufficient ❑

SOFT PALATE ❑ Class I ❑ Class II ❑ Class III ❑ Class IV ❑ Sufficient ❑ Excessive

SOFT TISSUES ❑ Thin ❑ Thick ❑ Healthy ❑ Irritated ❑ Pathologic

MUSCLE ATTACHMENTS	Low	Average	High
	❑	❑	❑

PALATAL THROAT FORM	Flat	Normal	Sharp
	❑	❑	❑

TONGUE POSITION	Subnormal	Normal
	❑	❑

LIP CONTOUR	Needs Support	Normal
Maxilla	❑	❑
Mandible	❑	❑

MAND/MOVEMENTS	Limited	Unlimited
Protrusive	❑	❑
Right Lateral	❑	❑
Left Lateral	❑	❑

Opening_____mm

MUSCLE TONE	Poor	Average	Good
	❑	❑	❑

SALIVA
Amount ❑ Insufficient ❑ Average ❑ Excessive
Character ❑ Normal ❑ Thin ❑ Thick ❑ Ropy

SAMPLE

Appendix Figure A-1 The data obtained during the extraoral and intraoral examination of partially edentulous and completely edentulous patients is recorded in the patient evaluation forms.

Dental Evaluation

Initial Soft Tissue Exam

LIPS	FLOOR OF MOUTH	PALATE	TONGUE	NECK & NODES
❑ WNL ❑ +				

Available Bone Classification

COMPLETELY EDENTULOUS ARCHES	TYPE I	TYPE II	TYPE III	
PARTIALLY EDENTULOUS ARCHES	CLASS I	CLASS II	CLASS III	CLASS IV
BONE DIVISION	DIVISION A	DIVISION B	DIVISION C	DIVISION D
BONE CHARACTER	DENSITY 1	DENSITY 2	DENSITY 3	DENSITY 4

Partially Endentulous

Implant Site

BONE CHARACTER	❑ Favorable Normal Trabeculae	❑ Marginal Recent Extraction	❑ Unfavorable Pathology
BONE TRAJECTORY	❑ Favorable Vertical	❑ Adequate Slight Flare	❑ Unfavorable Gross Flare
ATTACHED GINGIVA	❑ Favorable 3mm	❑ Adequate 1-2mm	❑ Unfavorable None
MUSCLE ATTACHMENT	❑ None	❑ Moderate	❑ Severe
INTERARCH SPACE	❑ Favorable	❑ Adequate	❑ Unfavorable
PERMUCOSAL POSITION	❑ Favorable	❑ Adequate	❑ Unfavorable
TISSUE SUPPORT AREA	❑ Favorable	❑ Adequate	❑ Unfavorable

Initial Perio Exam

GINGIVAL INFLAMMATION	❑ Slight	❑ Moderate	❑ Severe
SOFT PLAQUE BUILD-UP	❑ Slight	❑ Moderate	❑ Severe
HARD CALCULUS BUILD-UP	❑ Slight	❑ Moderate	❑ Severe
STAINS	❑ Light	❑ Moderate	❑ Severe
PERIODONTAL CONDITION	❑ Good	❑ Fair	❑ Poor
PERIODONTAL DIAGNOSIS	❑ Normal	❑ Gingivitis	❑ Periodontitis
PERIODONTITIS	❑ Early	❑ Moderate	❑ Advanced

General Dental Considerations

GENERAL HOME CARE	❑ Favorable	❑ Adequate	❑ Unfavorable
DENTAL I.Q.	❑ High	❑ Normal	❑ Unfavorable
DENTAL MUSCLE DYNAMICS	❑ Weak	❑ Normal	❑ Strong
GENERAL TMJ STATUS	❑ Symptom Free	❑ Incipient	❑ Dysfunction
OCCLUSAL PLANE	❑ Favorable	❑ Adequate	❑ Unfavorable
ARCH RELATIONSHIP	❑ Favorable	❑ Adequate	❑ Unfavorable
OPPOSING DENTITION	❑ Removeable	❑ Combination	❑ Fixed
EXISTING OCCLUSION	❑ Favorable	❑ Adequate	❑ Unfavorable
EXISTING PROSTHESIS	❑ Favorable	❑ Adequate	❑ Unfavorable
PONTICS	❑ 1	❑ 2	❑ 3 or more
TISSUE SUPPORT AREAS	❑ Normal	❑ Average	❑ Excessive
RESTING LIP LINE	❑ Low	❑ Normal	❑ High
HIGH LIP LINE (SMILE)	❑ Low	❑ Normal	❑ High
LOW LIP LINE (SPEECH)	❑ High	❑ Normal	❑ Low
ARCH POSITION	❑ Class I	❑ Class II	❑ Class III
ARCH FORM (Ant.-Post)	❑ Tapering	❑ Ovoid	❑ Square

Stresses

PARAFUNCTION			
BRUXISM	❑ None	❑ Occasional	❑ Frequent
CLENCHING	❑ None	❑ Occasional	❑ Frequent
TONGUE THRUST	❑ None	❑ Occasional	❑ Frequent
ORAL HABITS	❑ None	❑ Occasional	❑ Frequent
MASTICATORY DYNAMICS	❑ Light	❑ Normal	❑ Heavy
CROWN HEIGHT SPACE	❑ <1	❑ 1/1 TO 2/1	❑ >2/1
DENSITY OF BONE	❑ D1,2	❑ D3	❑ D4
DIRECTION OF FORCE	❑ Vertical	❑ <15 Degrees	❑ >15 Degrees
TONGUE SIZE	❑ Small	❑ Normal	❑ Large
MISSING TEETH _____			

SAMPLE

Dental Evaluation

Subjective Considerations

ORAL COMFORT POTENTIAL	❑ Excellent	❑ Normal	❑ Guarded
ORAL FUNCTION POTENTIAL	❑ Excellent	❑ Normal	❑ Guarded
ORAL ESTHETIC POTENTIAL	❑ Excellent	❑ Normal	❑ Guarded
PSYCHOLOGICAL STATUS	❑ Positive	❑ Normal	❑ Negative
PATIENT EXPECTATIONS	❑ High	❑ Normal	❑ Low
PATIENT ECONOMIC PRIORITIES	❑ High	❑ Normal	❑ Low

Natural Abutment (Optional: Repeat For Each Quadrant)

MOBILITY	❑ Minimal	❑ Moderate	❑ Severe
ENDODONTIC STATUS	❑ Favorable	❑ Potential	❑ Pathology
ATTACHED GINGIVA	❑ 3mm	❑ 1-2mm	❑ None
MUSCLE ATTACHMENT	❑ None	❑ Moderate	❑ Severe
ROOT CONFIGURATION	❑ Divergent	❑ Normal	❑ Tapered
TOOTH POSITION	❑ Favorable	❑ Exfoliation	❑ Angulation
PARALLELISM	❑ Favorable	❑ Guarded	❑ Unfavorable
CARIES	❑ None	❑ Moderate	❑ Severe

Medical Evaluation

RESULTS	❑ POSITIVE	❑ NORMAL	❑ NEGATIVE
VITAL SIGNS	mm Hg	BPM	
URINALYSIS			
CBC			
SMA 12			
PT PTT INR			
OTHER			

Patient Habits

TOBACCO HABITS	❑ SMOKING	❑ ORAL	❑ None	❑ Moderate	❑ Heavy
ALCOHOL CONSUMPTION			❑ None	❑ Moderate	❑ Heavy

Photographs

FULL FACE	❑ Before	❑ After	INTRAORAL	❑ Before	❑ After
PROSTHETIC	❑ Before	❑ After	SURGERY	❑ Before	❑ After

Diagnostic Records
